Medical knowledge and practice change constantly. This book is designed to provide accurate, authoritative information about the subject matter in question. However, readers are advised to check the most current information available on procedures included and check information from the manufacturer of each product to be administered, to verify the recommended dose, formula, method and duration of administration, adverse effects and contraindications. It is the responsibility of the practitioner to take all appropriate safety precautions. Neither the publisher nor the author(s)/editor(s) assume any liability for any injury and/or damage to persons or property arising from or related to use of material in this book.

This book is sold on the understanding that the publisher is not engaged in providing professional medical services. If such advice or services are required, the services of a competent medical professional should be sought.

Every effort has been made where necessary to contact holders of copyright to obtain permission to reproduce copyright material. If any have been inadvertently overlooked, the publisher will be pleased to make the necessary arrangements at the first opportunity.

PREFACE

"*utiṣṭhata* | *jāgrata* | *prāpya varānnibodhata* |
Arise. Awake. And stop not till the goal is reached."

— Swami Vivekananda

We have a passion for improving patient care. Emergency care is all about dealing emergencies in time-bound manner and the emergency department is a place where emergency physician manages most diverse acute conditions in the hospital. On the basis of the typical clinical clues' emergency physician can use accurate diagnostic tools, treatment pathways, and prognostic prediction. The practice of "emergency medicine" continues to evolve, bringing greater expectations of the physicians who provide field care in interhospital shifting by ambulance and medical oversight. The advent of postgraduation program in "emergency medicine", and the continuous broadening of the clinical practice of "emergency medicine" has made the formal study of the art and practice even more essential than ever before. Now we have to show our never-ending commitment to improve patient care across the entire scope of our practice as emergency physicians. The emergency physicians acquiring their knowledge and skills very rapidly to improve the patient care and show their worthiness. We have achieved many milestones along the road of development of the emergency medicine specialty. Our journey starts with Textbook of Emergency and Trauma Care, 1st edition with superb mentors who instilled in us a drive to become excellent clinicians and educators. Now, 2nd edition is updated with "250 Chapters in 22 Sections", extremely useful for emergency physicians, intensivists, family physicians, general practitioners, nurse practitioners, and physician assistants, where clinical clues significantly guide, improve, and expedite diagnosis as well as treatment. It is our most sincere hope that this text serves you well on your journey, wherever the practice of "emergency medicine" may take you.

We thank contributors and readers who have helped to make this 2nd edition possible.

No star is too distant to approach
No mountain too high to climb
No dream is too far to make reality
No quest too difficult to fulfil
No goal is too impossible to achieve
For those who have courage to try several times
So, meet the life challanges with determination
Each time each hour each day
To come out winning honest rewards!!

Devendra Richhariya
Bhawana Sharma

ACKNOWLEDGMENTS

I would like to thank all the authors for providing manuscripts in spite of their busy schedules. Special thanks to publisher Shri Jitendar P Vij (Group Chairman), Mr Ankit Vij (Managing Director), Mr MS Mani (Group President), Ms Chetna Malhotra Vohra (Associate Director—Content Strategy), Dr Richa Saxena (Associate Director—Professional Publishing), Ms Upasana Kak (Development Editor), and all members of M/s Jaypee Brothers Medical Publishers (P) Ltd, New Delhi, India for invaluable contribution.

We would like to thank Ms Avighna Richhariya for providing invaluable technical support for the textbook.

CONTENTS

Volume 1

SECTION 1: BASIC CONCEPTS OF EMERGENCY MEDICINE

1. Essential Qualities for Emergency Physician **1**

K Hari Prasad

• Qualities of Good Emergency Physician *1* • Other Basic Skills *3*

2. Designing and Staffing of Emergency Department **5**

Saleh Fares, Omar Ghazanfar

• Challenges for Emergency Department in India *5* • Emergency Department Function *5*
• Requirements for Creating New Infrastructure as Emergency Department *5*
• General Considerations for Designing Emergency Department *6* • Other Requirements *6*
• Patient Flow *7* • Dedicated Area within Emergency Department *7* • New Concepts in Emergency Department Design *7* • Staffing Model for Emergency Department *7*
• Deciding Factors for Staffing in Emergency *9* • Requirements of Emergency Physician for Emergency Department *9* • Requirements of Staff Nurse in Emergency Department *9* • Emergency Medical Technicians *9* • Staff for Minor Operation Theater *9* • Other Staff *9*

3. Observation and Isolation Unit **11**

Devendra Richhariya

• Observation Unit Design and Layout *11* • Protocol Development *12* • Observation Unit Management *13* • Quality Assurance Process and Metrics *14* • Guidelines for Setting up an Isolation Unit *14*

4. Observation Medicine **18**

M Rajadurai, Akmal Areeb, Devendra Richhariya

• Clinical Decision Rules *18* • Chest Pain *19* • Atrial Fibrillation *20*
• Acute Heart Failure *20* • Syncope *20* • Venous Thromboembolism *20*
• Acute Abdominal Pain *22* • Appendicitis *23* • Gastrointestinal Bleeding *25*
• Acute Pancreatitis *26* • Transient Ischemic Attack/Minor Stroke *27* • Dizziness/Vertigo *28*
• Back Pain *29* • Headache *29* • Seizures *32* • Asthma/Chronic Obstructive Pulmonary Disease *32* • Community-Acquired Pneumonia *33* • Infections *33* • Acute Traumatic Conditions *34* • Metabolic and Endocrine Conditions *34* • Additional Clinical Conditions *34*

5. Triaging **40**

Devendra Richhariya

• Emergency Department Triaging *40* • Requirement for Triaging *40*
• Triaging Scales *40* • Triaging Process *41* • Benefits of Triaging *42* • Early Warning Score *42*
• Triage in Mass Casualty Incident *42*

6. Rapid Assessment and Early Treatment **45**

Devendra Richhariya

• Benefits of Rapid Assessment *45* • Steps for Rapid Assessment and Early Treatment *45* • Clinical Quality Indicators for Rapid Assessment *46* • Implementation of Rapid Assessment and Early Treatment (Sepsis, Stroke, and Trauma) *47*

7. Patient Safety and Quality in Emergency Department **49**

Saravana Kumar

• Background of Emergency Department *49* • Approach to Quality Issues in the Emergency Department *50* • Adverse Events in the Emergency Department *50* • Safety Practice and Implementation Strategy *50* • Clinical Audit *53* • Fishbone Analysis for Quality Improvement in Emergency Department *53*

8. Hazardous Material (HAZMAT) and Waste **55**

KV Sarma, Devendra Richhariya

• Classification of Hazardous Material *55* • Storage and Transportation of Hazardous Materials *57* • Safe use of Hazardous Material *57* • Chemical Spill and Decontamination *58* • Hazardous Waste and Segregation *58* • Degree of Hazard Identification for Hazardous Materials *59* • Hazardous Material Safety Booklet *59* • Performance Standards and Performance Improvement *60* • Personal Protective Equipment in Hazardous Material Incidents *60*

9. Infection Prevention in Emergency Department **63**

Josephine Cyrill, Angelika Masih

• Adherence to Standard Infection Control Precautions *63* • Predetection and Triage Management *64* • Transmission-based Precautions *64* • Disinfection and Sterilization of Reusable Medical Devices *65* • Device-associated Infections *65* • Education and Training *66*

10. Personal Protective Equipment **68**

TV Ramakrishnan, Akilan Elangovan

• Standard Precautions *68* • Personal Protective Equipment *68* • Hand Hygiene *68* • Types of Personal Protective Equipment Used in Healthcare Settings *68* • Donning and Doffing Personal Protective Equipment *70* • Selecting the Appropriate Personal Protective Equipment for Healthcare Workers *74* • Transmission-based Precautions *74* • Levels of Personal Protective Equipment and Types of Precautions for Infection Control *75* • Optimizing Personal Protective Equipment Usage during Crisis *75* • Decontamination of Personal Protective Equipment for Reuse *75* • Limitations of Personal Protective Equipment *76* • Regulations and Efficiency of Personal Protective Equipment Usage *76*

SECTION 2: RECENT CONCEPTS IN EMERGENCY MEDICINE

11. Research Methodology **80**

Padam Singh, Pooja Sharma, Manish K Singh

• Literature Review *80* • Formulating a Research Question *80* • Essentials of Biostatistics *80* • Research Designs *82* • Sample Size *84* • Statistical Analysis *86* • Test of Significance for Population Mean (μ) *86* • Test for Proportions *88* • Other Commonly used Tests *88* • Statistical Software *88* • How to Read a Scientific Paper *88*

12. Transforming Emergency Department with Digital Technology **91**

Rajesh Kumar Gupta

• Ambulance Management *91* • Check-in at Emergency Room *93* • Triage *93* • Clinical Documentation *93* • Initiating a Care Protocol *95* • Discharge Home or Transfer to Inpatient Department *96* • Emergency Room Admin Dashboard *96* • Technology Hand in Hand with Emergency Room *97*

13. Advanced and Future Technology in the Emergency Department **99**

Devendra Richhariya

• Online Check-in *99* • Patient Flow Software *99* • Real-time Locating System *99* • Miniaturization of Imaging and Diagnostic Equipment *99* • Telemedicine *101* • Barcode Scanner *101* • Computers on Wheels *101* • Medical Drones *102* • Driverless Ambulance *103* • Apps Simplifying Communication Administration and In-flight Emergencies *103* • Video Games for Practicing Real Situations *103* • Future of Emergency Medicine *103*

14. Artificial Intelligence in Healthcare **105**

Sandhya Shankar Pandey, Devendra Richhariya

• Mapping Mind and Machine Through Brain–computer Interfaces *105* • Artificial Intelligence in Developing the Next Generation of Radiology Tools *105* • Artificial Intelligence in Expanding Healthcare in Developing Regions *106* • Artificial Intelligence in Reducing the Burdens of Electronic Health Record *106* • Artificial Intelligence and Antibiotic Resistance *106* • Artificial Intelligence in Analysis of Pathology Images *106* • Artificial Intelligence in Medical Devices and Machines *106* • Advancing the Use of Immunotherapy for Cancer Treatment *106* • Electronic Health Record as a Reliable Risk Predictor *106* • Artificial Intelligence in Monitoring Health Through Wearables and Personal Devices *107* • Making Smartphone Selfies into Powerful Diagnostic Tools *107* • Bedside Clinical Decision-making with Artificial Intelligence *107* • Administrative Applications of Artificial Intelligence *107*

15. Use of Simulation-based Education in Emergency Medicine **108**

Asit Misra, Brad Gable

• History of Simulation *108* • Educational Theory *108* • Simulation Types and Methods *110* • Planning a Simulation Case *110* • Use of Simulation in Emergency Medicine *111* • How to Integrate Simulation Education into an Emergency Medicine Curriculum *111*

SECTION 3: SPECIAL SITUATIONS IN EMERGENCY MEDICINE

16. Overcrowding Management in Emergency Department **114**

MI Nizami, Ashima Sharma

• Definition of Overcrowding *114* • Causes of Overcrowding *117* • Interventions *117*

17. Difficult Patient and Situations **119**

AN Venkatesh

• Difficult Situations *119* • Types of Difficult Patient *120* • Clinicians as Causative Factors *120* • How to Deal with Difficult Situations? *120* • Role of Emergency Physician to Resolve Difficult Situations *121*

18. Medicolegal Cases and Writing Medicolegal Reports **123**

Amit Nabar, Devendra Richhariya, Vivekanshu Verma

• Medicolegal Cases *123* • Medicolegal Reports *123* • Medicolegal Classification of Injuries *127* • How Does the Law Protect the Victim in Medicolegal Cases? *128* • Practical Tips for Medicolegal Case Writing *128* • Do's and Don'ts in Medicolegal Case Writing to Avoid Legal Punishment *129*

19. Medicolegal Issues in the Emergency Department **131**

Adarsh Kumar, Vivekanshu Verma, Devendra Richhariya

• What is Duty of Care Toward a Patient? *131* • What is Breach in Duty to Care? *132* • What is Doctrine of RES IPSA Loquitur? *132* • Why Medical Services were Included Under the Consumer Protection Act, 1986? *132* • What Kind of Medicolegal Issues are Faced in Dealing with International Patients? *133* • Medicolegal Guidelines for Managing a

Terminally Ill Patient in the Emergency Department *133* • Patients with Weak Financial Background in a Private Hospital *133* • Medical Negligence *133* • Medical Malpractice Stress Syndrome *134* • Medical Indemnity Insurance *134* • Do not Attempt Resuscitation Guidelines *134* • Euthanasia *135* • Discharge Against the Medical Advice from the Emergency Department *135* • Medicolegal Implications of a Prisoner Absconding from the Emergency Department *136* • How to Declare a Patient Brought Dead? *136* • Grief Counseling *136*

20. Examination of Sexual Abuse Victim **138**

Nikhil D Datar, Meghna Shedge

• Definition of Rape *138* • Presentation in an Emergency Department *138* • Examination *139* • Quick Assessment *139* • General Examination and Injuries *139* • Documentation *141* • Treatment *141* • Emergency Contraception *141*

21. End-of-life and Palliative Care in the Emergency Department **143**

Naeem Toosy

• Trajectory of Dying and End-of-life Decision-making *143* • Palliative Care and Bioethics *144* • Communication at the End of life *144* • End-of-life Symptoms Management *145*

22. Death Declaration **147**

Rammohan Radhakrishnan, Sahanya Ramesh Shetty

• Possible Circumstances of Death *147* • Effect of Death on Survivors *147* • Effect on Emergency Department Physicians *147* • Communication Strategies *148* • Viewing of the Body *149* • Medical Examination: Autopsy *149* • Organ Donation *149* • Organ Donation: Death of a Child *149*

23. Brain Death **151**

Bhawana Sharma, Devendra Richhariya

• Pathophysiology of Brain Death *151* • Recommendation *151* • Definition *152* • Prerequisites *152* • Documentation of Coma *152* • Documentation of Absence of Brainstem Reflexes *152* • Documentation of Apnea *153* • Additional Tests *154* • Other Tests *154* • Brain Death Mimic *154* • Movement Observable after Brain Death *155* • Brain Death Declaration and Organ Donation *155* • Care of the Potential Organ Donor *155*

24. Organ Donation and Transplantation **159**

Devendra Richhariya, Bhawana Sharma

• History of Organ Transplant: Worldwide and in India *159* • Evolution of Law: Transplantation of Human Organ Act *160* • Challenges *160* • How to Curb the Problems *161*

SECTION 4: PREHOSPITAL AND DISASTER MANAGEMENT

25. Ground Medical Transfer **163**

GV Ramana Rao

• What is Ground Medical Transfer? *163* • Salient Historical Milestones *163* • Current Context *163* • Key Principles Guiding the Ground Medical Transfers *163* • Models of Ground Medical Transfers *164* • Basic Tasks and Tenants *164* • Types of Road Ambulances *165* • Planning and Coordination *165* • Training Schedule for Emergency Medical Technician *166* • Quality Assurance *166*

26. Air Medical Transfer **168**

Saleh Fares, Michael J Nolan

• Decision for Air Medical Transfer *168* • Flight Physiology *168* • Standards of Care: Air Medical Transfer *169* • Special Considerations *170* • Recent Advances *170*

27. Basic Concepts of Disaster Management **172**

Venkat Changavalli, Devendra Richhariya

• Definitions *172* • Classification of Disasters *172* • Disaster Management Cycle *173* • Disaster Response Management *174* • Incident Command System *174* • Multiagency Coordination during Response *174* • Early Warning System for Disaster *175* • Role of Technology as Decision Support Tools *176* • Humanitarian Consideration in Disaster Response *176* • Conducting Exercise for Disaster Management *176* • Preparing the Emergency Department for Mass Casualties *177* • Mass Casualty Management *178*

28. Mass Casualty Management **180**

Saurabh Dalal

• Background *180* • Case Studies *181* • Innovation and Best Practices *181* • Bridging the Gap *182* • Incident Response System *182* • National Emergency Operational and Preparedness Structure *182* • Way Forward *182*

29. Preparedness for Chemical, Biological, Radiological, and Nuclear/Energetics Disasters **185**

Shaza Karrar, Mohammad Anzal Rehman, Saleh Fares

• CBRN Preparedness among Emergency Providers *185* • Approach to a Cbrne Incident *185* • Mitigation *186* • Preparedness *186* • Response *186* • CBRN Scene Management Zones *187* • Recovery *188* • Chemical Agents *188* • Biologic Agents *188* • Radiation/Energetics *191* • Mass Casualty Training *192*

30. Military Medicine **195**

Ahmed Humaid, Saleh Fares, Abdulla Alhmoudi

• Tactical Combat Casualty Care Principles *195* • Field Triage *196* • Approach to the Injured Soldier *196* • Medical Evacuation *199* • Challenges and Innovations *199*

SECTION 5: RESUSCITATION

31. Basic and Nondefinitive Airways **201**

Advait Thakor

• How to Recognize Airway Obstruction in an Emergency Department? *201* • Airway Positioning Maneuvers *201* • Airway Adjuncts *202* • Suctioning *203* • Bag-valve-mask Ventilation *203* • Supraglottic Airway Devices *205*

32. Advanced Airway Management **208**

Venugopalan Poovathumparambil

• Applied Anatomy *208* • Advanced Airway Management *209* • Airway Assessment *210* • Laryngoscopic Grading for Difficult Intubation *211* • Position for Intubation *211* • Technique of Intubation *212* • Rapid Sequence Intubation *212* • Delayed Sequence Intubation *215* • Intubation without Pharmacologic Agents *215* • Difficult Airway *215* • Failed Airway *215* • Protected Intubation in Highly Infected Patient—In View of Covid-19 *216* • Capnography *216*

33. Cardiopulmonary Resuscitation **219**

Mabel Vasnaik

• Steps of Resuscitation *219* • Postcardiac Arrest Care *222* • Cardiopulmonary Resuscitation in Children–how is it Different? *222* • Special Situations *223* • Defibrillation *224* • Cardioversion *226* • Recent Advances *227* • Recent Updates on Cardiopulmonary Resuscitation *227*

34. Cardiopulmonary Resuscitation in Special Situation **230**

Jesús Daniel López Tapia, Andrea Pechir Cerrillo

• Hypoxia *230* • Electrolyte Imbalances *230* • Hypothermia *230* • Hypovolemia *231* • Cardiac Tamponade *231* • Tension Pneumothorax *231* • Thrombosis (Coronary and Pulmonary) *231* • Toxins (Poisoning and Intoxications) *231* • Special Patients *231*

35. Postcardiac Arrest Syndrome **234**

Devendra Richhariya, Bhawana Sharma

• Postcardiac Arrest Syndrome—pathophysiology *234* • Airway and Breathing *234* • Circulation *236* • Disability-optimizing Neurologic Recovery *236* • Targeted Temperature Management *237* • Prognostication *238* • Rehabilitation *240* • Organ Donation *240*

SECTION 6: MANAGING CRITICALLY III PATIENT IN EMERGENCY DEPARTMENT

36. Oxygen Therapy and Oxygen Delivery System **241**

Bhawana Sharma, Devendra Richhariya

• Indications *241* • Classification of Oxygen Delivery System *242* • Low-flow System *242* • High-flow System *244* • Selection of Oxygen Delivery System *244* • Initiation of Oxygen Therapy in Emergency Department *244* • Long-term Oxygen Therapy *245* • Oxygen Toxicity *245* • High-flow Nasal Cannula Oxygen Therapy *245* • Medical Oxygen Cylinders: Types Capacity and Estimation of Running Time *246*

37. Hyperbaric Oxygen Therapy **249**

Amit Gupta

• History *249* • Physiology *249* • Rationale of use of Hyperbaric Oxygen Therapy/Mechanism of Action *249* • Equipment and Procedure *250* • Indications *250* • Contraindications *251* • Clinical Application *251* • Potential Harm, Safety, and Precautions *252*

38. Noninvasive Ventilation **254**

Kishalay Datta

• Modes of Noninvasive Ventilation *254* • Physiologic Changes with NIV: How does NIPPV Works? *255* • Selection Criteria for NIPPV *255* • Interface or Mask for NIPPV *255* • How to Initiate NIPPV in Patients? *256* • Monitoring of Patients on NIPPV *256* • Predictors of Success of NIPPV *256* • What Type of Ventilators can be used for NIPPV? *257* • What Modes of Ventilator can be used for Noninvasive Ventilation? *257* • How to Set the Ventilator for NIPPV? *257* • Weaning *257* • Complications of NIPPV *257* • High-flow Nasal Cannula *258*

39. Mechanical Ventilation **259**

Mrinal Sircar, Saurabh Mehra, Devendra Richhariya

• Physiology of Breathing *259* • Mechanical Determinants of "Patient–Ventilator" Interactions *259* • Indications of Mechanical Ventilation *260* • Types of Mechanical Ventilation *260* • Modes of Ventilation *261* • Initiation of Ventilation *263* • Monitoring after Initiating Ventilation *264* • Complications of Intubation and Ventilation *265* • Airway Pressures, Alarms, and Troubleshooting *265* • Mechanical Ventilation in Special Conditions *266*

40. Sedation and Analgesics for Mechanically Ventilated Patients **270**

Manish Garg, Devendra Richhariya

• Goals and Principles *270* • Medications *270* • Assessment *272* • Special Situations *273*

41. Extubation in Emergency Department **275**

Joanne Hng Mei Hwa, Ahmad Zulkarnain Ahmad Zahedi

• Patient Selection and the "ABC" Procedural Consideration *275* • Postextubation Complications and Management *277* • Palliative Extubation in Emergency Department *278*

42. Vascular Access **280**

Eric Revue

• Basic Knowledge of Pathophysiology *280* • How to Choose Appropriate Vascular Device? *281* • Peripheral Access *281* • Central Venous Catheters *283*
• Midline Catheters *285* • Peripherally Inserted Central Catheters *285*
• Use of Ultrasound for Central Venous Catheter Insertion *286* • Removal of Catheter *286* • Arterial Access *286* • Arterial Blood Pressure *287* • Emergency Conditions Where Femoral Artery Access is Recommended *287* • Intraosseous Device *288* • Complications *289*

43. Intravenous Fluids **291**

Ripenmeet Salhotra, Supradip Ghosh

• Crystalloids *291* • Balanced Salt Solutions *292* • Colloids *293* • Maintenance Fluids *293*

44. Assessment of Volume Status and Hemodynamic Monitoring **296**

Sangeeta Chakraborty, Debashish Dhar, Devendra Richhariya

• Static Methods of Volume Assessment and its Limitations *296* • Dynamic Methods of Volume Assessment and its Limitations *298* • Devices for Hemodynamic Monitoring *300*
• Invasive Hemodynamic Monitors *300* • Noninvasive Hemodynamic Monitors *301*

45. Arterial Blood Gas Analysis **303**

Devendra Richhariya, Bhawana Sharma

• Basics of Pulmonary Gas Exchange *303* • Disorders of Gas Exchange *304* • Basics of Acid-base Balance *304* • Disturbance of Acid-base Balance *305* • Concepts in Acid-base Disorders and Formulas *305* • Steps in the Interpretation of Arterial Blood Gas *305* • Strong Ion Difference Approach versus Traditional Approach *305* • Arterial Blood Gas Sampling Technique *309*

46. Electrolyte Imbalances **311**

Ayşegül Bayır

• Hypernatremia *311* • Hyponatremia *312* • Hyperkalemia *314* • Hypokalemia *315*
• Hypocalcemia *316* • Hypermagnesemia *317* • Hypomagnesemia *317*

47. Sepsis **319**

Ravi Jain, Yash Javeri

• Definition *319* • Epidemiology *319* • Pathophysiology *319* • Differentials *320* • Screening and Diagnosis of Sepsis *320* • Management *321* • Other Supportive Therapies *326*
• Disposition *326* • Code Sepsis *326*

48. Overview of Shock **328**

Khusrav Bajan, Devendra Richhariya

• Clinical Presentation *329* • Use of Ultrasound in Evaluation and Diagnosis of Shock *329* • Management of Shock *330* • Specific Measures *333*

49. Vasopressors and Inotropes in Resuscitation **335**

Manish Mehta

• Physiology: Receptors and Mechanisms of Action *335* • Common Pharmacological Agents *336* • Clinical Application of Vasopressors and Inotropes in Shock Resuscitation *338*
• Fundamental Concepts for use and Practical Issues *338* • Complications *339*
• Summary and Recommendations *340*

50. Perfusion Endpoint in Resuscitation of Shock **341**
Nisreen Hamza Maghraby, Zainab Musa Al Alawi
• Macrocirculatory Endpoint *341* • Microcirculatory Endpoint *342*
• Clinical Assessment of Perfusion *343*

51. Extracorporeal Membrane Oxygenation **345**
Basar Cander
• Historical Development of Extracorporeal Membrane Oxygenation *345* • Extracorporeal Membrane Oxygenation Techniques *345* • Extracorporeal Membrane Oxygenation Components *346* • Weaning *346* • Indications *347* • Contraindications *347*
• Complications *347* • Extracorporeal Membrane Oxygenation in Special Patient Groups *348*
• Future Projections *349*

52. Procedural Sedation and Analgesia **350**
Devendra Richhariya, Bhawana Sharma
• Sedation Policy and Guidelines *351* • Indications in Emergency Department *351* • Presedation Patient Evaluation *351* • Preparation *351* • Technique for Procedural Sedation and Analgesia *352*

53. Pain Management in Emergency Department **355**
Radhika Rani Chandra, Devendra Richhariya
• Pathophysiology *355* • Assessment of Pain in Emergency Department *356*
• Assessment Tools for Pain *356* • Pharmacologic Therapy for Pain *357* • Anesthetic Agents in Pain Management *361* • Regional Anesthesia (Peripheral Nerve Block) *362* • Nonpharmacologic Intervention for Pain *362*

54. Point-of-care Ultrasound in Resuscitation **364**
Won-Jun Kuk, Mohamed Moheb El Abd, Tiffany Fong
• Step 1: Pump *364* • Step 2: Tank *366* • Step 3: Pipes *369*

55. Ultrasound-guided Procedures **374**
Richa Manglorkar, Mohaned Moheb El Abd, Tiffany Fong
• Physics of Ultrasound *374* • Transducers *375* • Knobology *375* • Technique Overview *375* • Peripheral Venous Catheter Placement with Ultrasound Guidance *375*
• Central Venous Catheter Placement with Ultrasound Guidance *376* • Ultrasound-guided Pericardiocentesis *384* • Ultrasound-guided Peripheral Nerve Blocks *386*

56. Cricothyrotomy **394**
Sanjay Shah
• Applied Anatomy *394* • Indications *394* • Position of the Patient *395*
• Needle Cricothyrotomy *395* • Percutaneous Cricothyroidotomy (Seldinger Technique) *395*
• Surgical Cricothyroidotomy *396* • Complications *397*

57. Tracheostomy Related Emergencies **398**
Devendra Richhariya, Bhawana Sharma
• Emergent Life-threatening Complications *398* • Urgent Complications *400*
• Myiasis (Maggots) of Tracheostomy Wound *401*

SECTION 7: CARDIOVASCULAR EMERGENCIES

58. Chest Pain Evaluation in Emergency Department **403**

Devendra Richhariya

• Causes of Chest Pain *403* • Evaluation *405* • Diagnostic Approach *405*
• Electrocardiogram *407* • Other Studies *408*

59. Palpitation **409**

Roberta Petrino, Aldo Tua

• Etiology *409* • Pathophysiology *409* • Clinical Presentation *412* • Red Flags *412*
• Evaluation *412* • Investigations *413* • Treatment *413*

60. Syncope **415**

Brajesh Kumar Mishra

• Epidemiology *415* • Pathophysiology *415* • Classification *415* • Life-threatening Causes of Syncope *415* • Common Causes of Syncope *416* • Other Causes of Syncope *416*
• Objectives for Evaluation *417* • Investigation *418* • Treatment *419* • Risk Stratification for Syncope in Emergency Department *420* • Future Perspective *420*

61. Interpretation of ECG **421**

Kartikeya Bhargava

• Cardiac Arrhythmias *421* • Tachyarrhythmias *421* • Bradyarrhythmia *425*
• ST-T Changes *426* • QRS Morphology Amplitude Duration and Axis Pattern *430*
• Miscellaneous ECG Findings in Emergency *432*

62. Cardiac Biomarkers **434**

Omar Ghazanfar, Israa M Salih, Saleh Fares

• Ideal Cardiac Biomarker *434* • Troponin *434* • Creatinine Kinase-MB *435* • Myoglobin *435*
• Natriuretic Peptide *435* • Other Markers *435* • Multiple Marker Approach *435*
• Future Perspective *437*

63. Echocardiography in Emergency Department **438**

Manish Bansal

• Echo in Assessment of Acute Chest Pain *438* • Echo in Assessment of Dyspnea/Shortness of Breath *441* • Echo in Assessment of Hypotension and Hemodynamic Instability *444*
• Echo in Assessment of Stroke Patients *446* • Echo in Assessment of Syncope *447*
• Echo in Assessment of Pyrexia of Unknown Origin *448*

64. Coronary Computed Tomography in Chest Pain Evaluation **449**

Devendra Richhariya

• Indications of Coronary CT Angiography *449* • Contraindications for Coronary CT *450*
• Factors Affecting the Quality of Coronary CT Images *450* • Preparation and Instructions for Coronary CT *450* • Triple Rule-out Protocol *450* • Interpretation of Coronary CT *451*
• Coronary CT as Decision Making Tool *451*

65. Acute Coronary Syndrome **453**

Naveen Bhamri, Devendra Kumar Agarwal, Sudhanshu Sekhar Parida

• Etiopathogenesis and Risk Factors *453* • Management of Acute Coronary Syndrome *453*
• Common Strategies for Stemi and Nstemi Management *457* • Non-ST Elevation—ACS Management *457* • Stemi Management *457* • Special Consideration in Stemi/Nstemi Management *457* • Disposition *459*

66. Cardiogenic Shock **460**

Devendra Richhariya

• Definition *460* • Etiology *460* • Pathophysiology *460* • Diagnosis *461*
• Management *462* • Critical Care Support *462* • Revascularization Support *463*
• Mechanical Support *464* • Special Situation *466* • Reversible Myocardial Dysfunction (Myocarditis, Sepsis-induced Myocardial Dysfunction) *467*

67. Acute Heart Failure **468**

Devendra Richhariya

• Pathophysiology *468* • Precipitating Factors *468* • Classification *468*
• Clinical Features *469* • Diagnosis *469* • Emergency Department Treatment *469*
• Pharmacologic Therapy *469* • Mechanical Assistance *471* • Disposition *472*

68. Cardiac Arrhythmias: Identification and Management **473**

Ives Hubloue, Jamal Yusuf

• Bradyarrhythmias *473* • Tachyarrhythmias *476* • Supraventricular Tachycardias *476*
• Ventricular Tachycardias *478*

69. Cardiomyopathies **481**

Jamal Yusuf, Saurabh Sharma, Bhushan Shah

• Pathophysiology *481* • Clinical Presentation *482* • Diagnostic Evaluation *482*
• Treatment *483* • Mechanical Circulatory Support *483*

70. Valvular Emergencies **486**

Rahul Mehrotra, Mayank Gupta

• General Concepts of a Cardiac Murmur *486* • Acute Mitral Regurgitation *487* • Acute Aortic Regurgitation *488* • Prosthetic Heart Valve Thrombosis *488* • Acute Rheumatic Fever *490*

71. Cardiac Tamponade and Pericardiocentesis **492**

Laila Ali Hussein, Ayesha Almemari, Devendra Richhariya

• Overview of Cardiac Tamponade *492* • Etiology *492* • Clinical Features *492*
• Diagnostic Testing *492* • Management *494* • Pericardiocentesis *494*
• Methods for Removal of Pericardial Fluids *494*

72. Cardiac Temporary Pacing **497**

Kartikeya Bhargava

• Types of Temporary Pacing *497* • Indications of Temporary Pacing *498* • Temporary Pacing Procedure *498* • Complications of Temporary Pacing *499* • Postprocedure Care *499*

73. Postcardiac Surgery Emergencies **501**

Yatin Mehta, Devendra Richhariya

• Paravalvular Aortic/Mitral Regurgitation *501* • Bleeding *501* • Arrhythmias *502*
• Tension Pneumothorax *503* • Cardiac Tamponade *503* • Acute Coronary Syndrome Following Cardiac Surgery *505* • Intractable Hypotension *505* • Gastrointestinal Emergencies *505* • Stroke and Other Neurosurgical/Neurological Complications *506*
• Cardiac Surgery Associated Acute Kidney Injury *506* • Acute Decompensated Heart Failure *507*
• Perioperative Respiratory Failure *508* • Prevention of Postcardiac Surgery Complications *508*

74. Systemic Hypertension **510**

Au Kin Heng Constantine, Quintin Kwok

• Definition Classification Grading *510* • Etiology and Pathophysiology *510*
• Clinical Presentation *511* • Evaluation of Hypertension *512* • Stepwise Approach to Systemic Hypertension *512* • Therapeutic Approach to Hypertensive Emergencies and Urgencies *514*

75. Pulmonary Hypertension **517**

Asaad S Shujaa, Marah Alatrash, Noor Bamohammed

• Classification *517* • Pathophysiology of Pulmonary Hypertension *518*
• Clinical Presentation *518* • Evaluation *519* • Investigations and Interpretation *519*
• Treatments for Pulmonary Hypertension *519* • Disposition *520*

76. Pulmonary Embolism **521**

Ashima Sharma

• Risk Factors *522* • Clinical Presentation *522* • Pretest Probability, Scoring System and PERC *522*
• Diagnostic Workup *523* • Treatment *526*

77. Acute Aortic Dissection **530**

Devendra Richhariya

• Epidemiology *530* • Pathogenesis and Risk Factors of Aortic Dissection *530* • Classification of Acute Aortic Dissection *531* • Clinical Presentation of Acute Aortic Dissection *531* • Diagnostic Strategies for Acute Aortic Dissection in the Emergency Department *532* • Treatment *532*
• Acute Aortic Dissection in Pregnancy *535*

78. Antithrombotic Therapy **536**

Santosh Pandey

• Overview of Hemostasis *536* • Oral Anticoagulants *536* • Heparin *538*
• Antiplatelet Agents *538* • Fibrinolytic Drugs *538* • Adverse Effects *540*

79. Antithrombotic Reversal Agents **541**

Devendra Richhariya

• The Clotting/Coagulation Cascade *541* • Reversal of Warfarin *542* • Reversal of Direct Oral Anticoagulants *543* • Reversal of Heparin and Low-molecular-weight Heparins *545*
• Reversal of Antiplatelet Therapy *545*

80. Peripheral Arteriovascular Disease **547**

Prasad Rajhans, Ujwal Prakash Dhundi

• Etiology/Causes *547* • Pathophysiology *547* • Clinical Presentation *547*
• Diagnostic Strategies *548* • Management *549* • Disposition *549*

SECTION 8: RESPIRATORY EMERGENCIES

81. Cough **551**

Bhawana Sharma

• Acute, Subacute, and Chronic Cough *551* • Mechanism of Cough *551* • Etiology of Cough *551*
• Characteristics of Cough *551* • Associated Features of Concern (Red Flags) *552* • Complications of Cough *552* • Investigations *552* • Treatment *553*

82. Hemoptysis **556**

Veerottam Tomer

• Pulmonary Circulation *556* • Etiology of Hemoptysis *557* • Evaluation of Patient with Hemoptysis *557* • Management of Patient with Hemoptysis *558*

83. Clubbing and Cyanosis **563**

Vivek Chauhan, Suman Thakur

• Clubbing *563* • Cyanosis *566*

84. Acute Respiratory Failure **570**
Chitra Mehta
• Definition *570* • Classification *570* • Pathophysiology *570*
• Clinical Presentation *572* • Diagnostic Approach *572* • Management *572*

85. Acute Severe Asthma **575**
Bhawana Sharma, Devendra Richhariya
• Acute Asthma *575* • Pathophysiology *575* • Clinical Evaluation *576* • Investigations *577*
• Treatment *578* • Status Asthmaticus *579* • Pulmonary Function Test *580*
• Spirometry *580* • Interpretation of the Pulmonary Function Test *581*

86. Chronic Obstructive Pulmonary Disease **583**
Sudha Kansal
• Risk Factors *583* • Pathophysiology *583* • Initial Assessment *584*
• Diagnosis *584* • Treatment *585* • Acute Exacerbation of Chronic Obstructive Pulmonary Disease *587* • Management of Exacerbation *588* • Triage to Home or Hospital *589*
• Noninvasive Ventilation *589* • Mechanical Ventilation *589* • Criteria for Discharge and Advice *590* • Follow-up Assessment *590* • Prevention *590* • Prognosis *591*

87. Pneumonia **592**
Ashish Kumar Prakash, Reena Verma, Anand Jaiswal
• Classification of Pneumonia *592* • Pathophysiology *593* • Clinical Evaluation *593*
• Diagnostic Approach *594* • Hospital Admission Decisions *596* • Treatment of Pneumonia *597*
• Special Treatment Considerations *600* • Prevention *600*

88. Pneumothorax **602**
Bhawana Sharma, Devendra Richhariya
• Pathophysiology *602* • Clinical Features *603* • Primary Spontaneous Pneumothorax *603*
• Secondary Spontaneous Pneumothorax *603* • Catamenial Pneumothorax *603*
• Tension Pneumothorax *603* • Radiological Evaluation of Pneumothorax *604* • Management of Pneumothorax *604* • Intercostal Chest Drain Insertion *605* • Pneumomediastinum (Mediastinal Emphysema) *611* • Subcutaneous Emphysema *612*

89. Pleural Effusion, Lung Empyema, and Cavitary Lung Lesions **614**
Laxman Bhusal, Rabin Bom
• Pleural Effusion *614* • Lung Empyema *617* • Cavitary Lung Lesions *618*

90. Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) **621**
Devendra Richhariya, Bhawana Sharma
• Definition of Cases and Clinical Features *621* • Clinical Features *621* • Severity Classification of SARS-CoV-2, Investigations and Suggested Treatment *622* • CT Chest in SARS-CoV-2—Correlation with Disease Severity *622* • Remdesivir *623* • Favipiravir *624* • Tocilizumab *627*
• Convalescent Plasma Therapy in Patients with COVID-19 *627* • Vaccines for SARS-CoV-2 *628*
• SARS-CoV-2 Vaccines in India *629* • OMICRON—New Variant of SARS-CoV-2 *630*

SECTION 9: GASTROINTESTINAL EMERGENCIES

91. Abdominal Pain **633**
Roberta Petrino, Aldo Tua
• Etiology *633* • Pathophysiology *633* • Clinical Presentation *633*
• Evaluation *636* • Investigations *637* • Treatment *638*

92. Nausea, Vomiting, Hiccups, Constipation **640**
Devendra Richhariya
• Nausea and Vomiting *640* • Hiccups *643* • Constipation *646*

93. Diarrhea-associated Diseases **649**
Sanjay Kumar
• Pathophysiology *649* • Approach to Acute Diarrhea *649* • Traveler's Diarrhea *651*
• Persistent and Chronic Diarrhea *651* • *Clostridium Difficile*-induced Diarrhea *651*
• Inflammatory Bowel Disease *653* • Celiac Disease *653*

94. Gastrointestinal Bleeding **656**
Anukalp Prakash, Anshu Nagpal
• Epidemiology *656* • Causes *656* • Initial Assessment and Prognostication *657*
• History and Physical Examination *657* • Laboratory Investigations *658*
• Treatment *658* • Endoscopy Therapy *659*

95. Esophageal Emergencies **662**
Purushottam Vashistha
• Atypical Chest Pain *662* • Acute Dysphagia or Odynophagia *662* • Pill Injury *663*
• Esophageal Foreign Body *663* • Caustic Injury to Esophagus *664*
• Esophageal Injury and Perforations *664* • Mallory–Weiss Syndrome *665*
• Boerhaave's Syndrome *665*

96. Dyspepsia and Peptic Ulcer Disease **666**
Ravindra Kale
• Etiology *666* • Pathophysiology *666* • Clinical Presentation *666*
• Evaluation *667* • Treatment *667* • Prognosis *668*

97. Acute Pancreatitis and Cholecystitis **669**
Sanjay Kumar
• Acute Pancreatitis *669* • Acute Cholecystitis *672*

98. Acute Hepatitis **674**
Amit Mittal, Akanksha Rastogi
• Etiology *674* • Pathophysiology *674* • Clinical Presentation *675*
• Evaluation *675* • Investigations *675* • Treatment *676*

99. Chronic Liver Disease and Complications **677**
Ravindra Kale
• Malnutrition *677* • Infections *677* • Gastrointestinal Bleeding *678*
• Ascites *678* • Pulmonary Complications *678* • Hepatorenal Syndrome *679*
• Hepatocellular Carcinoma *679* • Hepatic Encephalopathy *679*

100. End-stage Liver Disease **682**
Uday Sanglodkar, Neeraj Mangla
• Definitions *682* • Management of Hepatic Encephalopathy *683* • Management of Gastrointestinal Bleed *683* • Management of Acute Kidney Injury *684* • Management of Sepsis *686* • Management of Ascites *687* • Management of Hepatic Hydrothorax *688*
• Liver Transplantation in Critically Ill ESLD Patients *688*

101. Liver Transplant and Related Complications **690**

Amit Ganguly

• Indications *690* • Contraindications *691* • Brain Dead Donor and Optimization *691* • Liver Transplant Procedure *691* • Complications of Liver Transplant *691* • Immunosuppression and Rejection *692* • Outcome *692*

102. Bowel Obstruction **694**

Jesús Daniel López Tapia, Aldo Emigdio Bartolini Salinas

• Etiology *694* • Pathophysiology *695* • Clinical Presentation *695* • Evaluation: History and Physical Examination *695* • Investigations *696* • Treatment *697*

103. Acute Appendicitis **699**

Mukund Khetan

• Anatomy *699* • History *699* • Etiopathogenesis *699* • Presentation *700* • Evaluation *700* • Investigations *701* • Appendicitis in Special Population *702* • Treatment *702* • Special Considerations during Appendectomy *703* • Recent Advances *704*

104. Anorectal Diseases **706**

Ashok Kumar Puranik, Devendra Richhariya

• Hemorrhoids *706* • Anal Fissure *708* • Anorectal Abscess *709* • Anal Fistula *711* • Pilonidal Disease *712* • Rectal Prolapse *714* • Rectal Trauma/Foreign Body *714* • Proctitis *715* • Pruritus Ani *715* • Proctalgia Fugax *715*

105. Vascular Abdominal Emergencies **717**

Devendra Richhariya

• Vascular Abdominal Anatomy *717* • Abdominal Vascular Thromboses *718* • Ischemic Bowel *719* • Aneurysm *720* • Visceral Artery Aneurysms *722*

SECTION 10: RENAL AND GENITOURINARY EMERGENCIES

106. Imaging Modalities in Genitourinary Disease **723**

Aman Gupta

• Conventional Plain Film Radiography *723* • Intravenous Urography *723* • Retrograde Urography *724* • Cystography *725* • Retrograde Urethrography and Voiding Cystourethrogram *725* • Percutaneous Nephrostomy and Antegrade Pyelography *725* • Ultrasound *726* • Doppler Sonography *727* • Computed Tomography *727* • Magnetic Resonance Imaging *728* • Nuclear Medicine *729*

107. Hematuria **731**

Puneet Ahluwalia

• Classification of Hematuria *731* • Etiology *731* • History and Initial Evaluation *731* • Stepwise Approach for Evaluation *733* • Unexplained Hematuria *734* • Follow-up after Initial Negative Evaluation *734* • Treatment *734*

108. Acute Urinary Retention **738**

Puneet Ahluwalia

• Epidemiology *738* • Etiopathogenesis *738* • Categories of Urinary Retention *740* • Clinical Presentation *740* • Evaluation *740* • Initial Management of Acute Urinary Retention *741*

109. Acute Kidney Injury and Rhabdomyolysis **743**

Ankit Purohit, Devendra Richhariya

• Pathophysiology *743* • Acute Kidney Injury *744* • Definition *744* • Risk Factors and Causes for Acute Kidney Injury *744* • Clinical Evaluation *747* • Diagnostic Testing *747*
• Management of Acute Kidney Injury in the Emergency Department *747*
• Acid-base Derangement in the Critically Ill Acute Kidney Injury *749*
• Renal Replacement Therapy *750* • Rhabdomyolysis *750* • Disposition *751*

110. End-stage Renal Disease **753**

Devendra Richhariya

• Chronic Kidney Disease *753* • End-stage Renal Disease *754* • Pathophysiology *754* • Clinical Features of Uremia *754* • Hemodialysis *756* • Peritoneal Dialysis *758* • Renal Transplant *759*

111. Kidney and Ureteral Stones **761**

Devendra Richhariya

• Risk Factors *761* • Cause *762* • Clinical Presentation *762* • Emergency Department Evaluation *762* • Imaging Modalities *763* • Management and Treatment *764*
• Prognosis *764* • Complications *764* • Special Concerns *765*

112. Urinary Tract Infection **766**

Krunal Desai

• Definitions and Classification *766* • Pathophysiology *766* • Risk Factors and Uropathogens *766* • Clinical Features *767* • Differential Diagnosis *767* • Diagnostic Evaluation *767* • Treatment *768* • Disposition *771*

113. Penile Emergencies **773**

Puneet Ahluwalia, Devendra Richhariya

• Anatomy *773* • Priapism *773* • Zipper Injury and Penile Entrapment *775*
• Balanitis and Posthitis *775* • Peyronie's Disease *776* • Penile Calciphylaxis *776*
• Phimosis *776* • Paraphimosis *779* • Penile Fracture *781*

114. Acute Scrotal Emergencies **784**

Devendra Richhariya

• Anatomy *784* • Etiology of Acute Scrotum *784* • Painful Scrotum *785*
• Painless Swollen Scrotum *787* • Erythematous Scrotum *787* • Traumatic Scrotum *787*
• Diagnosis *787* • Treatment *788*

115. Renal Transplant Related Complications **791**

Vishal Saxena, Yogeshman Anand

• Hypertension Following Kidney Transplant *791* • Surgical and Urologic Complication *791*
• Infection after Kidney Transplantation *793* • Cytomegalovirus Infection *793* • BK Polyomavirus Infection *793* • Fungal Infections Post-transplant *793* • Allograft Rejection *793* • New-onset Diabetes after Transplant *794* • Post-transplant Malignancy *794*

SECTION 11: NEUROLOGICAL EMERGENCIES

116. Headache **796**

Devendra Richhariya

• Etiology *796* • Pathophysiology *796* • Clinical Presentation *797*
• Evaluation *797* • Investigations *797* • Treatment *798*

117. Acute Dizziness and Vertigo **801**

Ramyajit Lahiri, Subhra Choudhury

• Definition *801* • Etiology *801* • Physiology *802* • Pathophysiology *803*
• Concerning Clinical Features *804* • Evaluation-history and Physical Examination *804*
• Other Test *808* • Investigations *809* • Management *809*

118. Altered Mental Status: Delirium **814**

Devendra Richhariya

• Definition *814* • Subtype of Delirium *815* • Recognizing the Delirum *815* • Pathophysiology of Delirium *815* • Etiology *815* • Evaluation *816* • Management *817* • Disposition *818*

119. Acute Ischemic Stroke **820**

Chandril Chugh

• Epidemiology and Risk Factors *820* • Ischemic Stroke Classification *820*
• Clinical Presentation *821* • Radiological Investigations in Acute Stroke *821*
• Management of Acute Stroke *823* • Intravenous Thrombolysis *824*
• Endovascular Treatment for Stroke *825* • Cryptogenic Stroke *826*

120. Subarachnoid and Intracerebral Hemorrhage **828**

Alireza Baratloo, Arash Safaie

• Etiology/Causes *828* • Pathophysiology of the Condition *828*
• Clinical Presentation and Red Flags *829* • Evaluation and Interpretation of Findings *829*
• Investigations *829* • Treatment *829* • Disposition *831*

121. Seizures and Status Epilepticus **833**

Gouri A Ranade, Priyanka G Mahale

• Common Causes of Status Epilepticus *833* • Classification and Stages of Status Epilepticus *833*
• Initial Evaluation and Management *834* • Phase Wise Management of Status Epilepticus *834*
• Special Situations in Status Epilepticus *835* • Systemic Complications of Status Epilepticus *836*

122. Acute Flaccid Paralysis **838**

Priyanka G Mahale, Rahul Kulkarni, Devendra Richhariya

• Guillain–Barré Syndrome *838* • Myasthenia Gravis *839* • Transverse Myelitis *839*
• Botulism *840* • Inflammatory Myopathy *840* • Systemic or Metabolic Disorders Causing Acute Flaccid Paralysis *840* • Weakness Associated with Critical Illness *841* • Trauma Induced Acute Flaccid Paralysis *841* • Evaluation of Acute Flaccid Paralysis *842* • Lathyrism *842*

123. Meningitis Encephalitis and Brain Abscess **844**

Atul Tungikar, Priyanka G Mahale, Devendra Richhariya

• Evaluation of Meningitis *844* • Management of Meningitis *845* • Encephalitis *846*
• Brain Abscess *848*

124. Coma: Evaluation and Management **849**

Noel Fernando

• Pathophysiology *849* • Differential Diagnosis *849* • Clinical Finding *849* • Clinical Examination *849* • Grading of Coma *851* • Investigations *851* • Treatment *851*

SECTION 12: ENDOCRINAL EMERGENCIES

125. Type 1 Diabetes Mellitus and Insulins **855**
Amit Gupta, Vinod Kumar
• Type 1 Diabetes Mellitus *855* • Diagnosis *855* • Insulin *856*

126. Type 2 Diabetes Mellitus: Management **859**
Ashok K Taneja
• Epidemiology: Prevalence in World and India *859* • Risk Factors *859*
• Etiology and Pathogenesis *859* • Diagnosis and Screening *860* • Management *860*
• Stepwise Approach of Managing Type 2 Diabetes Mellitus *865*

127. Hypoglycemia **867**
Jugal Kishor Sharma, Dinesh Sharma
• Etiology *867* • Pathophysiology *868* • Clinical Features *868* • Diagnosis *868*
• Classification of Hypoglycemic Events *868* • Treatment *869* • Prevention *869*

128. Diabetic Ketoacidosis **871**
Rajeev Chawla, Shalini Jaggi, Sidhant Trehan
• Epidemiological Aspect *871* • Pathogenesis of Diabetic Ketoacidosis *871* • Precipitating Factors for Diabetic Ketoacidosis *871* • Presenting Features for Diabetic Ketoacidosis *871*
• Ketosis Prone Type 2 Diabetes Mellitus *871* • Evaluation of Patient for Diabetes Ketoacidosis *872*
• Diagnostic Criteria for Diabetic Ketoacidosis *872* • Treatment Goals for Diabetic Ketoacidosis *873*
• Complications of Diabetic Ketoacidosis *875* • Preventive Measures for Diabetic Ketoacidosis *875*

129. Hyperosmolar Hyperglycemic Syndrome **877**
Dheeraj Kapoor
• Diabetes Overview *877* • Etiology *877* • Pathophysiology *878* • Diagnosis *879*
• Differential Diagnosis *879* • Treatment Approach *880* • Prognosis *880*

130. Hypothyroidism and Myxedema Coma **882**
Ajay Agarwal, Danendra Sahu, Rupak Wadhwa
• Classification and Etiopathogenesis *882* • Clinical Presentation *882*
• Diagnosis *883* • Myxedema Coma *883* • Treatment *885*

131. Hyperthyroidism—Graves' Disease and Thyroid Storm **888**
Dheeraj Kapoor, Abhishek Goyal
• Epidemiology *888* • Clinical Presentation *888* • Pathogenesis *888* • Diagnosis *889*
• Treatment *889* • Thyroid Storm *891*

132. Acute Adrenal Crisis **893**
Dheeraj Kapoor, Abhishek Goyal
• Basic Anatomy and Physiology of the Adrenal Gland *893* • Classification *894*
• Pathophysiology *894* • Causes *895* • Clinical Presentation *895* • Diagnosis *896*
• Confirmatory Diagnostic Testing *896* • Evaluation and Management in Emergency Department *897* • Prevention and Patient Education *897*

Volume 2

SECTION 13: EYE, EAR, NOSE, THROAT, AND ORAL EMERGENCIES

133. Eye Emergencies **899**

Carreen Pakrasi, Sudipto Pakrasi

• Anatomy *899* • Penetrating Ocular Injuries *900* • Nonpenetrating Ocular Injuries *901*
• Chemical Injuries *903* • Contact Lens-related Emergencies *903* • Conjunctivitis *903*
• Corneal Ulcers *903* • Uveitis *904* • Glaucoma Emergencies *904*
• Neuro-ophthalmology Emergencies *904* • Optic Neuritis *904* • Papilledema *904*
• Vascular Emergencies *904* • Vitreous Hemorrhage *905*

134. Ear Emergencies **907**

Shaarang Sachdev, Salil Malik

• Anatomy of Ear *907* • Common Symptoms of Ear Problems *908* • Outer Ear Infections *909*
• Middle Ear Infection *910* • Inner Ear Infections *911* • Trauma to Ear *911*
• Procedures Related to Ear *912*

135. Nasal Emergencies **915**

Harshil Mehta

• Epistaxis *915* • Nasal Fracture *918* • Nasal Septal Hematoma *919*

136. Face and Jaw Emergencies **921**

Devendra Richhariya, Harshil Mehta

• Facial Swelling *921* • Localized Facial Swelling *921* • Generalized Facial Swelling *922*
• Facial Cellulitis *923* • Jaw Dislocation *924*

137. Neck, Throat, Oral, and Dental Emergencies **928**

Aman Sharma, Devendra Richhariya

• Pharyngitis *928* • Epiglottitis *929* • Peritonsillar Abscess *930* • Ludwig's Angina *931*
• Retropharyngeal Abscess *932* • Infectious Mononucleosis *933* • Oral Candidiasis *934*
• Oral Herpes Simplex *935* • Dental Pain *936* • Gingivitis *936* • Dental Abscess *940*
• Bleeding after Dental Surgery *940* • Dental Trauma *941*

138. Management of Foreign Bodies of Ear, Nose and Throat **944**

Mohammad Anzal Rehman, Neha Hudlikar, El Rasheed Salih

• History Taking and Presentation 944 • Approach and Management 944 • Foreign Bodies of the Ear 945
• Foreign Bodies of the Nose 947 • Foreign Bodies of the Throat 948

SECTION 14: HEMATOLOGY AND ONCOLOGY

139. Anemia **952**

Akanksha Rastogi, Amit Mittal

• Pathophysiology *952* • Types of Anemia *952* • Classifications *952* • Clinical Presentation *952*
• Red Flags *953* • Evaluation of Anemia *953* • Differential Diagnosis *954* • Investigations *954*
• Hemolytic Anemia *956* • Treatment *956*

140. Approach to Pancytopenia **958**

Benita Florence, Dodiy Herman

• Definition *958* • Etiology *958* • Clinical Features *959* • Diagnostic Workup *959*
• Aplastic Anemia *959* • Inherited Aplastic Anemia *960*

141. Approach to Leukemia **962**

Dodiy Herman, Benita Florence

• Epidemiology *962* • Risk Factors *962* • Clinical Presentation *962* • Classification *963* • Clinical Manifestation and Assessment *963* • Investigations *963* • Treatment in the Emergency Department *964* • Other Emergencies *964* • Precautions *965*

142. Oncological Emergencies **967**

Amit K Jain

• Oncological Emergencies Related to Local Tumor Effects *967* • Oncological Emergencies Related to Biochemical Derangements *971* • Oncological Emergencies Related to Hematological Derangements *973* • Oncological Emergencies Related to Therapy *975*

143. Thrombocytopenia, Bleeding, and Coagulopathy **979**

Ragesh Radhakrishnan Nair, Isha Gambhir

• Primary Hemostasis *979* • Coagulation Cascade *980* • Approach to Thrombocytopenia *981* • Disorders of Coagulation *983*

144. Blood Transfusion Therapy and Related Complication **986**

Aseem Kumar Tiwari, Geet Aggarwal

• Responsibility of Emergency and Blood Bank Team *986* • Transfusion Approach and Massive Transfusion Protocol *987* • Role of Specific Blood Components *988* • Adverse Effect of Blood Transfusion *990* • Hemovigilance (Hemovigilance Program of India) *991*

145. Therapeutic Plasmapheresis **993**

Rahul Solanki, Devendra Richhariya

• History *993* • Indications *993* • Techniques *994* • Complications *995*

146. Sickle Cell Disease **997**

Devendra Naik

• Pathophysiology *997* • Clinical Features *997* • Approach to Sickle Cell Disease Patient in Emergency Department *999* • Management *999*

147. Thrombotic Microangiopathies **1002**

Sirisha Kadali, Devendra Richhariya

• Thrombotic Thrombocytopenic Purpura *1002* • Hemolytic Uremic Syndrome *1005* • Immune Thrombocytopenic Purpura *1005* • Hellp Syndrome *1006* • Disseminated Intravascular Coagulation *1007* • Heparin-induced Thrombocytopenia *1009*

SECTION 15: DERMATOLOGY, RHEUMATOLOGY AND PSYCHIATRY

148. Approach to Skin Diseases in Emergency **1013**

Ramanjit Singh, Nidhi R Sharma

• History Taking *1013* • Examination of the Patient *1013* • Diagnostic Tests *1013* • Bedside Tests in Dermatology *1018* • Evaluation of the Nature of Diseases *1021* • Vesiculobullous Disorders *1021* • Drug Rash with Eosinophilia and Systemic Symptoms/Drug-induced Delayed Multiorgan Hypersensitivity *1021* • Infectious Diseases *1021* • Noninfectious Causes of Hemorrhagic Lesions *1022* • Necrotizing Fasciitis *1022* • Urticaria and Angioedema *1022* • Erythroderma *1022* • Inflammatory Cutaneous Disorders *1023* • Environmental Disorders *1023* • Acute Skin Failure *1023*

149. Generalized Dermatologic Emergencies **1025**

Tejas D Patel

• Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis *1025* • Pyoderma Gangrenosum *1026* • Staphylococcal Scalded Skin Syndrome *1027* • Necrotizing Fasciitis *1027* • Urticaria (Hives), Angioedema, and Anaphylaxis *1027* • Pemphigus Group of Diseases *1029* • Vasculitis *1030* • Lepra Reaction *1030* • Psoriasis (Erythrodermic Psoriasis) *1030* • Acute Skin Failure *1030*

150. Approach to Joint Pain **1033**

Sourabh Malviya

• Evaluation of Joint Pain *1033* • Laboratory Tests *1035* • Synovial Fluid Analysis *1035* • Imaging *1035* • Treatment *1037*

151. Overview of Rheumatological Disorders **1039**

Neeraj Jain, Amit Dua

• Classification and Definition *1039* • Etiology *1039* • Evaluation *1039* • Diagnosis *1042* • Treatment *1044*

152. Evaluation of Mental Health and Common Psychiatric Emergencies **1047**

Mohammad Anzal Rehman, Mansoor Masarrat Husain

• Evaluation of Mental Health *1047* • Investigations *1049* • High-risk Psychiatric Presentations in the Emergency Department *1050* • Overview of Psychiatric Illness *1051* • Thought Disorders, Psychosis, and Schizophrenia *1054*

SECTION 16: OBSTETRICS AND GYNECOLOGICAL EMERGENCIES

153. Acute Pelvic Pain **1056**

Dolly C Yadav

• Anatomy, Pathophysiology, and Etiology *1056* • Emergency Department Evaluation *1056* • Treatment *1059* • Disposition and Follow-up *1059* • Specific Conditions in Nonpregnant Females *1060*

154. Abnormal Uterine Bleeding **1066**

Sanjukta Dutta, Mainak Majumdar

• Basic Physiology *1066* • Etiology *1066* • Evaluation of Abnormal Uterine Bleeding *1067* • Investigations *1069* • Management *1069* • Disposition *1070*

155. Ectopic Pregnancy **1072**

Sonal Parihar

• Causes *1072* • Types of Ectopic Pregnancy *1072* • Clinical Presentation *1073* • Evaluation *1074* • Investigations *1074* • Treatment *1075*

156. Emergencies during Pregnancy **1078**

Devyani Misra, Mariyum Faruqi

• Nausea and Vomiting of Pregnancy and Hyperemesis Gravidarum *1079* • Spontaneous Abortion *1081* • Septic Abortion *1083* • Hypertension in Pregnancy *1086* • Hellp Syndrome *1095* • Placenta Previa *1095* • Prelabor Rupture of Membranes *1098* • Preterm Labor *1099*

157. Comorbid Conditions and Pregnancy **1104**

Laxman Bhusal, Rabin Bom

• Diabetes *1104* • Thyroid Diseases *1105* • Cardiovascular Diseases *1105*
• Asthma *1106* • Epilepsy *1106*

158. Emergency Delivery **1108**

Sangeeta Kaushik Sharma

• Prehospital Care *1108* • Emergency Department Care *1108* • Complicated Delivery *1110*
• Umbilical Cord Prolapse *1110* • Cesarean Section *1112* • Postpartum Complications *1112*

159. Resuscitation in Pregnant **1114**

Vijaya Banu Mohan, Dodiy Herman, Benita Florence

• Physiological Changes in Pregnancy *1114* • Critically Ill Maternal Patients *1114* • Maternal Collapse *1114* • Maternal Cardiac Arrest *1115* • Approach to Critically Ill Obstetric Patient *1115* • Approach to Maternal Cardiac Arrest *1116* • Management after Resuscitative Hysterotomy *1119* • Amniotic Fluid Embolism *1119*

SECTION 17: PEDIATRIC EMERGENCIES

160. Pediatric and Neonatal Transport **1121**

Trevor L Tredway

• Referring and Receiving Hospital Responsibilities *1121* • Criteria for Transfer *1121* • Mode of Transport *1121* • Transport Team *1122* • Patient Monitoring and Care *1122*

161. Pediatric Resuscitation **1124**

Mohammad Anzal Rehman, Thiagrajan Jaiganesh

• Systematic Approach to the Critically Ill Child *1124* • Primary Survey *1124*
• Secondary Survey *1127* • Pediatric Shock—Identification and Management *1128*
• Cardiopulmonary Arrest *1129* • Overview of Neonatal Resuscitation *1133*

162. Examination of Newborn **1136**

Nilu Sunil, Devendra Richhariya

• General Evaluation *1136* • Vital Signs *1137* • Systemic Examination *1138*

163. Crying Infant **1142**

Prabhat Maheshwari, Upasana Iyer

• What is Cry? *1142* • Normal and Excessive Crying *1142* • Etiology *1142*
• Pathophysiology *1142* • Features of Concern (Red Flag Signs) *1142*
• Prehospital Care *1142* • Evaluation of Crying Infants in Emergency Department *1144*
• Investigations *1145* • Treatment *1145*

164. Immunization in Pregnant Women, Infant and Children **1147**

Ashok Mishra

• Historical Aspects of Vaccination *1147* • Vaccination in Pregnancy *1148*
• Vaccination in Children *1150* • Cold Chain *1154* • Adverse Event Following Immunization *1155*

165. Pediatric Fever and Other Life-threatening Infections **1158**
Faiz Ahmad, Devendra Richhariya
Etiology *1158* • Pathophysiology of Fever *1158* • Clinical Presentation *1159*
• Features of Concern—red Flags *1159* • History and Physical Examination *1160*
• Diagnosis and Management *1160* • Antipyretics *1161* • Urinary Tract Infection *1162*
• Occult Bacteremia *1162* • Pneumonia *1162* • Severe Acute Respiratory Syndrome Coronavirus 2 Infection in Children *1162* • Multisystem Inflammatory Syndrome in Children Related to Covid-19 *1163*

166. Pediatric Abdominal Pain **1169**
Thiagrajan Jaiganesh, Faiz Ahmad
• Evaluation of Acute Abdominal Pain in Children *1169*
• Evaluation of Chronic or Recurrent Abdominal Pain in Children *1172*

167. Vomiting, Diarrhea, Dehydration in Children **1177**
Deepak Goyal
• Etiology *1177* • Assessment of Child with Vomiting and Diarrhea *1177*
• Dehydration in Diarrhea *1178* • Treatment *1178*

168. Pediatric Fluid and Electrolyte Therapy **1181**
Devendra Richhariya
• Physiologic Differences *1181* • Fluid Therapy *1181* • Maintenance Electrolytes *1183*
• Electrolyte Abnormalities *1183* • Monitoring Fluid and Electrolyte Therapy *1183*

169. Respiratory Problems in Infants and Children **1185**
Sandip Kumar
• Etiology *1185* • Pathophysiology *1186* • Clinical Presentation *1187*
• Evaluation *1187* • Investigations *1188* • Treatment *1188*

170. Pediatric Cardiac Emergencies **1190**
Munesh Tomar, Aditi Gupta
• Neonatal Cardiac Emergencies: An Overview *1190* • Presentation *1190*
• Case Scenarios—Cyanosis *1190* • Case Scenario—Cardiovascular Collapse *1192*
• Case Scenario—Acute Congestive Heart Failure *1193* • Pediatric Cardiac Emergencies *1193*
• Drugs Commonly Used in Cardiac Emergencies *1199*

171. Pediatric Diabetic Ketoacidosis **1201**
Devendra Richhariya
• Epidemiology *1201* • Pathophysiology *1201* • Clinical Presentation *1202*
• Diagnosis *1202* • Emergency Department Management *1203* • Complications *1206*
• Disposition *1206*

172. Pediatric Seizure **1208**
Devendra Richhariya
• Causes *1208* • Pathophysiology of the Condition *1208* • Clinical Presentation *1210*
• Febrile Convulsion *1210* • Status Epilepticus *1210* • Evaluation *1211*
• Investigations *1211* • Antiepileptic Drugs *1212* • Treatment *1212*

173. Pediatric Oral and Dental Emergencies **1215**
Trevor L Tredway
• Classification and Management of Traumatic Dental Injuries *1217*
• Classification and Management of Tooth Fractures *1217*

174. Rashes in Newborn and Infant **1220**

Nadeem Uddin Qureshi, Irene Oriaifo, Rekha Gadiparthi, Mohammed Moiz Qureshi

• Terminology of Primary Lesions *1221* • Benign Neonatal Skin Lesions *1221*
• Disorders of Pigmentation *1225* • Vascular Lesions of Infancy *1226*

175. Pediatric Antibiotic Prophylaxis **1228**

Veena Raghunathan, Devendra Richhariya

• Traumatic Wounds *1228* • Bite Wounds *1229* • Endocarditis Prophylaxis *1230*
• Chest Tube Insertion *1230* • Meningococcal Exposure *1231* • Pertussis Exposures *1231*
• Influenza Exposures *1233*

176. Pediatric Gastrosurgical Emergencies **1235**

Meera Luthra, Apurva Arora

• General Approach to a Sick Child with Abdominal Symptoms *1235* • Neonatal Necrotizing Enterocolitis *1235* • Duodenal Obstruction *1236* • Intestinal Malrotation and Volvulus *1236*
• Anorectal Malformation *1236* • Hirschsprung's Disease *1236* • Infantile Hypertrophic Pyloric Stenosis *1237* • Intussusception *1237* • Constipation *1238* • Mesenteric Lymphadenitis *1238* • Abdominal Trauma *1238* • Obstructed Hernia *1238*
• Foreign Body Ingestion *1239* • Appendicitis *1239* • Meckel's Diverticulum *1240*
• Cholecystitis *1240* • Pancreatitis *1240* • Abdominal Cyst *1241* • Features of Concern *1241*
• Postoperative Complications *1241* • Management *1241*

SECTION 18: GERIATRIC EMERGENCIES

177. Geriatric Emergency Department **1243**

Don Melady, Thom Ringer

• What is a Geriatric Emergency Department? *1243*
• A Practical Approach to Geriatric Emergency Department Optimization *1244*

178. Comprehensive Geriatric Assessment **1247**

Lorraine Lau, Rebecca Schonnop

• Medical Assessment *1247* • Psychological Assessment *1249*
• Functional Assessment *1249* • Social and Environmental Assessment *1249*

179. Geriatric Syndromes **1251**

Devendra Richhariya

• Falls *1251* • Urinary Incontinence *1252* • Pressure Ulcers *1252*
• Delirium *1253* • Functional Decline *1254*

180. Abuse or Neglect in Geriatric Population **1256**

M Sai Surendar

• Definition: Elder Abuse *1256* • Neglect *1257* • Statistics of Ground Reality *1257*
• Identify Eledr Abuse in the Emergency Department *1257* • Prevention of Elder Abuse *1257*
• Legal Framework *1258*

181. Drug Therapy in a Geriatric Patient **1259**

Phraewa Thatphet

• Physiologic Changes *1259* • Common Problems of Drug Use in an Older Adult *1260*
• Prescribing Inappropriate Medications *1260* • Polypharmacy *1261* • Uncordinated Care *1263*
• Adverse Drug Event *1264* • Principles of Geriatric Drug Use *1264*

182. Pain Management in a Geriatric Patient **1266**

Elif Dilek Cakal, Mohammad Anzal Rehman, Arif Alper Cevik

• Undertreatment of Pain *1266* • Understanding Pain in Elderly *1266*
• Differences of Pain Management in the Elderly *1267* • Pain Assessment *1267*
• Pain Assessment Tools *1268* • Management *1268* • Pharmacologic Options *1269*
• Nonpharmacologic Options *1269* • Reassessment *1270*

183. Geriatric Gynecology **1271**

Laxman Bhusal, Rabin Bom

• Osteoporosis *1271* • Vulvovaginitis *1271* • Urogynecologic Issues *1271* • Breast Cancer *1271* • Vaginal Bleeding in the Postmenopausal Patient *1272* • Ovarian Cancer *1272* • Cervical Cancer *1272* • Benign Causes of Vaginal Bleeding *1272* • Menopausal Symptoms and Hormone Replacement Therapy *1272* • Pelvic Organ Prolapse *1273*

SECTION 19: INFECTIOUS DISEASE EMERGENCIES

184. Emerging and Re-emerging Infections **1275**

Dharmesh Lal

• Important Terms *1275* • Enabling Factors *1276* • Diseases Profile *1276*
• Control Measures *1286* • Elements of an Epidemic Management System *1286*
• Vaccine Development *1288*

185. Immunization and Postexposure Prophylaxis for Infections **1290**

Sara Nooruddin Kazim, Devendra Richhariya

• Influenza *1290* • Pertussis *1291* • Diphtheria *1291* • Tetanus *1291*
• Pneumococcus *1291* • *Meningococcus* *1292* • Herpes Zoster (Varicella) *1292*
• Human Papillomavirus *1292* • Tuberculosis *1292* • Measles/Mumps/Rubella *1292*
• Chickenpox *1293* • Hepatitis A *1293* • Hepatitis B *1293* • Yellow Fever *1293*
• Polio *1293* • Typhoid *1294* • Japanese Encephalitis *1294* • Rabies *1295*
• Smallpox *1295* • Anthrax *1295*

186. Tropical Infections in Travelers **1298**

Ananthakrishnan C, Devendra Richhariya

• Etiology/Causes *1298* • Evaluation: History and Physical Examination *1298*
• Clinical Presentaion *1300* • Tropical Infections Presenting as Undifferentiated Fever *1300*
• Hepatitis A *1302* • Meningococcal Meningitis *1303* • Tropical Diseases Presenting as Diarrhea *1303* • Tropical Infections with a Primarily Dermatologic Presentation *1303*
• Important Tropical Diseases Rarely Occurring in Travelers *1304* • Pediatric Considerations *1304*
• Protection of Contacts and Staff *1305*

187. Zoonotic Infections **1307**

Olita Shilpakar, Devendra Richhariya

• Tick-Borne Infections *1307* • Rocky Mountain Spotted Fever *1307* • Tick Paralysis *1307* • Lyme Disease *1308* • Tick-Borne Relapsing Fever *1309*
• Tularemia *1310* • Babesiosis *1310* • Treatment of Tick-Borne Infection *1310*
• Zoonotic Meningitis and Encephalitis *1310* • Zoonotic Respiratory Infection *1310*
• Zoonotic Dermatologic Infection *1311* • Zoonotic Infections from Pets *1311*
• Emerging Zoonotic Viruses of Bat Origin *1311* • Emerging Zoonotic Viruses from Other Sources *1312* • Prevention and Control of Emerging Zoonotic Diseases *1312*

188. Tetanus **1314**

Sayuri Enriquez Saenz, Devendra Richhariya

• Pathophysiology of Tetanus Toxin *1314* • Symptomatology of Tetanus *1314* • Diagnosis *1315* • Treatment of Tetanus *1315* • The Role of Botulinum Toxin in Tetanus-induced Rigidity and Spasms *1315* • Advantages and Disadvantages of Botulinum Toxin Treatment in Tetanus *1316*

189. Dengue Fever **1317**

Sahanya Ramesh Shetty, Neeraj Mangla

Epidemiology *1317* • Modes of Transmission *1317* • Transmission *1318* • Immunopathogenesis *1318* • Clinical Picture *1318* • Clinical Manifestations *1318* • Severe Dengue *1319* • Step-wise Approach to Treatment *1321* • Diagnosis *1321* • Management *1322* • Complications in Severe Dengue *1323* • Complication: Compensatory Shock *1323* • Complication: Hypotensive Shock *1323* • Hemorrhagic Complications *1325* • Complication: Fluid Overload *1326*

190. Malaria **1328**

Sahanya Ramesh Shetty, Neeraj Mangla, Devendra Richhariya

• Incidence *1328* • Causative Agent, Types, and Life Cycle *1328* • Pathophysiology *1329* • Clinical Features *1329* • Investigation and Diagnosis *1329* • Treatment of Uncomplicated Malaria *1332* • Radical Treatment *1333* • Chemoprophylaxis to Travelers *1333* • Treatment of Severe Malaria *1333* • Chronic Complications of Malaria *1334* • Cerebral Malaria *1334*

191. Tuberculosis **1336**

Suman Thakur, Vivek Chauhan

• Etiology/Causes *1336* • Pathophysiology *1336* • Clinical Presentation *1336* • Evaluation *1337* • Investigations *1337* • Treatment *1338* • Disposition *1339*

192. Rabies **1341**

Ashok Mishra

• Current Scenario *1341* • Pathogenesis *1342* • Clinical Presentation *1343* • Diagnosis *1343* • Management of Human Rabies (Hydrophobia) *1344* • Prevention of Human Rabies *1344* • Modern Antirabies Vaccine *1345* • Rabies Immunoglobulin for Passive Immunization *1346* • Specific Situations *1346* • Control of Rabies *1347*

193. Skin and Soft Tissue Infections **1349**

Javier Saavedra Urbe, Devendra Richhariya

• Microbiology *1349* • Impetigo *1349* • Abscess *1351* • Purulent Cellulitis *1352* • Nonpurulent Cellulitis *1352* • Erysipyelas *1353* • Necrotizing Soft Tissue Infections *1353*

194. Musculoskeletal Infections **1356**

Avdi S Tahiri, Artan Bejta

• Osteomyelitis *1356* • Spondylodiscitis (Vertebral Osteomyelitis) *1358* • Spinal Epidural Abscess *1359* • Septic Arthritis *1359* • Periprosthetic Joint Infection *1360*

195. Management of Sexually Transmitted Infection **1362**

Shahbaz Anees, Durre Aden

• Epidemiology *1362* • Role of the Emergency Department *1362* • Risk Factors *1362* • Evaluation *1362* • Investigations *1362* • *Chlamydia* *1363* • Gonorrhea *1363* • Trichomonas Vaginitis/Bacterial Vaginosis *1363* • Syphilis *1364* • Herpes Simplex Virus *1364* • Pelvic Inflammatory Disease *1365* • Special Scenario *1365*

196. HIV Infections **1367**
Susmeet Mishra, Ushirin Bose
• Etiology *1367* • Pathophysiology *1367* • Clinical Presentation *1368*
• Evaluation *1368* • Investigations *1369* • Treatment *1370* • Immune Reconstitution Inflammatory Syndrome *1370* • Postexposure Prophylaxis *1373* • Disposition *1373*

197. Care of Immunocompromised and Transplant Patient **1375**
Charu Malhotra, Brunda RL, Ritin Mohindra
• Neutropenia *1375* • Diabetes *1377* • Alcoholism and Cirrhosis *1377*
• Renal Failure *1377* • Functional or Surgical Asplenia *1377* • Corticosteroid *1377*
• Transplant Patient Care *1377* • General Approach to Transplant Patient *1377*
• Graft-versus-Host Disease *1378* • Transplant-Specific Problems *1378*

SECTION 20: TOXICOLOGY

198. Analytical Toxicology **1381**
VV Pillay
• Biochemical and Hematological Tests Useful in Toxicology *1382* • Analytical Methods used in Toxicology *1383* • Qualitative Assays *1383* • Quantitative Assays *1385*

199. General Management of Poisoning **1392**
VP Chandrasekaran, Balaji Muruga B
• Setting up a Poisoning Center *1392* • Primary Toxicology Survey and Stabilization *1392*
• Secondary Toxicology Survey *1394* • Removal of Poisoning *1394*

200. Common Pesticides Poisoning in India **1404**
VV Pillay
• Organophosphorus Poisoning *1404* • Carbamates *1415* • Aluminum Phosphide Poisoning *1417*

201. Anticholinergics **1421**
Shikha Tandon
• History *1421* • Pharmacology *1421* • Etiology of Anticholinergic Toxicity *1422*
• History and Evaluation *1422* • Clinical Features *1422* • Differential Diagnosis *1422*
• Management *1423* • Disposition *1423*

202. Antidepressant Antipsychotic **1425**
Devendra Richhariya
• Antidepressant *1425* • Overdose and Toxicity *1425* • Treatment *1427*
• Serotonin Syndrome *1428* • Antipsychotics *1428* • Extrapyramidal Symptoms *1429*
• Drug-induced Heat Stroke *1429* • Neuroleptic Malignant Syndrome *1429*

203. Anticonvulsants Barbiturates and Phenytoin Toxicity **1431**
Vivekanshu Verma
• Barbiturates *1431* • Phenytoin Toxicity *1432*

204. Sedatives Benzodiazepine and Nonbenzodiazepine **1435**
Chidrupi Sharma
• Benzodiazepines *1435* • Nonbenzodiazepines *1437*

205. Opioids **1439**

Olita Shilpakar

• Pathophysiology *1439* • Toxicokinetics *1440* • Clinical Evaluation *1440*
• Differential Diagnosis *1440* • Investigation *1441* • Treatment *1441*
• Disposition *1441* • Opioid Withdrawal *1441*

206. Substance Abuse **1443**

Ramesh K Maharjan, Jukel Shrestha, Rashmisha Maharjan

• History *1443* • Epidemiology *1443* • Hallucinogens *1444* • Lysergamides *1444*
• Marijuana and Synthetic Cannabinoids *1444* • Amphetamines *1445* • Cocaine *1446*

207. Alcohol **1449**

Ajay Singh Thapa, Devendra Richhariya

• Alcohol Intoxication *1449* • Alcohol Withdrawal Syndrome *1451* • Methanol Poisoning *1452*

208. Cardiovascular Drug Overdose **1455**

Rahul Solanki

• β-Adrenergic Antagonists and Calcium Channel Antagonists *1455*
• Cardioactive Steroid Toxicity *1459* • Antihypertensive *1461* • Antiarrhythmics *1463*

209. Salicylates, Acetaminophen, and Nonsteroidal Anti-inflammatory Drugs **1466**

Ajay K Mishra, Jitendra Chandrakar

• Mechanism of Action *1466* • Salicylates *1466* • Acetaminophen *1467* • Nonsteroidal Anti-Inflammatory Drugs *1469*

210. Hydrocarbons and Volatile Substances **1472**

Atanu B Bhattacharya

• Classification and Properties *1472* • Pathophysiology *1472* • Clinical Presentation *1473*
• Red Flags *1474* • Evaluation *1474* • Investigation *1474* • Treatment *1474* • Disposition *1475*

211. Caustic Ingestion **1477**

Narendra Nath Jena, Subbulakshmi Dhanabal

• Pathophysiology *1477* • Etiology *1478* • Clinical Features *1478*
• Evaluation *1478* • Investigations *1479* • Management *1479* • Complications *1479*
• Disposition and Follow-up *1479*

212. Inhaled Toxins **1481**

Subramanian Senthilkumaran, Ponniah Thirumalaikolundusubramanian

• Etiology *1481* • Pathogenesis *1481* • Clinical Features *1482*
• Investigation *1482* • Diagnosis *1482* • Management *1482* • Asphyxiants *1484*
• Carbon Monoxide Poisoning *1484* • Cyanide Poisoning *1485*

213. Iron and Heavy Metals **1487**

Sameer Thapa, Anup Raj Upreti

• Iron *1487* • Lead *1488* • Mercury *1489* • Arsenic *1489* • Investigations *1490*
• Other Metal Poisoning *1490*

214. Dyshemoglobinemias **1492**

Gireesh Kumar KP

• Methemoglobinemia *1492* • Sulfhemoglobinemia *1495*
• Carboxyhemoglobinemia—Carbon Monoxide Poisoning *1496*

215. Toxic Plants **1499**

TV Ramakrishnan, Mona Lisa

• *Thevetia peruviana 1499* • *Nerium odorum 1500* • *Datura metel 1500*
• *Abrus precatorius 1500* • *Myristica fragrans 1501* • *Nicotiana tabacum 1501*
• *Strychnos Nux-vomica 1501* • *Gloriosa superba 1502* • *Ricinus communis 1502*
• *Calotropis 1502* • *Cannabis sativa 1503* • *Cleistanthus collinus 1503*

216. Pediatric Toxicology **1505**

Section 1: Basic Concepts of Emergency Medicine

1
CHAPTER

Essential Qualities for Emergency Physician

K Hari Prasad

INTRODUCTION

I work in a hospital and have been in and out of emergency most of the times. I guess I have spent most of the part of my career in emergency units. When you are serving the patients, you do not get the time and opportunity most of the times to sit back and think about the scenario. But, if you step back and just stay around in the department for an hour, you can observe so much that would be fulfilling for an almost lifetime experience (provided you do not get scared of witnessing emergency cases and blood at times).

The units are busy 24/7—sometimes more and sometimes less. Staff is always running around dealing with patients' requirements; then an additional pressure of families/friends to continuously update them; police at times; and many other relevant stakeholders. The staff performing to the best of their capabilities to serve and save everyone, relieve everyone of his/her pain through the most compassionate ways.

At all times, it would be apt to say that emergency is the door of any hospital. It brings in patients for the hospitals, so that they could perform their duties righteously. If we consider the other side, that is of the patients, it is right as well. No one wants to come to the hospital by themselves unless it is really called for. Most of the times, we are forced to visit, because it includes an end to our miseries, sufferings, and pain of ours or one of our loved ones. In such a situation, when you are really in need of something, you expect that to be provided to you in the best manner—in the most courteous and efficient way, as expected and deserved by you.

Going to an emergency department of any hospital is never by invitation. But, when we visit someone's home, we expect them to be welcoming us. The first point of contact in any emergency department would ideally be an emergency physician or a nurse. Let us start talking about the emergency physician here first. Emergency medicine is relatively a very new branch of superspecialized medicine that involves training of young doctors to be a "pro" at treating patients under pressure.

It is a job that is under stress and immense pressure of family/friends of patients and too many hopes/expectations of people are set on them and a lot many times—it is also about dealing with difficult situations. Till recent years, we did not have specialized doctors with appropriate skill sets to work in these scenarios. This does not mean emergency units were not running or patients were not treated, but it means that we did not focus enough in this area to train doctors with the right and most fitting competencies.

In India, it is a rapidly progressing field and today many hospitals have specialized doctors in emergency units. They cover the unit 24/7 and provide their services. For such scenarios, hence, they must fit in the work profile and they need to have clarity on expectations—from the patients, family members, colleagues, legal teams, hospital management, and the community. They need to deal with different levels of emotions that each one of them may display in different situations.

QUALITIES OF GOOD EMERGENCY PHYSICIAN

Being the emergency physician is not easy because of too much stressful work, paperwork, irritated patient, and too much competition. So, emergency physician must have professional qualities and should be calm, approachable, passionate, knowledgeable, enthusiastic leader, reliable mentor, efficient learner, and facilitator. Few qualities are described below.

Multitasking

Emergency physician needs to have unique skill sets, multitasking, and the attitude to serve and take up challenges. Every patient that walks into our doors is a challenge many a times—some physically, some emotionally, or some mentally. They may be brought dead, may come in with heart attacks or strokes, road traffic accidents, or even for fever, cough, cold, mild cuts, etc. Everyone's requirements are not the same and so multitasking is the first skill that is required besides the right education on emergency medicine.

Be Efficient and A Team Leader

As said earlier, this is a skill to work under pressure and sometimes with unexpected number of patients (e.g., epidemic or disasters). Some days/nights are worse for them than the others. The laid down policies and guidelines of the department should help him to work more efficiently—the way

staffing is done, resource allocation to name a few. Emergency physician is the chief executive officer (CEO) of the "hospital" (emergency unit) in the hospital. He is responsible to lead the team of his staff members, be prepared and deal with all situations, good clinical outcomes, patient satisfaction, and an administrator. He needs to play the role of being an "example" for his team to look up to him.

Communicator

Communication skills are required in every profession and every work that one does (**Fig. 1**). But here, we are talking about communication being a very different kind of a skill set. It includes being able to communicate happiness about the delivery of a child or safety of the patient. It includes communicating about taking up the next course of action for patients about admission/surgery/follow-up, etc. It could be about breaking bad news about death, bad outcomes, or the actual patient condition that most of the times people are not prepared to listen and accept. The preparation for any such conversation is completely different from one another. Some relatives/family members/patients can understand the situation/outcome, some are irate, some unhappy and some angry. Emergency physician has obviously to deal with all types of these, especially when such things happen in the middle of the night or odd hours and when there is less dependency on others in the hospital.

Compassionate and Empathetic

They need to be compassionate and understand the patient/family's situation—their concern, what they must be going through and then, communicate accordingly. It is said unless you do not fit yourself in their shoes, you do not get the emotion what they must be going through. On the other side, it is also important for him to be firm to be able to handle situations. At the same time, they also need to keep their emotions under control. There are times, due to stressful long hours, they may feel frustrated, tired, and irritated, but these are the testing and most vulnerable times. For a doctor, the patient may be one of many who may have walked-in during his shift, but for that patient or his family, he is the only one. It is a very normal emotion that we face and I also faced many a times, but controlling them is what the best, I learnt over time. Some patients are very impatient and being empathetic helps them to respond even better.

Professional, Confident, and Bold Enough to Take Decisions

Professionalism is expected without even an iota of a doubt (**Fig. 2**). As said earlier, that emergency is the door to the hospital and emergency physician is the first member whom the patient/family meets. Their act of professionalism says a lot and spreads very easily through the word of mouth. Displaying confidence as the head of the family or head of the hospital in that scenario is again very important. The complete body language, behavior, and courage to take decisions in the best interest of the patients are important skills for an emergency physician. Respect must be earned and it could only be earned by our actions and behavior—not by just being there and wearing a white coat with an emergency doctor tag on it.

Work Ethics

No matter what goes on in our personal life or our environment, once I used to wear my white coat in the department and take charge, everything used to take a back seat. I personally feel, this is what we need to do as physicians always. In that situation, only patient is important and just work with a single mind toward good clinical outcomes and patient satisfaction (**Table 1**).

Connecting the Dots

Knowledge of the diseases, clinical pathways, and hospital policies is the most basic required skill set obviously. This also means using the right "mix and match" of knowledge to fit into that patient's condition—to see, evaluate, order the right tests, prescribe, and diagnose it right. Here, attention to details

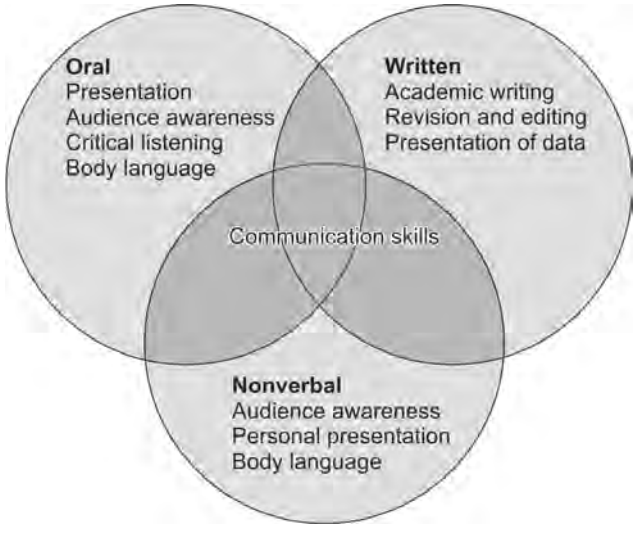

FIG. 1: Components of the communication skills.

FIG. 2: Various aspects of professionalism.

TABLE 1: Do's and don'ts for emergency physician.

Emergency physician should perform	*Emergency physician should avoid*
• Attend and manage all types of emergencies • State authorities should be informed in case of epidemic and fatal communicable diseases • Attend court for medicolegal case	• Advertising • Association with drug manufacturer • Association with patient • Adultery • Addiction, alcohol consumption on duty

and asking the right sets of questions are very important. One simple data point, if missed, may take the complete treatment in a different direction. Connecting the dots and in the right way is the key and this comes with focus, experience, and a positive mind set.

Listen! Listen! Listen!

Keep your eyes and ears open—listen to everything that the patient/family says (**Fig. 3**). They give you the most important piece of information that may help you to move on the first course of action in that short time, when lives matter and time could be controlling that.

Grow and Continue to Learn

Emergency physicians should keep them abreast of the changes in the field of medicine continuously. They need to learn about new technologies, new processes and systems, newer drugs, research, and new clinical guidelines or pathways (**Fig. 4**).

Disaster Management

These are the types of situations that generally emergency physicians face being in the department. Any major external or internal disasters when happen, they automatically play the role of the leader. Handling multiple patients at the same time, managing resources (staffing, equipment, medications, food, water, utilities, etc.), managing the community, press/media, and communicating the right and apt information become challenging.

OTHER BASIC SKILLS

Some of the other basic skills that they are expected to learn and demonstrate are:

- Ability to triage patients as per the most evidence-based guidelines in the time as expected for effective care and good clinical outcomes.
- Being able to obtain history and perform a physical examination. This should also help him to decide the next course of action. You may receive patients with simpler clinical conditions to children who have been abused or drugged or road traffic accidents. The ability to provide accurate care under these circumstances becomes crucial.
- Knowledge of resuscitation and continuously update themselves (at least every 2 years or as and when guidelines change) on basic life support and advanced forms of life support for neonates, pediatrics, adults, and trauma victims.
- He should be able to make an initial diagnosis to consider different investigations that may be required and then interpret the outcomes to establish the plan of care with right measurable goals to achieve.
- Based on the trainings and competencies, hospital may privilege him for the basic emergency procedures that may be required to be done in the department itself, e.g., lumbar puncture, bone marrow aspiration, biopsy, etc.
- Should know the next steps in every situation—outpatient (OP) discharge, brought dead, medicolegal case, admission to ward/intensive care unit (ICU), completing diagnosis, being taken for a surgery/procedure, etc.
- Good documentation is what stands out always. The more details are mentioned, the better care could be given to the patient. It is right to believe that what is not documented is not done.
- Respect patient privacy and confidentiality always.
- Being sensitive to patient's culture, age, gender, and spiritual requirements.

FIG. 3: Careful listening for key information.

FIG. 4: Continuous clinical update by emergency physician.

SUMMARY

Emergency medicine is a relatively new academic field in India. Emergency is a situation or condition of any life-threatening consequences requiring immediate intervention. As the medical field is an ever-growing field, and emergency medicine is rapidly progressing, a good emergency physician is a need of Indian healthcare. A dedicated emergency medicine faculty is the key factor in developing emergency care workforce. Good emergency faculty should be expert in resuscitation and able to treat each disease of almost every specialty.

"I have gone through this and I see them in my hospitals daily, it is not an easy task. Doctors are made by God especially to serve the mankind, but I believe emergency doctors are especially crafted by God to screen and be at the first level to save lives."

—Dr K Hari Prasad

2 CHAPTER

Designing and Staffing of Emergency Department

Saleh Fares, Omar Ghazanfar

INTRODUCTION

The emergency department (ED) plays a central role in providing vital access to acute healthcare to the public. An ED is also an important gateway to many inpatient and outpatient services offered by the hospital. In addition, a major proportion of acute admissions to inpatient beds are via ED. The major characteristics which make the ED unique include:

- Emerging and novel models of ED care and design
- Varying levels and types of staffing models
- Undifferentiated case mix including critical and life-threatening illnesses, major trauma, dependent on the hospital status, and a wide spectrum of age groups from pediatrics to geriatrics.
- The presence of patients and relatives with varying levels of anxiety
- High patient turnover
- Variable admission and discharge pathways
- Medical services provided largely by specialist emergency physicians, supported by junior doctors, and allied nursing and other health professionals.

CHALLENGES FOR EMERGENCY DEPARTMENT IN INDIA

- There is mismatch between the capacity of healthcare facility and population of that area resulting in overcrowding at the limited number of available facilities.
- Lack of funds or poor planning leads to poor Infrastructure at the existing healthcare facilities.
- Unawareness of National Standards and Guidelines leads to inadequately equipped healthcare facilities.
- Inadequately skilled manpower—suboptimal quality care at the existing health facilities
- Unawareness of standard operating procedures regarding managing a patient
- Lack of quality care as nonaccountability and lack of monitoring mechanisms

EMERGENCY DEPARTMENT FUNCTION

The primary function of the ED is to receive, resuscitate, and provide acute healthcare to patients. It should also be equipped to handle disasters and mass causalities. Varied patient population requiring varying medical inputs includes, but the list is not exhaustive: Major trauma, geriatrics, pediatrics, mental health disorders, patients with abuse (any age group), custodial patients, patients with infectious diseases, and mass causalities (to include chemical, biological, and radiological contaminants).

REQUIREMENTS FOR CREATING NEW INFRASTRUCTURE AS EMERGENCY DEPARTMENT

There are a number of factors which must be considered, when structuring an ED. This will include both staff requirements and patient needs and demographics. The needs of these varying patient groups can be addressed through, for example, suitably placed furniture and art, adequate access to information and communications technology, and appropriately designed rooms and equipment that are suitable for use by particular patient population.

While the needs of patients and relatives are highly important, it is also necessary that a healthy working environment for staff is facilitated by the design of the ED. These needs can be catered to through the use of well-placed staff bases, staff rooms large enough to accommodate the maximum number of possible users, and ensuring that staff facilities are located separately from clinical areas, in order to promote effective breaks from patient care.

Designing of an efficient ED should look at certain elements, which will aim to make the department efficient, reliable, and cost-effective. The design needs to be practical and reflect the needs of the professionals who run the department and treat patients with varied needs and requirements.

The structure and design should reflect the spatial relationships between staff and patients and improve the flow and continuity of care from the front door of the hospital to admission or discharge of patients. It should be kept in mind that the ED functioning is very fluid with ebb and flow of patients changing during a 24-hour/7-day week, and flexibility is needed to enable reallocation of treatment spaces as required.

The ED should aim to create a healthy environment through proper application of occupational health standards to ensure a safe working environment. The well-being of patients and staff should be an important consideration through proper and safe use of design and space.

GENERAL CONSIDERATIONS FOR DESIGNING EMERGENCY DEPARTMENT

- Emergency department design should be smooth, rapidly accessible to from all areas with a minimum cross traffic.
- The resuscitation area, triaging areas, and treatment areas should be close enough, as staff may require to rush from one place to another.
- Visitor and patient access to all areas should not traverse through clinical areas.
- Patient protection of privacy should be considered while designing at the same time, the need for observation of patients by staff should also be considered.
- Emergency department design should accommodate radiological imaging, laboratory, and other diagnostic services of hospital with the close proximity of the ED.
- Appropriate signs consistent with the applicable regulations and laws should indicate the direction of the accident and ED from major thorough fares along with broad outline of services available.
- Safety of the ED staff, patients, and visitors must be top priorities while designing and implementation.
- The entrances of the ED should be clearly visible from all possible sides and should be located on the ground floor for easy accessibility.
- It should be close to public transport.
- Adequate bilingual signage should be available to ensure ease-of-way finding.
- Illuminated signage is required for some signs to ensure visibility at night. The use of graphic and character display "EMERGENCY" is recommended.
- Car parking should be well-lit and available exclusively for patients and their relatives and staff should be close to the entrance.
- Undercover parking should be available for appropriate number of ambulances. This will be determined by case load.

OTHER REQUIREMENTS

- *Bed spacing*: In the acute treatment area, there should be at least 10 feet of clear floor space between beds.
- *Lighting*: Clinical area should have exposure to daylight, helpful in minimizing the disorientation in patient as well as in staff also. Provision of high standard focused examination light should be done in all treatment areas. Each examination light should have a power output of 30,000 lux, illuminate a field size of at least 150 mm and be of robust construction.
- *Sound control*: Designed so as to minimize the transmission of sound between adjacent treatment areas.
- *Service panels*: Service panels should be minimally equipped as follows:
  - Centralized oxygen outlet
  - Centralized suction outlet
  - Sockets
  - *Physiological monitors*: Each acute treatment area bed should have access to a physiological monitor which should include a minimum of:
    - Electrocardiogram (ECG)
    - Noninvasive blood pressure (NIBP)
    - Temperature
    - Oxygen saturation (SpO_2)
- *Cabling*: Adequate cabling should be provided to ensure availability of sockets to all clinical and nonclinical areas. Cabling of telephone and computers should be nearer to workplace, where these are necessary.
- *Medical gases*: All patient care areas should be internally piped for medical gases.
- *Doors*: All doors measurement is appropriate enough to accommodate a full hospital bed.
- *Corridors*: Adequate width of corridors is necessary, allows the cross passage of two hospital beds or a hospital bed and linen trolley without difficulty. There should be adequate space for trolleys to enter or exit any of the consulting rooms and to be turned around. Storage of equipment, linen, waste, or patients should not be kept in standard corridors.
- *Air conditioning*: Infectious disease isolation room in ED should have special flow and filtering requirements—heating, ventilation, and air conditioning (HVAC) system.
- *Information/Communications support*: Telecommunications and information technology is one of the important parts of ED. All staff stations and all consultation areas should be equipped with telephones, intercoms, and public address system that can reach all areas of the ED. Public telephones should be available in the waiting area. Direct communication should be installed between the ambulance service and the ED.
- *Patient call facilities*: All patient care areas including toilets and bathrooms require individual patient call bell facilities. Emergency department bed spaces should be equipped with call buttons, easily accessible to patient on the ED trolley.
- *Handwashing facilities*: Adequate handwashing facilities should be available. Hands free taps should be available in clinical areas. Treatment area should be equipped with basins for handwashing at a ratio of 1:8 in observation area and at the ratio of 1:1 for every procedure/consulting room/triage/isolation area. Standard infection prevention precautions should be taken and sufficient quantities of personal protective equipment (PPE) should be present for all the staffs.
- *Emergency power*: Backup emergency power must be available to all lights, ventilators, and computer terminals in the resuscitation and treatment/observation areas of the department. All areas should be equipped within emergency lighting. In the event of a total power failure, sufficient space and power points should be available to enable a backup system.
- *Wall finish*: Hospital beds, ambulance trolleys, and wheelchairs may cause damage to walls, so all wall surfaces

in areas, which may come into contact with mobile equipment, should be reinforced.
- *Floor covering*: The floor covering of all patient-care areas and corridors should have following features:
  - Nonslip surface
  - Impermeable to water and body fluids
  - Durable
  - Easy to clean
- *Wall clocks*: Clinical areas and waiting areas should be equipped with wall clocks and should be visible to all patients. Time clocks are desirable in the resuscitation, procedure, and plaster rooms. Time displayed in all areas and on computers must be synchronized.

PATIENT FLOW

The ED has a wide case mix and varying volume of patients presenting with various pathologies and different part of the day and the week. Many different models have been used successfully internationally taking into account both staff and patients to aid the flow of care through the emergency service. No single system works for all hospitals as this is largely dependent on patient needs and adequate and safe staffing. Some of the concepts of patient care that affect flow within the ED include:
- *Medical-led triage with senior nursing staff*: Triage done by senior nurse to make definitive investigations and decision making on the patient's arrival to the ED.
- *Traditional models of care* which filtered patients on the basis of their primary complaints. This was a medical-surgical model, which still exists in some healthcare systems.
- *Rapid assessment team (RAT) for critically ill patients*: Senior doctor, nursing staff, administrative staff, phlebotomist, and scribe.

This team may either be mobile within the department or be stationed in specific assessment areas and can be mobilized as per needs and requirements.

DEDICATED AREA WITHIN EMERGENCY DEPARTMENT

As part of the structural design of an ED, a variety of considerations needs to be taken into account. These include dedicated clinical areas for ED staff, access to the main hospital, multidisciplinary team areas, staff facilities, and areas for special and specific clinical requirements. These are summarized in **Table 1**. Patient and staff experience is essential in designing and developing an ED and various factors need to be taken into account to facilitate this. This is summarized in **Table 2**.

NEW CONCEPTS IN EMERGENCY DEPARTMENT DESIGN

The breathing emergency department: Studies conducted to determine the benchmark size for an ED patient unit indicate that smaller EDs with fewer visits function more efficiently and have higher patient satisfaction rates than larger EDs. These studies suggest that the functional ED patient unit should be of 13 beds to enable better management of patients and tasks. However, as patient visits increase, the majority of EDs increase their footprint and number of beds, decreasing efficiency. There are a few models designed to divide the department into smaller, more manageable units, including *the fast-track approach* (focused on lower acuity flow, discussed below). This design divides an ED into two separate departments based on patient acuity. Another option to help reduce unit size *is the breathing emergency department*, which subdivides the department into smaller units and opens and closes them based on the cyclical cycle of peak patient visit times.

STAFFING MODEL FOR EMERGENCY DEPARTMENT

Medical and practitioner staffing in emergency departments: Correct staffing is the key to delivering timely and high-quality care in the ED. There is no one-size-fits-all staffing model for ED. Intelligent staffing models will also allow for rota patterns that are realistic and sustainable and will involve the use of clinicians from a range of professional backgrounds. A tiered approach to staffing is, therefore, necessary with consideration of sustainability for each tier. Correct staffing in EDs results in safer care with improved quality, better performance, increased efficiency, and happy and resilient workforce.

How to staff an emergency department? Staffing an ED is a complex and demanding job and requires input from a variety of different internal and external factors. In essence, staffing is a function of: *(1) Capacity, (2) Capability, (3) Sustainable working, and (4) Resilience.*

Capacity: Required capacity can be calculated on the basis of predicted demand. Demand needs to be considered in terms of volume, case mix, and segregated work streams. Capacity calculations need to be considered. EDs should be staffed to meet variation in demand, aiming to cope with normal demand variation.

Capability: A capable system does what it is supposed to do. This essentially means that the right number of clinicians with the appropriate skill mix is needed at the right time. Senior and experienced clinicians generally more efficient while junior clinicians generate additional work for senior colleagues. There is a natural desire to specify the productivity of different groups of clinicians. The best estimate of local productivity is local data (**Table 3**).

Tier 1 clinicians (interns) or clinicians with enhanced supervision requirements, e.g., doctors in difficulty may have minimal or even negative productivity due to the senior input required on cases they see. *Tier 2 doctors* (junior residents/rotating doctors) are generally thought to see about one patient per hour, perhaps slightly more on minors, although this depends on the case mix seen. A consultant *(Tier 5)*, supervising a department, may see no new patients in order to maximize their efficacy in the command and control role and to avoid potentially disadvantaging patients, they do see through interruptions and multitasking. The productivity of the remaining groups (senior residents and other senior ED physicians) will vary between about 1 and 3 patients per hour, depending on variables such as experience, professional development, case mix, the effectiveness of efforts to maximize workforce efficiency, the requirement to move between physical areas, procedures undertaken, and supervisory demands.

TABLE 1: The dedicated areas within an emergency department.

Hospital access areas	*Clinical areas*	*Multidisciplinary team areas*	*Special areas*	*Administrative areas*
• Proximity to main entrance • Streamlined access to investigative areas • Close or cohabited areas for other acute services • Helipad • Angiography • HDU/CCU/ICU • Operating theaters • Clear route to wards • Outpatient access • Communication hub • Areas for disaster management	• Entrance, waiting room, and reception area • Triage • Resuscitation area • Mental health assessment area Clinical consultation area to include fast track, subacute minors or ambulatory care • Acute treatment area • Investigative areas—X-ray, short stay, investigation room, etc.	• Equipment storage • Refreshment areas • Physiotherapy, OT assessment area • Staff and amenities areas	• Eye/ENT/gynecology/plaster rooms • Storage areas • Disposal room • Medication room • Office space • Staff room • Ambulance offloading area • Decontamination area • Ambulatory/Urgent care	• Storage • Drug preparation room • Clean and dirty utility • Teaching and research areas • Patient amenities • Toilets

(CCU: cardiac care unit; ENT: ear, nose, and throat; HDU: high-dependency unit; ICU: intensive care unit; OT: operation theater)

TABLE 2: Factors to consider in the design to improve staff and patients experience in the emergency department.

Staff experience	*Patient experience*
• Comfortable seating areas at staff bases and bedside • Easy and ready access to equipment • Efficient workflow design with good access to all work space areas • Design which limits overcrowding • Confidential discussion rooms • Air quality with ventilation control • Good staff rest facilities with appropriate amenities and storage facilities • Overnight facilities for staff	• Clear signs for pathways and facilities • Information about ED process to include triage and/or waiting times • Multilingual signs • Public health educations leaflets • Friendly staff • Security personnel • Clean and well presented • Information desks • Appropriate waiting areas ideally with color coding • Availability of refreshments

(ED: emergency department)

All EDs require a senior doctor, immediately available at all times. Larger departments will require several senior doctors on duty to manage the supervisory workload, to see the sickest and the most complex patients, and to undertake dedicated tasks such as rapid assessment. Larger departments may be able to develop specific areas led predominantly by *Tier 2* or *Tier 3* clinicians.

Sustainable working and sustainable staffing: There are significant concerns around attrition rate in EDs. Sustainable working requires attention to specific details taking into account and work-life balance due to the antisocial nature of shift work. These include the following:

- Workload and work intensity, when on duty
- A balanced mix of clinical, nonclinical, and academic activity, particularly for senior clinicians
- Professional development
- Physiological and physical limitations of staff (e.g., age, chronic illness, or disability)
- Compensation for late night/overnight working

Rotas for individual tiers can be combined provided attention is paid to skill-mix. Sustainable working leads to more effective working. Tired or burned-out staffs are less safe, less efficient, and less effective. Sustainable working is also the key to building an emergency medicine (EM) workforce for the future. Furthermore, many emergency physicians are concerned how they will work in EDs as they get older, and in particular, how they will cope with intense, late, and overnight working. Constructing sustainable working for an aging workforce, while ensuring development within the consultant role into the third and fourth decades of consultant life, is key consideration for workforce planning. Alongside sustainable working, consider sustainable staffing. This means paying attention to recruitment and retention. Retention is the first part of recruitment. Permanent workforces are more safe and more efficient than using locums or relying on staff to internally cover gaps and vacancies.

Consider how to keep your staff happy and fulfilled. This is partly about how you set up the workforce in general:

- Enough staff of the right skill-mix, doing work they enjoy.
- Develop a culture that genuinely values staff (rather than paying lip service to the concept).
- Provide a reasonable and healthy working environment.
- Offer terms and conditions that recognize the intensity and demands of ED shift work.
- Invest in professional development.

TABLE 3: The different (TIER classification) tiers working in an emergency department.	
Tier 1	Require complete supervision. All patients must be signed-off before admission or discharge e.g., interns/ junior residents
Tier 2	Require access to advise or direct supervision, or practice independently, but with limited scope doctors, some primary care clinicians, and junior residents
Tier 3	More senior/experienced clinicians, requiring less-direct supervision. Generally fewer limitations in scope of practice. Senior residents and experienced practioners
Tier 4	Senior clinicians able to supervise a department alone with remote support possess some extended skills. Full scope of practice
Tier 5	Senior clinicians with accredited and advanced qualifications in EM/full set of extended skills. Consultants in EM

(EM: emergency medicine)

Resilience: Staffing models need build in resilience to contributes toward sustainable working and research. Further research is needed into:

- Staffing models for EDs of different sizes
- The relationship between appropriate staffing and patient safety
- Decision making density and interruptions within EDs
- The combined effects of age, time of day, and shift patterns on safe decision making in clinicians
- Recruitment and retention in acute specialties

Action is needed to build an EM workforce fit to meet the demands of the future. This includes attracting people into EM and then retaining them. This comes down to providing professionally satisfying workplaces, sustainable working patterns, attractive terms and conditions, and professional development.

DECIDING FACTORS FOR STAFFING IN EMERGENCY

- Patient volume
- Patient acuity
- Patient length of stay
- The capabilities of physicians
- The role of nonphysician staffing
- The hospital's expectations
- Nursing expectations
- Financial goals and expectations

REQUIREMENTS OF EMERGENCY PHYSICIAN FOR EMERGENCY DEPARTMENT

In three shifts during 24 hours at the rate of approximately 25 patients/shift, total patients = 75

- 75 patients/24 hours = 2 medical officers/shift (total 6 medical officers during 24 h)
- 75–100 patients/24 hours = 3 medical officers/shift (total 9 medical officers during 24 h)
- More than 100 patients/24 hours = 4 medical officers/shift (total 12 medical officers during 24 h)

It is assumed that morning and evening shift is of 6 hours and night shift is of 12 hours. All medical officers should be supervised by consultant/senior consultant in each shift. As per predefined roster, all the specialists to be available on call round the clock.

REQUIREMENTS OF STAFF NURSE IN EMERGENCY DEPARTMENT

When triaging nursing staff is separated from other clinical staff:

- More than 75 patients/24 hours = 4 staff nurses/shift (total 12 staff nurses during 24 h)
- For every additional attendance of 25 patients, add 2 more staff nurses in 24 hours
- For emergency ward—1:4 per shift + 15% leave reserve

EMERGENCY MEDICAL TECHNICIANS

One emergency medical technician (EMT), trained nursing assistant/ambulance/shift, they can assist nursing staff or staff posted in minor, when they are not accompanying ambulance. Duration and number of shifts may vary depending upon workload.

STAFF FOR MINOR OPERATION THEATER

- For the workload of less than 25 patients/24 hours = 1 operation theater (OT) technician and/or dresser/shift (total 3 OT assistants/dresser during 24 h) for dressings, splint applications, and suturing of minor injuries.
- 25–50 patients/24 hours = 2 OT technician and or dresser/ shift during morning shift and 1 OT assistant and/or dresser during evening and night shifts.
- 50–100 patients/24 hours = 2 OT assistants and/or dresser/shift during morning and evening shifts and 2 OT assistants and/or dresser during night shift.

OTHER STAFF

- *Registration clerk*: A dedicated person to be present for registration of patients in all shifts.
- *Data entry operator*: A dedicated person for computerized medicolegal record entry in all shifts.
- *Laboratory technician (LT)*: For emergency sample collection center:
  - Less than 75 samples/24 hours = 1 LT/shift (total 3 LT during 24 h)
  - 75–150 samples/24 hours = 2 LT/shift (total 6 LT during 24 h)
- *Security staff*: For a workload of:
  - 75–100 patients/24 hours = 1 security staff/shift (total 3 security staff during 24 h)
  - 100–150 patients/24 hours = 2 security staff/shift (total 6 security staff during 24 h)

- *Housekeeping staff*: For a workload of:
  - 75–100 patients/24 hours = 1 housekeeping staff/shift (total 3 housekeeping staff during 24 h)
  - 100–150 patients/24 hours = 2 housekeeping staff/shift (total 6 staff during 24 h)
- *Group D staff*: For a workload of:
  - Less than 100 patients/24 hours = 1 group D staff/shift (total 3 group D staff during 24 h)
  - More than 100 patients/24 hours = 2 group D staff/shift (total 6 group D staff during 24 h)

SUMMARY

Emergency department design and structure works hand-in-hand in conjunction with the staffing structure to provide a safe, productive, efficient, and reliable service to provide ultimate and immediate care to the unscheduled and undifferentiated patient population which presents to the emergency healthcare services.

3

CHAPTER

Observation and Isolation Unit

Devendra Richhariya

INTRODUCTION

Emergency services are becoming more organized in India, and by adopting best practices in the emergency department (ED), it is now possible to provide the best quality care. One of the best practices is the establishment of an observation unit (OU) in the ED , a dedicated area for observation of a patient which provides safe and efficient care. The concept of the emergency department observation unit (EDOU) is now well developed and clearly described. Knowledge of the various types of OUs, their locations, sizes, designing, staffing, and development of protocols can be implemented while establishing and managing the OU , and leadership can sustain service excellence for their patient in the OU.

OBSERVATION UNIT DESIGN AND LAYOUT

While designing the OU in the ED, the clinical effectiveness and financial viability are the top priorities. Various types of OU designs have been described by Ross and colleagues.

Types of Observation Units

The first type of OU is protocols-driven that is termed *type 1 OU*. Another type of OU is that managed by clinical direction given by an individual clinician (not based on protocols) termed *type 2 OU*. In *type 3 OU*, patients can be observed in any hospital bed but care is protocol-based. In *type 4 OU,* the patient is observed in a nonprotocolized manner in any hospital bed.

Open or closed unit: Another classification of OU is a closed or an open OU. In a closed OU, the patient is managed under a single group or specialty, such as an emergency medicine specialist. In the open OU, the patient is managed by individual clinician directives. Evidence shows that protocol-driven and closed OUs are much superior and also commonly designed. Protocol-based type 1 OUs are superior because of:

- Unified leadership
- Condition-specific protocol
- Inclusion and exclusion criteria
- Timely interventions
- Inpatient and discharged criteria

Other than these points, appropriate patients are placed in the OU, there is better adherence to time-bound protocols, and targeted feedback and education can be provided because of the closed unit which can enforce accountability and quality.

Hybrid Unit

Sometimes, for a smaller hospital, it is not justifiable to create an OU in view of the extra cost incurred in the salary of nursing and other support staff. In these situations, the "hybrid" OU is also used as a recovery unit and observation patients, as well as patients of elective procedure, can also be recovered and discharged afterward. The hallmark of a hybrid OU is to maximize the operational capacity. In case of extreme hospital census, a hybrid unit can also be used to hold the patient, who is waiting for inpatient beds, though these practices should be avoided because long waiting hour for the patient in ED results in lack of beds for acute care and this results in vicious cycle.

Location

The location of OU is critical from the logistic and patient points of view. Placement of OU away from the ED causes difficulty in clinical re-evaluation, communication, and transport. Placing this OU within or just adjacent to the ED gives the following benefits:

- Highest patient comfort
- Minimal disruption of the process
- Close proximity to clinicians
- Close proximity to supply and equipment
- Cost-saving

Volume Capacity

After identifying the space for the OU, another important part in establishing the OU is deciding the capacity of the unit. Various studies suggest that 5–10% of all the ED patients can be good candidates for OU care or a new facility OU should be started with a minimum of five to eight beds with a 1:5 or 1:4 nursing ratio.

Observation Unit Layout

Careful designing of OU and utilization of physical space are required to optimize clinical care. Other factors such as allocated funds, state, city, and health regulations influence the OU design. Structuring the space in which the patient–clinician

interaction is maintained is important, so a curtained cubical which faces the nursing station is generally recommended. Curtained cubical and closed room have their own advantages and disadvantages. A semicircular nursing station facing cubical provides direct visualization of the patient and allows the patient to feel better cared for during his/her stay. Areas such as medication preparation area, consultant workplace, nursing workplace, and utility rooms are equally important parts of an OU layout.

Time Cut-off

Patient length of stay (LOS) cutoff is an important consideration for a successful EDOU. Most of the EDOUs use a 24-hour maximum cutoff; during this time frame, a decision for safe discharge or for further in-hospital hospitalization is taken.

PROTOCOL DEVELOPMENT

Phases of Emergency Department Observation Unit Protocol Development

Once the EDOU is established, clinical pathways and protocols are required for successful medical and surgical acute care. Pathways and protocols enable a clinician to select an appropriate patient for EDOU and manage him/her with evidence-based diagnostics and interventions. There are five main phases of protocol development (**Fig. 1**):

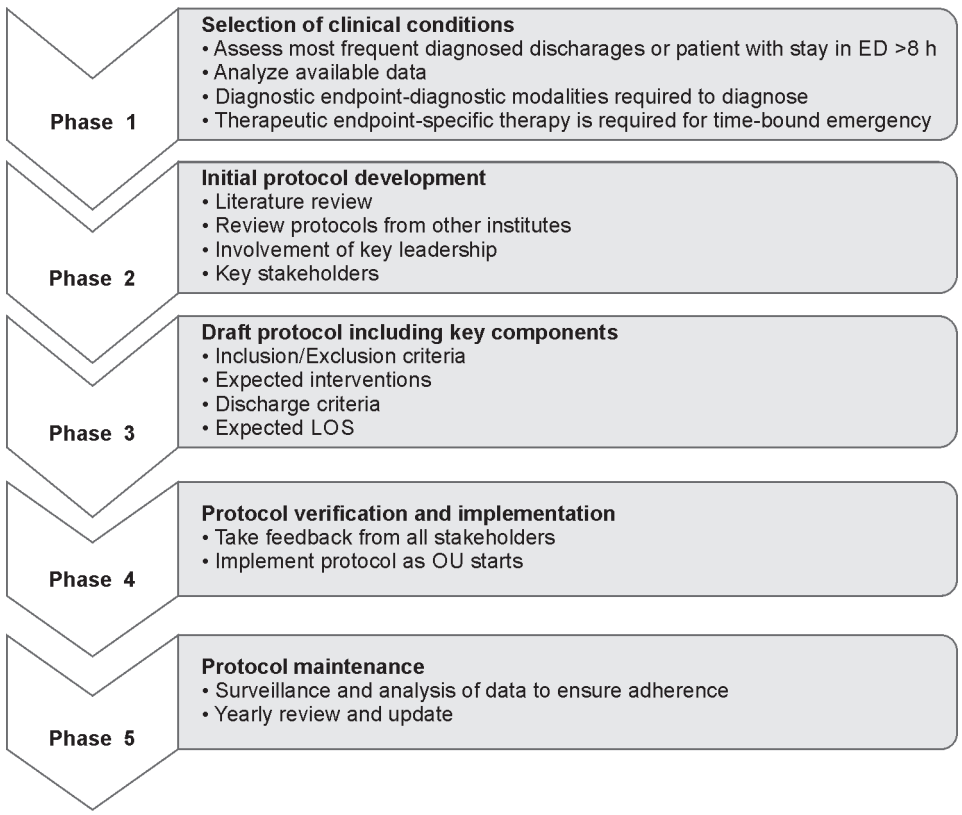
1. Selecting the clinical condition
2. Initial protocol development
3. Draft the protocol with key components
4. Verification and implementation of protocol
5. Maintenance of protocol

Selection of clinical condition: Since many decades, chest pain was the focus while establishing a protocol in the ED; later on, transient ischemic attack (TIA), stroke, asthma, atrial fibrillation, syncope, heart failure, and pulmonary embolism were also included. Other conditions such as abdominal pain, dehydration, renal colic back pain, pyelonephritis, cellulitis, chronic obstructive pulmonary disease (COPD), community-acquired pneumonia, deep vein thrombosis (DVT), electrolyte imbalance, and psychiatric emergencies are also managed in EDOU. The next important area is a discussion with key leadership and analyzing the hospital data regarding the most frequent diagnosis and discharges from the inpatient team and their LOS. After leadership approval and guided decision-making, EDOU is started with widely established pathways and later other conditions are included through further analysis.

It is a matter of discussion whether a patient with behavioral health problems such as a patient with suicidal tendency should be included in OU care or not. Each institution should examine its own policy, security, resources, and discussion with the psychiatrist and take the decision.

Diagnostic and therapeutic endpoints: For any given clinical situation, necessary diagnostic modalities are selected to diagnose a particular condition in EDOU. Similarly, therapeutic protocols are selected so that necessary time-bound therapies are delivered.

Protocol development: After the conditions and diagnostic and therapeutic endpoints are selected, the next step is the development of a protocol which enables the clinicians



Phase 1
Selection of clinical conditions
• Assess most frequent diagnosed discharages or patient with stay in ED >8 h
• Analyze available data
• Diagnostic endpoint-diagnostic modalities required to diagnose
• Therapeutic endpoint-specific therapy is required for time-bound emergency
Phase 2
Initial protocol development
• Literature review
• Review protocols from other institutes
• Involvement of key leadership
• Key stakeholders
Phase 3
Draft protocol including key components
• Inclusion/Exclusion criteria
• Expected interventions
• Discharge criteria
• Expected LOS
Phase 4
Protocol verification and implementation
• Take feedback from all stakeholders
• Implement protocol as OU starts
Phase 5
Protocol maintenance
• Surveillance and analysis of data to ensure adherence
• Yearly review and update

(ED: emergency department; LOS: length of stay; OU: observation unit)

FIG. 1: Phases of protocol development for observation unit.

in selecting the patient for OU management. The process starts with literature review and discussion with the various institutions who have an established protocol. Further, relevant stakeholders such as EDOU leadership and appropriate consultant are included for the joint development of EDOU pathways. A well-developed protocol should include inclusion and exclusion criteria, expected intervention in EDOU and disposition criteria, expected LOS, and medical records. Patients should be avoided for OU management who clearly require inpatient treatment or can be discharged home safely. Disposition criteria are helpful in maintaining the appropriate patient flow and efficiency within the EDOU. LOS is variable in each patient depending on the condition, but the expected time for discharge is also helpful in maintaining the flow of the OU.

Protocol verification, implementation, and maintenance: During this process, feedback is obtained from all stakeholders. After sufficient review and editing, the protocol can be operational in EDOU. Protocol development is a dynamic process and not static, so the final phase of protocol development is maintenance. The protocol can be updated yearly to ensure optimal use of EDOU.

OBSERVATION UNIT MANAGEMENT

Leadership

Successful management of OU depends on strong leadership which consists of the clinical director, nursing director, and operation director who works in coordination and are accountable for efficient patient care. This group of leadership is responsible for implementing protocols, monitoring utilization and quality, and encouraging research and educational activities.

Individual responsibilities: The clinical director is primarily responsible for monitoring the physical activities and workflow and developing protocols for new conditions. The nursing director monitors nursing interventions, care coordination, and case management. The operational director is responsible for finances, interfacing with hospital administration, workflow metric reporting, and compiling the annual report and overall return on investment of the EDOU. Another important role of the leadership trio is a strong commitment to the hospital leadership and a quarterly meeting with the organization's leadership where the annual report can be reviewed. Communication among all the leadership and the frontline staff is necessary to ensure success. Usually, 6–9 months are allocated for the development of the OU. This timeline allows planning, construction, staffing, and protocol development in a smooth fashion. Creating and implementing new protocols take several months. Communication should be established and several meetings are required with the various departments, which will get impacted with the opening of the OU, to explain its purpose and gain their support.

Staffing

Clinician, support staff, ancillary support: For effective management of OU, appropriate staffing is essential. Staffing of OU consists of physician, nurses, and medical assistants. For managing the OU, a popular model exists in which the physician and nurses take all the responsibilities of each patient in OU. Critical decisions are taken by a physician in the presence of a decompensated patient or if there is any concerning diagnostic or imaging report. From a nursing point of view, OU is staffed by skilled and trained nursing staff. A newly developed OU does not necessarily require all new staffing; rather the existing staff of inpatient care can be given responsibilities and the patient–nursing ratio can be similar to that in the inpatient floor, i.e., one nurse is allocated per shift—1:4 or 1:5 (one nurse in every four patients or one nurse in every five patients). Apart from physician and nurses, additional staff such as care coordinator, unit clerk, and medical assistant are important who play a key role in disposition of decision to maintain good flow through OU. One clerk and one nursing assistant are required in every eight beds of OU. A care coordinator (a nurse by training) should be available from 7 AM till late evening who helps the patient going to rehabilitation, requiring home services, going to home, or getting admitted.

Consulting or referral services enable smooth delivery of care process and management within OU and afterward in an outpatient setting also. So, in every clinical pathway, priority access should be clearly established for the consultant attending to the patient for appropriate investigations and follow-up. Primary consultants for OU include cardiologist, neurologist, gastroenterologist, general surgeon and urologist and further depend on the patient population.

Imaging Modalities

For efficient and effective care in OU, access to key imaging modalities is essential. Communication and agreement over the turnaround time with cardiology and radiology should be the focus of effort. Computed tomography (CT), magnetic resonance imaging (MRI), echocardiography, and stress testing are the imaging modalities in priority.

Workflow

Smooth workflow of OU which is essential for optimizing patient care depends on various factors such as LOS documentation and communication. According to various studies, approximate LOS is 15 hours. Patient population with LOS of 8–15 hours is best managed and those who require more than 24-hours' LOS, it is better to admit them in inpatient facilities for efficient management. Taking rounds with the attending physician and nurse along with documentation of the initial examination and management is the initial minimum requirement. Further documentation of decision-making, results of test and imaging, and plan of care should also be documented in the patient's chart or in the electronic medical record. Orders are placed in OU which enables a hospital for billing for appropriate hospital services. A progress note is entered in electronic medical records for optimal patient care and a discharge summary should also be maintained and one copy should be given to the patient which includes physical examination, clinical course in the OU, diagnosis, follow-up advice, and schedule for an outpatient visit.

QUALITY ASSURANCE PROCESS AND METRICS

To optimize the use of EDOU and to maximize safety and efficiency of OU key metrics are important concerns for leadership. Important metrics of focus include:

- LOS
- Occupancy rate
- Discharge to home
- Inpatient conversion rate
- Revisit to ED rate
- Patient satisfaction

For the LOS assessment tracking, LOS <6 hours hours, LOS >24 hours, LOS >36 hours, LOS >2 midnights as well as LOS as per the patient's conditions should be noted. The appropriate standard for occupancy rate is 60–75% which may increase further depending on additional patient volume on ED and inpatient services. The discharge to home and inpatient conversion rate benchmarks are 80% and 20%, respectively. Close monitoring of these indicators is helpful in the following ways:

- Maintaining effective patient flow through ED.
- More effective way of disposition can be generated.
- Lessen both ED and inpatient overcrowding.

Effective OU and patient care should be paramount over all other management issues and financial concern.

Dashboard

Data are collected from different sources, and key performance indicators are summarized in a visual presentation. The focus should be on choosing the best data, which should be easy to read and interpretable. Monthly updates in the dashboard are helpful in continuous quality improvement, and this can be used across the healthcare. It is important to develop a dashboard during the planning process itself and not once the operation has started.

Policy Manual

Developing and maintaining the policy manual for OU is one of the best practices, which provides a unified solution to any key issue to staff members. The policy manual is helpful in addressing the problem with a clear path for resolution. It consists of specific processes and documentation expectations in detail, and the staff feels more secure and confident while performing their duties. The policy manual should be developed in the early phase of management and should be updated every 6–12 months.

Annual Report

At the end of the fiscal and calendar year, a formal annual report should be prepared and discussed with departmental and hospital leadership to highlight EDOU contribution, hospital bed-hours saved, safety record, patient satisfaction, and revenue generation.

GUIDELINES FOR SETTING UP AN ISOLATION UNIT

In view of the recent COVID-19 outbreak, the World Health Organization has declared the COVID-19 (SARS-CoV-2) outbreak as a public health emergency of international concern. Preparedness for COVID 19 outbreak includes containment, including active surveillance, early detection, isolation and case management, contact tracing, and prevention of the onward spread of SARS-CoV-2 infection. The mainstay of outbreak containment is the isolation of cases and quarantine of contacts. Quarantine and isolation are helpful in breaking the chain of transmission in the community and are important mainstays of cluster containment.

Quarantine: Individuals (who are not yet ill) but exposed to infectious diseases/COVID-19 are separated from nonexposed people, because they have the potential to become ill. Home quarantine of contacts of suspect/confirmed cases can also be done as per the government guidelines.

Isolation: Individuals who are ill and suspected or confirmed of infectious disease/COVID-19 are separated. These individuals are hospitalized and kept in isolation (designated area in a hospital) till they are tested negative. Positive cases remain hospitalized till the time two of their samples are tested negative or as per the government guidelines.

Patients may develop lower respiratory involvement (pneumonia in 15%), and a few of them may require ventilatory support (5%). Hence, intensive care beds are also identified with the support of a dialysis facility and extracorporeal membrane oxygenator (ECMO) facility for managing the respiratory/renal complications/multiorgan failure. If these facilities are not available, then the nearest tertiary care center is identified and it becomes a part of the plan. There are various ways of isolating the patient. Single-isolation rooms or negative-pressure rooms with 12 or more air changes per hour are recommended. Alternatively, all positive COVID-19 cases can be cohorted in a ward with good ventilation in a resource-constrained setting. Likewise, all suspect cases should also be separated into different wards. However, at least 1-m distance between two beds needs to be maintained and patients need to wear a triple-layer surgical mask at all times. Infection prevention control practices should be followed strictly in all health facilities because nosocomial infections in patients and attending healthcare personnel are well documented in the current COVID-19 outbreak as well. To ensure that all healthcare personnel are well aware of infection-prevention practices, Infection Prevention and Control committees should be formed.

The designated hospitals will ensure that personal protective equipment (PPE) and other logistics (hand sanitizer, soap, water, etc.), are in place and that all healthcare staff have been trained in washing of hands, respiratory etiquettes, donning/doffing, proper disposal of PPEs, and biomedical waste management (BMWM). Three-layered surgical masks and gloves are necessary at all times for doctors, nurses, and paramedics working in the clinical areas. Full complement of PPE should be worn by the medical personnel working in isolation and critical care facilities (including N95 masks) and also by the support staff engaged in cleaning and disinfection. Environmental cleaning should be done twice daily which should consist of damp dusting and floor mopping with Lysol or other phenolic disinfectants and cleaning of surfaces with sodium hypochlorite solution. Detailed guidelines available on the Ministry of Health and Family Welfare (MoHFW) website guideline can be followed.

Setting up an Isolation Facility/Ward

An isolation room/area helps in controlling the airflow in the room, so the number of airborne infectious particles is also reduced to a level where cross-infection to other people within a healthcare facility is highly unlikely. This may be achieved by:

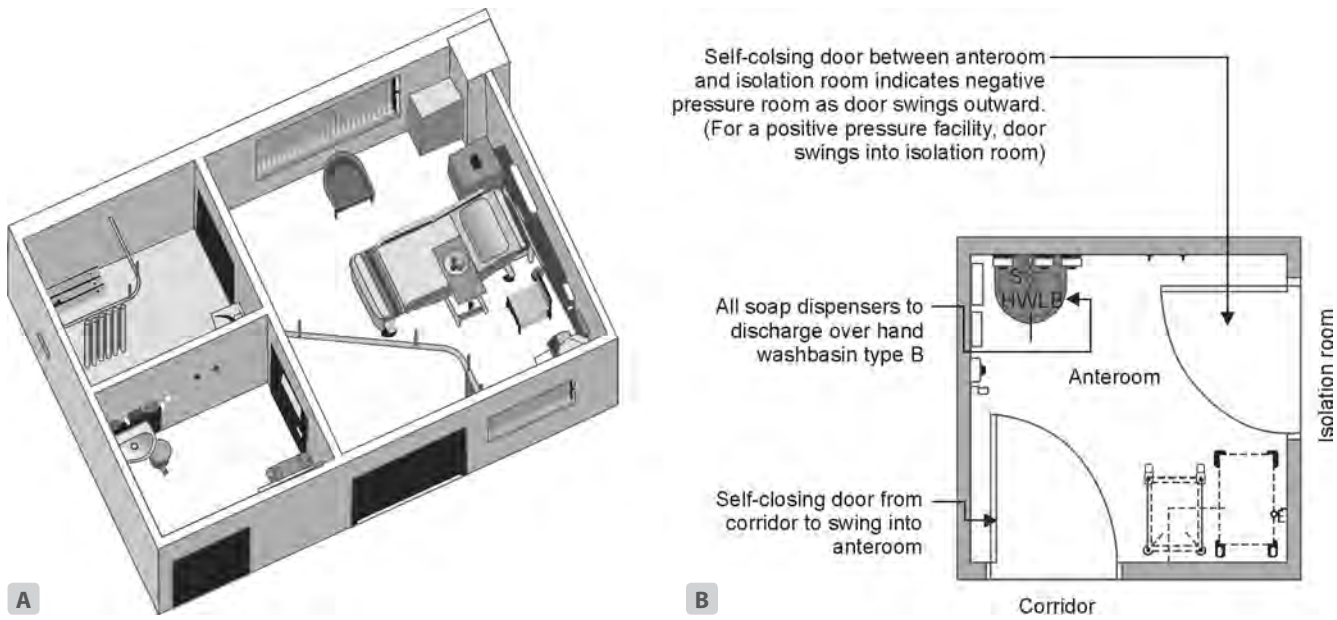
- Controlling the quantity and quality of the intake or exhaust air.
- Maintaining different air pressures between the adjacent areas.
- Designing airflow patterns for specific clinical procedures.
- Diluting infectious particles with large air volumes.
- Air filtration—high-efficiency particulate air (HEPA) filters, etc.

A state-level isolation facility should have at least 50 beds and a district-level isolation facility should have 10-bed isolation wards. Well-illuminated/visible signages on the door indicating that the space is an isolation area should be posted. Only essential furniture in the room that can be easily cleaned (does not retain dust or moisture) should be kept. A single room is preferred for COVID-19 patients. Single-room availability is not always present in a healthcare facility, so a 10-bed facility can be created with a minimum space of 2,000 sqft with the beds being separated from each other by at least 1 m (3 feet). The isolation area should be away from postsurgical wards/dialysis unit/sick newborn care unit (SNCU)/labor room, etc., and preferably have separate entry and exit. The isolation area should be accessed through separate stairs and lift, with restriction of visitors.

In most of the healthcare facilities, visitors' entries are unavoidable as they are anxious to see their family members. Hospital guidance should be provided for proper use of PPE and hand hygiene practices prior to entry into the isolation room/area. A communication setup should be installed within the isolation area; a dedicated smartphone should preferably be provided in the isolation area so that video calls can be arranged with family members. This may reduce family members' entry into the isolation area.

Isolation room entry should be through a double door, equipped with adequate PPE waste disposal bins and anteroom (for changing PPE) for doctors and nurses (**Figs. 2A** and **B**). BMWM guidelines should be used for disposal of PPE. A checklist may be useful to ensure that all equipment is available. Use a touch-free bin and place appropriate waste bags in a bin. Ensure that bins and a puncture-proof container for sharps disposal remain inside the isolation room which should be managed as per the BMWM guidelines. Water bottles and cups, tissue wipes, and all items necessary for personal hygiene should be within the patient's reach. The personal belongings of the patient should be minimum. If possible, a stethoscope, thermometer, blood pressure cuff, and sphygmomanometer should be dedicated for the patient or else should be thoroughly cleaned and disinfected before use.

Room ventilation should be adequate. Ensure 12 air changes/h and filtering of exhaust air, if the room is air-conditioned. Patients requiring aerosolization procedures (intubation, suction, nebulization) a negative pressure in isolation rooms is desirable. These rooms may have standalone air-conditioning. Isolation areas should not be a part of the central air-conditioning. If air-conditioning is not available, negative pressure could also be created by installing three to four exhaust fans which drive the air out of the room. In a hospital where large spaces with natural ventilation are available, a natural unidirectional flow of air is maintained through large windows on the opposite walls of the room. The principle of natural ventilation is to allow and enhance the flow of outdoor air by natural forces from one opening to another to achieve the desirable air change per hour. A separate toilet with proper cleaning and supplies is the priority for an isolation area. A checklist is important to keep things updated (**Box 1**). For possible outbreak investigation and contact tracing, keep a roster of all staff working in the isolation areas. Appoint dedicated doctors, nurses, and paramedics to the isolation facility and they should not be allowed to work in other patient-care areas. Portable X-ray, ultrasound and other equipment should be dedicated to the isolation area only.



A
Self-colsing door between anteroom and isolation room indicates negative pressure room as door swings outward. (For a positive pressure facility, door swings into isolation room)
All soap dispensers to discharge over hand washbasin type B
HWLB
Anteroom
Isolation room
Self-closing door from corridor to swing into anteroom
Corridor
B

FIGS. 2A AND B: (A) Typical isolation room; (B) Typical anteroom.

Wearing and Removing Personal Protective Equipment

Before entering the isolation room or area: Collect all equipment needed. Perform hand hygiene with an alcohol-based hand rub. Put on PPE in the order that ensures adequate placement of PPE items and prevent self-contamination and self-inoculation while using and taking off PPE; an example of the order in which to don PPE when all PPE items are needed is hand hygiene, gown, mask or respirator, eye protection, and gloves.

Leaving the isolation room or area: Remove PPE in the anteroom or, if there is no anteroom, make sure that the PPE should not contaminate other parts of isolation or other people.

General principles for removing PPE: Removal of PPE should be such that it prevents self-contamination or self-inoculation. Perform hand hygiene immediately after removing gloves. Remove the mask or particulate respirator last. Discard disposable items in a closed rubbish bin. Perform hand hygiene with an alcohol-based hand rub (preferably) or soap and water whenever ungloved hands touch contaminated PPE items. Details of PPE are given in Chapter 10.

BOX 1: Checklist for isolation rooms.

- Eye protection (visor or goggles)
- Face shield (provides eye, nose, and mouth protection)
- Gloves reusable, vinyl or rubber gloves for environmental cleaning, latex single-use gloves
- Particulate respirators (N95, FFP2, or equivalent)
- Medical (surgical or procedure) masks
- Gowns and aprons, single-use, long-sleeved, fluid-resistant
- Alcohol-based hand rub
- Plain soap (liquid if possible, for washing hands in clean water)
- Clean single-use towels (e.g., paper towels)
- Sharps containers
- For disinfection of surfaces, appropriate detergent disinfectant
- Large clinical waste bags, linen bags

Classification of Isolation Rooms

Isolation rooms are broadly classified into four classes (**Table 1**):

1. *Class-S standard pressure rooms*: For the patient with contact and droplet isolation. A normal air-conditioned room is appropriate.
2. *Class-N negative pressure rooms*: Used for airborne droplet nuclei isolation. It is also known as "airborne infection isolation" or "infectious isolation unit." The negative pressure gradient is maintained from the room to the anteroom as well as the ambient air. The air change rate should be 12 air changes/h.
3. *Class-P positive pressure rooms*: Rooms are positive pressure relative to ambient air used for an immuno-compromised and transplant patient.
4. *Class-A alternating pressure (negative/positive) rooms*: Room with alternate negative and positive pressure. Usually, these are not recommended as there is difficulty in maintaining the appropriate airflow.

Transport of Infectious Patients

Transfer and movement of the infectious patients should be limited and only on advice by clinicians, e.g., for diagnostic or treatment purposes. In cases where infectious patients are required to be transported to other units within the hospital or outside, the following precautions may be implemented. The patient should be dressed in a mask and gown, covered with sheets, and transferred to a protective environment isolation room.

To ensure suitable accommodation on arrival, the destination unit should be contacted and notified prior to the transfer. It is preferred that the patient is not transported through public access corridors but by dedicated corridors and lifts. During planning stages, design can assist the transfer of infectious patients by providing service corridors and strategically placed lifts, capable of separation from other lifts. The nominated lift may be isolated from public and staff transit through access control measures and cleaned following transit of the infectious patient. A designated floor for horizontal bed transfers of infectious patients away from busy clinical areas

TABLE 1: Classification of the isolation room.

	(S) standard	*(N) negative*	*(P) positive*	*(A) alternate*
Ventilation criteria	No pressure difference between room and adjacent corridor	Air pressure is less in the room than the adjacent corridor	Air pressure is more in the room than the adjacent corridor	Pressure can be adjusted either positive or negative
Indication	Contact or droplet	Airborne	Immunocompromised/Transplant patient, prevention of infection from the outside environment	Not recommended
Examples	• VRE • Gastroenteritis • Meningococcal disease • Hepatitis A • Cutaneous anthrax	• Measles • Chicken pox • Suspected or proven pulmonary/laryngeal tuberculosis	Prevention of infection in bone marrow transplant patient	Not recommended
Pressure	NA	Room –ve 30 Pa Ensuite –ve 30 Pa Anteroom –ve 15 Pa	Room +ve 30 Pa Ensuite +ve 30 Pa Anteroom +ve 15 Pa	NA

(VRE: vancomycin-resistant enterococci)

should be considered. The designated floor may be located at mid-level in the hospital. A combination of nominated lifts, corridors, and a bed transfer floor would assist in the movement of infectious patients through the hospital and minimize the risk of spread of infection.

SUMMARY

The design, location, layout, and process of EDOU are carefully selected to enable optimal care and finances. Several acute medical and surgical conditions are amenable to the OU clinical pathway; developing and maintaining protocols to guide patient selection and clinical care are critical; collaborative leadership model, appropriate staffing, and a robust monitoring system for quality, safety, and finances are required for ongoing strong OU management. Department and hospital leaders can generate and sustain service excellence for their observation patient population with a better understanding of these principles of OU establishment and management. Healthcare facilities should develop, implement, assess, and revise infection-control policies and practices that are appropriate to their particular needs based on the patient population demography and the facility's specialties. In view of the present pandemic of COVID-19, healthcare facilities requiring larger isolation areas to accommodate patients at the same time should take all measures to prevent the transmission also.

4 CHAPTER

Observation Medicine

M Rajadurai, Akmal Areeb, Devendra Richhariya

INTRODUCTION

Observation medicine deals with care of patients managed in the emergency department (ED) who require a short period (<24 h) of stay for evaluation and treatment in the dedicated observation unit (OU). These patients are managed using focused, condition-specific, and accelerated diagnostic or therapeutic protocols, which help to prevent inappropriate discharges or admissions while improving healthcare resource utilization. Observation care in such OUs has better outcomes than inpatient admission in terms of shorter length of stays, lower costs, lesser diagnostic uncertainty, and improved patient satisfaction. An ideal OU should have the following characteristics:

- Located within or immediately adjacent to ED and referred to as emergency department-based observation units (EDOUs)
- Comprises about 5–10% of all ED patients or a minimum of five to eight beds
- Protocol driven
- A strong collaborative and leadership model consisting of a physician director, a nurse director, and an administrative operations director
- Appropriate staffs consisting of physicians, physician assistants, and nurses
- Follows a robust monitoring system for quality, safety, and finances
- Prioritized support of consulting services such as cardiology, neurology, general surgery, urology, and gastroenterology and imaging modalities such as computed tomography (CT), magnetic resonance imaging (MRI), and echocardiogram.

CLINICAL DECISION RULES

Clinical decision rules (CDRs), also known as decision, are evidence-based tools or protocols to assist the emergency physician/clinicians in decision-making for common complaints in ED. These CDRs are often helpful in the ED setting to identify patients who might be at a higher risk for serious conditions, such as pulmonary embolism (PE) or subarachnoid hemorrhage (SAH), or to prevent overuse of unnecessary testing.

Although CDRs are termed "rules," these are not the replacement of critical thinking from experienced practitioners. In fact, many of the CDRs are compared with clinician gestalt or clinical practice, and they do not always fare better. In fact, some rules actually adopted clinician gestalt whereas, a rule cannot be applied unless the pretest probability (based on a physician's judgment of the likelihood of the disease) is below a predetermined threshold. Also, CDR is only useful for the practitioner, if it is practical. If a CDR has too many complicated variables, it is unlikely to be successful in a busy clinical environment of ED. CDRs must be applied appropriately.

Evolution and Validation of Clinical Decision Rules

Clinical decision rules evolve through a process of derivation to validation to impact analysis of the tool. After the tool is derived (level 4 evidence), the tool is validated in a limited patient setting (level 3 evidence), then a broader validation setting (level 2 evidence), and, finally, the impact of the tool is assessed (level 1 evidence). The tool must be validated in a patient population with similar characteristics to the clinician's patient population. For example, the tool may not perform the same (have the same sensitivity and specificity) if the prevalence of the disease is different between the study and actual patient populations. Also, the clinicians/emergency physicians must be familiar with the *inclusion and exclusion criteria* for a particular CDR. The tool could be misused, if the tool is derived and validated for over 18 years of the patient population and if used inappropriately in a pediatric setting.

Purpose of the Clinical Decision Rules

The practitioner must also understand the purpose of the CDR and whether, it is a *one-way or two-way rule.* As noted by Green, for example, the Ottawa Ankle Rules are intended to be a two-way rule; if the patient meets criteria, you do an X-ray. If they do not meet criteria, you do not do an X-ray. There are two paths you can take after you apply your CDR. Alternatively, the pulmonary embolism rule-out criteria (PERC) demonstrate a one-way rule. This tool was developed to identify a subset of patients at very low risk for PE such that no further testing needs to be done. If the patient is "PERC positive," this should

not imply that further testing for PE such as a D-dimer should be done. Whether or not additional testing should be done remains up to the practitioner and depends on many variables including whether an alternate diagnosis is much more likely. PERC was simply designed to help "rule out" the diagnosis of PE and not "rule in." This rule only guides you down one path, potentially to do no testing; it makes no judgment as to what you should do if the patient is "PERC positive."

Other Risk Stratification Tools

In addition to CDRs, there are many risk stratification tools or scales that are currently used for serious conditions such as PE and acute coronary syndrome (ACS). Others are being developed for use in the ED setting for common conditions such as congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), and transient ischemic attack (TIA) to identify patients at higher risk for acute severe complications. From a practical perspective, the ED physician will often use these risk stratification devices to help determine which patients require admission. However, these tools are less prescriptive in that they are not rules that suggest what an emergency physician should or should not do; rather, they help the emergency physician more objectively look at the risk for an individual patient. Then the emergency physician must decide what level of risk he/she comfortable with in regard to inpatient or outpatient management, which may greatly depend on the resources available in those environments such as in the OU. Most of the risk stratification tools encompass multiple variables with more complicated scoring systems; as they are not easily memorized, most of these would typically be used by ED physicians with real-time access to a computer or smartphone with appropriate apps.

Benefits of Implementation of Clinical Decision Rules

Given the many pitfalls noted above regarding CDRs, the goals of using evidence-based medicine to reduce practice variability, maximize the use of resources, and help identify and diagnose high-risk conditions are important. It is equally important that the ED physician critically appraise these tools and selectively apply them in appropriate ways. *MDCalc.com* provides a summary of the most common tools that are being used with easy-to-use online calculators, additional information on inclusion and exclusion criteria, and pearls and pitfalls for each tool. This chapter reviews the most commonly used CDRs in the EDOU.

CHEST PAIN

Patients presenting with chest pain to ED with normal electrocardiogram (ECG) and cardiac markers on arrival should be observed for a period of 6–12 hours before ruling out ACS (**Table 1**). Simultaneously, other life-threatening causes of chest pain such as PE, tension pneumothorax, cardiac tamponade, and aortic dissection should be considered high risk based on clinical presentation and managed and admitted immediately. In EDOU, performing serial ECG/cardiac biomarkers and stress tests helps to identify ACS or patients at risk who would benefit from timely intervention to reduce their risk of a major adverse cardiac event (MACE). *TIMI (thrombolysis in myocardial infarction) score* (**Table 2**) and *HEART score* (**Table 3**) are used for risk stratification in chest pain. Managing low-risk chest pain in EDOU and *Vancouver Chest Pain Rule* for safe discharge are summarized in **Flowchart 1**.

TABLE 1: Patient selection criteria to treat in observation unit—chest pain.

Inclusion criteria	*Exclusion criteria*
Low-risk unstable angina patients 8–12 h after presentation who: • Are symptom free • Have normal serial cardiac markers/ECG • Have no signs of heart failure	• AMI within 2 days • High-risk unstable angina • Left main coronary artery stenosis • Hypertrophic cardiomyopathy • Uncontrolled symptomatic heart failure • Uncontrolled cardiac tachyarrhythmias or bradyarrhythmia • Acute pulmonary embolism or pulmonary infarction • Acute myocarditis or pericarditis • Endocarditis • Symptomatic severe aortic stenosis • Acute aortic dissection • Severe arterial hypertension (>200/110 mm Hg) • Acute noncardiac issue (sepsis and toxicologic) • Electrolyte abnormalities • Mental or physical impairment leading to inability to exercise adequately
Stress tests—aid in identification of inducible myocardial ischemia by use of stressors and help rule out CAD before the discharge of at-risk patients presenting with chest pain. • Exercise stress test (treadmill test) using Bruce protocol • Stress echocardiography using dobutamine—indicated if the patient cannot exercise • Myocardial perfusion imaging	

(AMI: acute myocardial infarction; CAD: coronary artery disease; ECG: electrocardiogram)

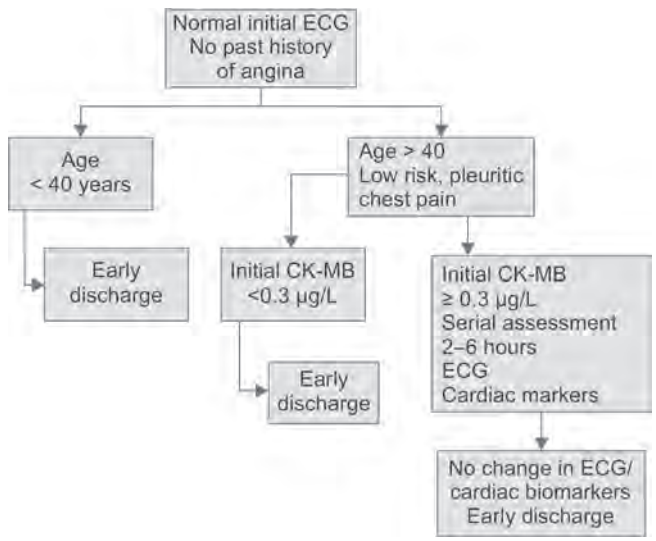
TABLE 2: Risk stratification—TIMI score—1 point for each positive score.

History	Age > 65 years
	Three or more risk factors for CAD
	Known CAD
	Aspirin use in the past 7 days
Presentation	Recent (<24 h) severe angina
	Positive cardiac biomarkers
	ST deviation > 0.5 mm
Higher *TIMI scores* mandate admission. Predicts risk of an adverse cardiac outcome within 14 days of presentation with unstable angina or non-STEMI. *Vancouver Chest Pain Rule*—used to determine very low-risk chest pain patients and help in early discharge.	

(CAD: coronary artery disease; STEMI: ST-segment elevation myocardial infarction; TIMI: thrombolysis in myocardial infarction)

TABLE 3: Risk stratification—HEART risk score for chest pain patients in the emergency department.		
History	Highly suspicious	2
	Moderately suspicious	1
	Slightly suspicious	0
ECG	Significant ST depression	2
	Nonspecific repolarization changes	1
	Normal	0
Age	>65 years	2
	45–65 years	1
	<45 years	0
Risk factors	>3 risk	2
	1 or 2	1
	No risk	0
Troponins	>3 × normal limit	2
	1–3 × normal limit	1
	<normal limit	0
Heart score	**Risk of MACE**	**Recommendations**
0–3	0.9%	ED discharge
4–6	12%	Observation
>6	65%	Cardiology admission

(ED: emergency department; MACE: major adverse cardiac event)



(ECG: electrocardiogram; CK-MB: creatine kinase myocardial band)

FLOWCHART 1: Managing low-risk chest pain and safe discharge from observation unit (Vancouver Chest Pain Rule).

ATRIAL FIBRILLATION

Atrial fibrillation is the most common clinically significant arrhythmia and its incidence increases with age which required a new and innovative management strategy. The patient should be carefully selected for the OU (**Table 4**). Protocol-based management is started for atrial fibrillation. Risk stratification is important before starting the anticoagulation therapy by *CHA_2DS_2-VASc scoring* and *HAS-BLED* (*hypertension, abnormal renal/liver function, stroke, bleeding history or predisposition, labile INR, elderly, drugs/alcohol*) *scoring* system (**Table 5**). A stepwise systematic approach (**Flowchart 2**) is required to be implemented in the management of atrial fibrillation as the patient has a risk of developing the stroke, if not managed properly.

ACUTE HEART FAILURE

Recommendations on risk stratification as well as EDOU management of acute heart failure (HF) syndrome are published by The Society of Chest Pain Centres (now the Society for Cardiovascular Patient Care). Most of the patients with acute HF are not appropriate for observation care. High-risk patients can be identified by multiple risk stratification schemes. These patients are at high risk for inpatient morbidity or mortality and not be good candidates for observation management. Therefore, it is important to identify those patients who are completely inappropriate for care in the OU. Most of the patients with acute symptoms of HF presenting to the ED should be admitted to an inpatient unit because these patients require initial workup and management which generally surpass the recommended 24-hour observation time. The summary of EDOU recommendation for acute HF is given in **Table 6**.

SYNCOPE

For syncope, multiple risk stratification rules are published, but a physician's judgment is more important because none of the published rules demonstrated an improvement in outcome because syncopal episodes are generally considered as the precursor to sudden cardiac death in patients with cardiovascular history and frequently admitted to the hospital. The most common markers of risk factors include family history of sudden cardiac death, severe cardiac disease [including dilated cardiomyopathy, aortic stenosis, hypertrophic cardiomyopathy, or left ventricular (LV) outflow disease], ECG abnormalities (such as preexcitation syndrome, Brugada syndrome, QT interval abnormalities, or conduction blocks), or exertional syncope. Patients who are considered low risk should usually be discharged. Syncope management in EDOU is summarized in **Table 7** and **Flowchart 3**.

VENOUS THROMBOEMBOLISM

Acute venous thromboembolism (VTE) disease, which includes deep venous thrombosis (DVT) and PE, is a frequent reason for patients to present to the ED and require hospitalization. The therapeutic strategy for VTE has remained unchanged for decades: Anticoagulation (**Table 8**) to prevent clot propagation, new or recurrent PE, secondary pulmonary hypertension, and, in the case of DVT, mitigate longer term and nonlethal complications, such as post-thrombotic syndrome. Historically, treatment of VTE mandated hospital admission for unfractionated heparin (UFH) infusion while vitamin K antagonists (VKAs) were administered. The availability of low-molecular-weight heparin (LMWH), which can be administered subcutaneously with a predictable therapeutic effect,

TABLE 4: Patient selection for the management of AF in EDOU.

Protocol for AF relies on algorithms incorporating anticoagulation, rate and rhythm control, and mechanisms to ensure rapid outpatient follow-up.

Ideal patients	**Contraindicated patients**
• Hemodynamically stable patients • No signs of cardiac ischemia • Onset of AF of <48 hours' duration	AF secondary to the underlying causes such as sepsis, pulmonary embolism, gastrointestinal (GI) bleed. Unstable AF patients

Relative contraindications

- Acute renal insufficiency
- Pregnant patients
- Unknown time of AF onset
- Expected length of stay >36 h due to comorbidities
- Patients having poor health literacy
- Patients lacking close follow-up
- Inability to adhere to a treatment

- Risk factors for immediate stroke following cardioversion of AF
- Unknown time from onset
- History of transient ischemic attack (TIA) or stroke in last 6 months
- History of valve disease

Management of AF in EDOU anticoagulation—based on economic considerations

Warfarin—Vitamin K antagonist

- Requires frequent monitoring of INR
- Interacts with many foods and medications
- Requires bridging or overlapping therapy with UFH/LMWH for 3–5 days

DOACs

- Edoxaban, dabigatran—require additional lead in therapy with UFH/LMWH for 5 days
- Apixaban rivaroxaban—do not require bridging/lead in therapy with parenteral anticoagulation
- Preferred over warfarin in:
  - Patients with nonvalvular AF
  - Patients who cannot be relied upon to get their INR levels checked or
  - Patients who cannot adhere to diet restrictions required when taking warfarin
- Cardiology consultation
- Echocardiography—to rule out valvular heart disease

Anticoagulation

- Long-term anticoagulation following cardioversion or rate control should be initiated in individuals at risk of stroke and thromboembolism. The risk stratification is done with CHA2DS2-VASc score and prior to initiating anticoagulation patients' bleeding risk must also be assessed using HAS-BLED score simultaneously

Discharge criteria

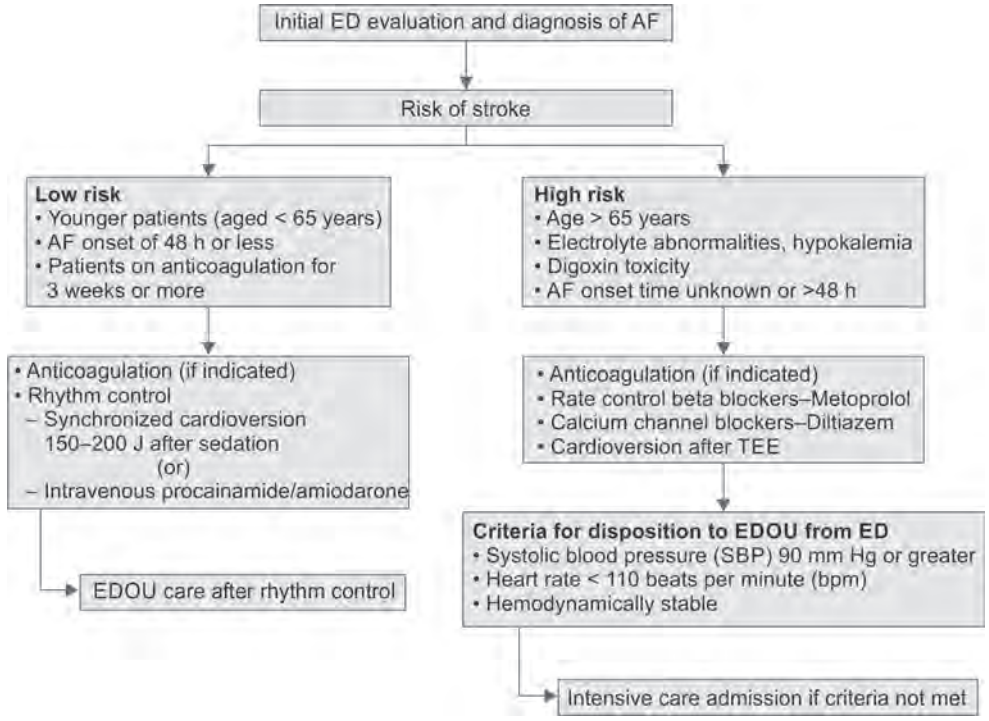
- AF rate controlled or rhythm converted to normal sinus for at least 1–2 h
- Negative serial cardiac biomarker tests if ACS is suspected
- Discharge advice
- Cardiology follow-up in 3–5 days
- Prescribe 30 days of anticoagulation if indicated
- Prescribe the lowest long-acting oral dose of rate control medication equivalent to what they received in EDOU, if discharged on rate control medications
- Educate patients and family about risks of bleeding or stroke, medication side effects, and dietary precautions

(ACS: acute coronary syndrome; AF: atrial fibrillation; DOAC: direct oral anticoagulant; EDOU: emergency department-based observation unit; HAS-BLED: hypertension, abnormal renal/liver function, stroke, bleeding history or predisposition, labile INR, elderly, drugs/alcohol usage; LMWH: low-molecular-weight heparin; UFH: unfractionated heparin)

TABLE 5: Risk stratification for anticoagulation therapy in atrial fibrillation patients.

CHA_2DS_2-VASc scoring system		***HAS-BLED score***	
Components	*Score*	*Components*	*Score*
Congestive heart failure	1	Hypertension	1
		Abnormal liver and kidney	1
Diabetes	1	Stroke	1
Hypertension	1	Bleeding predisposition	1
Stroke/TIA/thromboembolism	2	Labile INR	1
Age > 75 years	2	Elderly >65	1
Age 65–74 years	1	Drugs (use of antiplatelet and alcohol)	1
Sex: Female	1	A score of 3 or greater indicates a high risk of bleeding	
Total maximum score 9: AHA recommends oral anticoagulation for a score of 2 or greater. Aspirin is recommended in known CAD patients even with a score of 0			

(AHA: American Heart Association; CAD: coronary artery disease; HAS-BLED: hypertension, abnormal renal/liver function, stroke, bleeding history or predisposition, labile INR, elderly, drugs/alcohol usage; INR: international normalized ratio; TIA: transient ischemic attack)



(ED: emergency department; EDOU: emergency department-based observation unit; TEE: transesophageal echocardiography)

FLOWCHART 2: Stepwise systematic approach to atrial fibrillation.

shifted the initial management of uncomplicated DVT toward the outpatient setting. The diagnosis of PE, however, remained a reason for hospital admission for anticoagulation and monitoring for hemodynamic compromise.

Patients with underlying HF, pulmonary disease, or active cancer have significantly higher mortality rates in the setting of acute PE and may, therefore, require higher levels of care than patients without such comorbidities. Scoring systems, such as the *PESI (pulmonary embolism severity index), sPESI (simplified pulmonary embolism severity index), Hestia score*, and *Geneva score*, incorporate medical history and clinical criteria into a score that establishes patients at either low or very low risk for adverse outcomes. Both the PESI and the sPESI have demonstrated sufficient sensitivity to indicate outpatient or observation management in patients with low scores (**Table 9**). Likewise, a Hestia score of 0 indicates low risk (**Box 1**).

ACUTE ABDOMINAL PAIN

Gastrointestinal (GI) emergencies, such as abdominal pain, are one of the common symptoms in ED. The traditional teaching for a patient with abdominal pain is to perform a rapid diagnostic workup with pain management. After

TABLE 6: Patient selection for EDOU care acute heart failure.

Exclusion criteria	*Patient management*	*Disposition*
• Newly diagnosed HF patients • HF with new ischemic ECG changes or elevated troponins • HF with unstable cardiac arrhythmia • HF with cardiogenic shock/ symptomatic hypotension • Difficulty weaning off NIV or persistent respiratory distress • BNP > 1,000 pg/mL or NT-pro BNP > 5,000 pg/mL • HF with impaired renal function	• Record weight and oxygen requirement on arrival • Strict input and output measurement • Cardiac monitoring for early detection of malignant arrhythmias • Measurement of electrolytes, serial troponins • Diuretics and fluid restriction to reduce fluid overload • Consider initiation of a synergistic thiazide diuretic, if there is an inadequate response to the initial intravenous diuretic dose • Initiate vasodilators with caution as hypotension occurs following initial diuresis • Identify the trigger for HF and educate the patient • Look for medication noncompliance	• *Home* • Hemodynamic stability • Resolution of dyspnea and edema • Admit into hospital • No improvement in fluid balance, oxygen requirement, vital signs • The decline in cardiac, pulmonary, or renal function

Discharge advice

- Educate patient and family members regarding medication and diet compliance
- Dietary restriction of sodium to 1,500 mg/day
- Educate patients and families to look out for and recognize signs and symptoms of worsening HF such as increasing dyspnea, increased weight gain, and increasing fatigue

(BNP: brain natriuretic peptide; HF: heart failure; NIV: noninvasive ventilation; NT-pro BNP: N-terminal pro-brain natriuretic peptide)

TABLE 7: Patient selection for observation unit treatment—syncope.

Transient loss of consciousness due to cerebral hypoperfusion, the cause for which can be life-threatening or benign	
Suspected cause of syncope	EDOU monitoring/management
GI bleed	Serial hemoglobin, hematocrit
Dehydration	• Rehydration with fluids • Assessment of metabolic panel
Cardiac	• Serial troponin measurements • BNP measurement • Continuous cardiac monitoring
• EDOU management • Vitals monitoring • Clinical/laboratory reassessments based on the suspected cause	
Discharge • Severe disease ruled out • Patients discharged without a clear diagnosis—advice to follow up with a physician • Outpatient cardiac monitoring (Holter monitoring and Loop recorders) in consultation with cardiology—if cardiac arrhythmia suspected but could not be confirmed during EDOU stay	

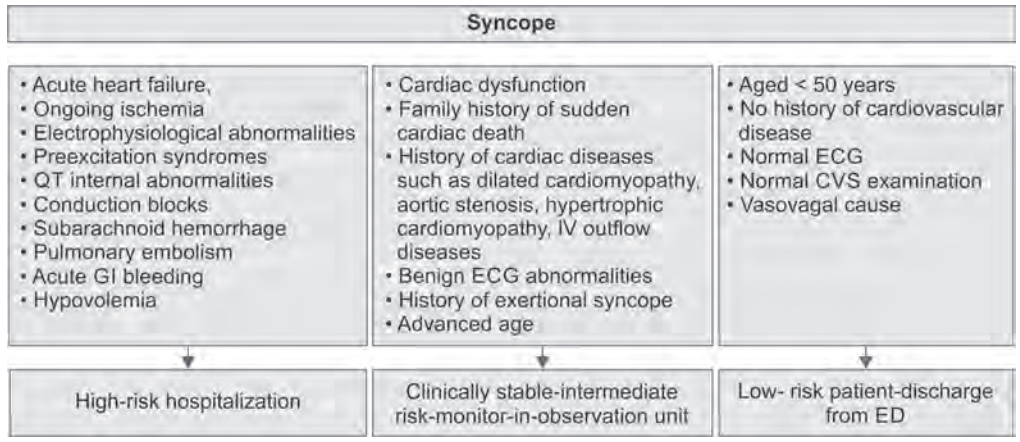
(BNP: brain natriuretic peptide; EDOU: emergency department-based observation unit; GI: gastrointestinal)

the initial ED workup, patients are either discharged home or admitted to a surgical or medical inpatient service (**Box 2**). Rapid and accurate diagnosis and treatment of patients increasingly rely on early radiographic testing. EDOUs are helpful in improving the patient experience by using appropriate imaging modalities. EDOU management is helpful in reducing the morbidity and mortality and health care expenditures. Inclusion and exclusion criteria related to GI complaints for EDOU protocols may remain the same. Three levels are considered for inclusions and exclusions: (1) Healthcare system level, (2) general patient level, and (3) within the specific patient protocol. Capacity constraints, availability of required resources, unit factors, and team factors are important at the level of the healthcare system.

APPENDICITIS

In patients who present to the ED with abdominal pain, the most common diagnosis that is suspected is appendicitis, which requires surgery. History, physical examination, and laboratory evaluation are included in the initial ED, although no single laboratory value can rule in or rule out the diagnosis of appendicitis. Risk scores and imaging scoring systems are included in the evaluation of patients with suspected appendicitis. Alvarado score, also known by its mnemonic MANTRELS (Migration to the right iliac fossa, Anorexia, Nausea/Vomiting, Tenderness in the right iliac fossa, rebound pain, Elevated temperature (fever), Leukocytosis, and Shift of leukocytes to the left) score, is commonly used in addition to the history, physical, and laboratory values. Eight predictive factors are used in the Alvarado score (**Table 10**) given a point value of 1 or 2 based on diagnostic weight.

Pediatric appendicitis score, appendicitis inflammatory response score, Raja Isteri Pengiran Anak Saleha appendicitis score, and the adult appendicitis score are the other scoring systems that may be used to categorize the patients into low, intermediate, and high risk for appendicitis. Imaging studies are obtained if the clinical scoring system places the patient in the moderate to high-risk group. The approach to a patient with appendicitis in EDOU is summarized in **Flowchart 4**.



Syncope
• Acute heart failure,
• Ongoing ischemia
• Electrophysiological abnormalities
• Preexcitation syndromes
• QT internal abnormalities
• Conduction blocks
• Subarachnoid hemorrhage
• Pulmonary embolism
• Acute GI bleeding
• Hypovolemia
• Cardiac dysfunction
• Family history of sudden cardiac death
• History of cardiac diseases such as dilated cardiomyopathy, aortic stenosis, hypertrophic cardiomyopathy, IV outflow diseases
• Benign ECG abnormalities
• History of exertional syncope
• Advanced age
• Aged < 50 years
• No history of cardiovascular disease
• Normal ECG
• Normal CVS examination
• Vasovagal cause
High-risk hospitalization
Clinically stable-intermediate risk-monitor-in-observation unit
Low- risk patient-discharge from ED

(CVS: cardiovascular; ED: emergency department; GI: gastrointestinal)

FLOWCHART 3: Approach to syncope in observation unit.

TABLE 8: Patient selection for observation unit treatment—venous thromboembolism (DVT + PE).

Inclusion criteria	*Exclusion criteria—DVT*	*Exclusion criteria—PE*
• Stable patient • No comorbidities • Low-risk PE or DVT based on risk stratification scores	• Critical limb ischemia • Large iliac/pelvic DVTs • Decompensated comorbidities • Require inpatient monitoring	• Hemodynamically unstable—hypotension, shock, acute cardiac arrest • Presence of RV dysfunction • Elevated BNP or NT-pro BNP levels • Elevated troponin level • Patients with comorbidities—heart failure, pulmonary disease, active cancer
Risk stratification • PESI, sPESI • Hestia score		
Patient management • Anticoagulation—based on economic considerations • Establish follow-up with the physician • Educate about dietary restrictions and monitoring therapy if initiated on VKAs • Educate patients and caregivers about the disease and bleeding risks		

(BNP: brain natriuretic peptide; DVT: deep venous thrombosis; NT-pro BNP: N-terminal pro-brain natriuretic peptide; PE: pulmonary embolism; RV: right ventricular; VKAs: vitamin K antagonists; PESI: Pulmonary Embolism Severity Index; sPESI: simplified Pulmonary Embolism Severity Index)

TABLE 9: Assessing risk score for managing VTE patients in an observation unit.

Characteristics	*PESI*	*sPESI*
Age	1 point per year of age	1 point if aged >80 years
Male sex	10 points	–
Cancer	30 points	1 point
History of HF	10 points	1 point if either/both
Chronic pulmonary disease	10 points	
Heart rate > 100	20 points	1 point
SBP < 100 mm Hg	30 points	1 point
Respiratory rate > 30	20 points	–
Temperature < 36°C/96.8°F	20 points	–
Altered mental status	60 points	–
Oxygen saturation < 90%	20 points	1 point
• *sPESI score*: 0—low-risk patient; *PESI score*: <65 years—very low 30-day mortality risk • Low PESI and sPESI indicate outpatient or observation management • Hestia score of 0 indicates low risk		

(HF: heart failure; PESI: pulmonary embolism severity index; sPESI: simplified pulmonary embolism severity index; SBP: systolic blood pressure)

BOX 1: Hestia risk stratification score (any one positive response requires inpatient management).

- Hemodynamically unstable
- Indication for fibrinolysis or thrombectomy
- At high risk for bleeding:
  - GI bleeding within the last 14 days
  - Stroke within 4 weeks
  - Surgery within 2 weeks
  - Bleeding diathesis
  - Thrombocytopenia (<75–109/L)
  - Uncontrolled hypertension (SBP > 180 mm Hg, diastolic blood pressure > 110 mm Hg)
- Supplemental oxygen required for oxygen saturation > 90%
- PE occurred while on anticoagulation
- Parenteral pain medication required
- Medical or social reason necessitating inpatient admission
- Creatinine clearance < 30 mL/min
- Severe hepatic impairment
- Pregnant
- History of heparin-induced thrombocytopenia

(GI: gastrointestinal; PE: pulmonary embolism; SBP: systolic blood pressure)

BOX 2: Patient selection for observation unit treatment—abdominal pain.

- Exclusion criteria
- Unstable vital signs
- Surgical abdomen
- Severe sepsis
- Immunocompromised
- Diagnostic workup reveals any emergent surgical condition
- Differential diagnosis of abdominal pain ranges from very low-risk conditions, such as constipation, to catastrophic conditions, such as a ruptured abdominal aortic aneurysm. EDOUs may be used for evaluation and possible treatment of conditions such as appendicitis, GI bleeding, and pancreatitis
- Several emergent conditions may initially appear to have a GI etiology such as epigastric pain of an inferior wall, acute myocardial infarction, right upper quadrant pain of hepatic congestion in congestive heart failure, generalized abdominal pain with nausea and vomiting in diabetic ketoacidosis, back and flank pain in pulmonary embolism

(EDOUs: emergency department-based observation units; GI: gastrointestinal)

TABLE 10: Patient selection for treatment of appendicitis in observation unit.

Diagnosis is considered based on history, physical examination, and laboratory values

Alvarado score/MANTRELS score—used to risk stratify suspected patients

Suspected appendicitis patient with:

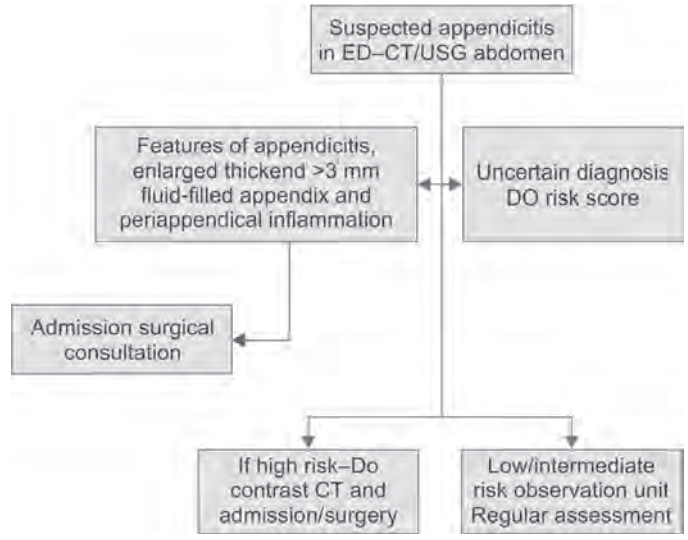
- Negative or indeterminate initial imaging results
- Diagnostic uncertainty and lower risk scoring

Nonoperative treatment of appendicitis should not be considered in EDOU

Alvarado scoring system for appendicitis

Characteristics		***Points***
Symptoms	Nausea and/or vomiting	1
	Anorexia	1
	Migration of pain to right lower quadrant	1
Signs	Tenderness in the right lower quadrant	2
	Rebound	1
	Temperature > 37.3°C (99.1°F)	1
Laboratory tests	>10,000/dL	2
White blood cell count	Left shift	1

Score	**Risk**	**Management**
1–4	Low risk	• Observation • Serial clinical reassessment and laboratory studies • Repeat risk assessment with Alvarado score
5–6	Intermediate risk	
7–10	High risk	• Admission • Contrast-enhanced CT of abdomen



Suspected appendicitis in ED–CT/USG abdomen
Features of appendicitis, enlarged thickend >3 mm fluid-filled appendix and periappendical inflammation
Uncertain diagnosis DO risk score
Admission surgical consultation
If high risk–Do contrast CT and admission/surgery
Low/intermediate risk observation unit Regular assessment

(ED: emergency department; USG: ultrasound)

FLOWCHART 4: Approach to appendicitis in EDOU.

GASTROINTESTINAL BLEEDING

Gastrointestinal bleeding (GIB) is usually classified as upper gastrointestinal bleeding (UGIB) and lower gastrointestinal bleeding (LGIB). This categorization is done anatomically at the ligament of Treitz, the ligament that suspends the duodenojejunal flexure and inhibits the reflux of gastrointestinal contents distal to this site. Bleeding from

the upper GI tract indicates hematemesis. Clinical severity, risk of mortality, treatment requirements, length of stay, and cost are different in each and every patient who present with gastrointestinal bleed. Clinical risk scores such as Glasgow Blatchford Score and Clinical Rockall Score (**Table 11**) are used and helpful for an emergency physician in recognizing and managing these factors.

ACUTE PANCREATITIS

Acute pancreatitis (AP) is a frequent cause of abdominal pain. The diagnosis of AP requires the presence of two out of three features: (1) Abdominal pain consistent with AP, (2) serum lipase or amylase at least three times the upper limit of normal, or (3) characteristic findings on abdominal imaging, generally

TABLE 11: Patient selection for observation unit treatment—GI bleed.

Exclusion criteria for observation care	***EDOU strategy in GI bleed management***
• Hemodynamic instability • Persistent orthostasis despite 1-L intravenous fluid bolus, syncope • Evidence of active bleeding in ED—frequent episodes of hematemesis, melena, bright red blood per rectum • Coagulopathy • Known esophageal varices • Transfusion requirement • Comorbidities such as heart failure, ischemic heart disease, renal failure, liver failure, disseminated malignancy	• Keep patient NPO • Place two large-bore I catheters • PPI • Frequent reassessments—vital signs, pallor, orthostasis, repeat Hb/PCV • Identify the source of bleeding • Gastroenterology consultation for OGDScopy or colonoscopy within 24 h ideally • Bowel preparation if planned for colonoscopy

	Upper GI bleed	***Lower GI bleed***
Clinical features	• Melena • Past history of UGIB • Positive nasogastric tube aspirate	• Blood clots in stool • Hematochezia • Past history of LGIB
Laboratory value	BUN to Cr ratio >30	BUN to Cr ratio <30
Common causes	• Peptic ulcer disease • Variceal bleeding • Esophagitis • Mallory–Weiss tear	• Diverticular bleeding • Hemorrhoids • Polyps • Colorectal cancer • Intestinal ischemia • Colitis

Glasgow Blatchford criteria—low-risk GI bleed Clinical Rockall score—low-risk bleed		
BUN	<18.2 mg/dL	Age <60 years
Hemoglobin	Men >13 g/dL	Blood pressure > 100 mm Hg systolic
Hemoglobin	Women >12 g/dL	Pulse < 100/min
SBP	>109 mm Hg	• No syncope, melena, liver disease, heart failure • No heart failure, ischemic heart disease, renal failure, liver failure, disseminated malignancy, or other major comorbidities
Pulse	<100 beats per minute	

Low-risk GI bleed patients meeting Glasgow Blatchford criteria can be observed in OU

Discharge criteria
- Clinically stable
- Stable hemoglobin/hematocrit level
- No evidence of rebleeding
- No concern of high risk of rebleeding on endoscopy
- Discharge advice
- Avoid NSAIDs, anticoagulants, alcohol consumption
- Timely follow up in outpatient service

(BUN: blood urea nitrogen; ED: emergency department; GI: gastrointestinal; Hb: hemoglobin; LGIB: lower gastrointestinal bleeding; NPO: nil per oral; NSAIDs: nonsteroidal anti-inflammatory drugs OGD: oesophago-gastro-duodenoscopy; OU: observation unit; PCV: packed cell volume; SBP: systolic blood pressure; UGIB: upper gastrointestinal bleeding)

contrast-enhanced CT. The Atlanta Classification of AP most recently modified its classification of AP into two phases: (1) Early and (2) Late. Further classification is based on severity. Mild AP has no organ failure, or local or systemic complications, and often resolves within the 1st week, which may be ideal for EDOU management. Moderately severe AP is defined by the presence of transient organ failure, local complications, or exacerbation of the comorbid disease. Severe AP is defined by persistent organ failure for >48 hours. The Atlanta Classification is used to provide nomenclature regarding the severity of AP, but it does not provide an assessment of risk. Several scoring systems providing an assessment of risk have been published. Some of the most commonly known scores are the Ranson criteria, Glasgow score, and the APACHE II (acute physiology and chronic health evaluation II) score, which are based on clinical variables. Limitations of these scores at the time of ED disposition include that the Ranson criteria and the Glasgow score require the input of clinical variables at 48 hours, whereas the APACHE II is very complex and not specific to AP.

More recent risk predictors may provide critical information earlier in the course of the presentation of AP (**Table 12**). The *HAPS (harmless acute pancreatitis score)* is made up of three parameters and is used to help identify patients with AP who would not require intensive care unit (ICU) level of care and could potentially not require inpatient treatment at all. The HAPS could provide utility in the evaluation of AP to determine if hospitalization or an OU stay is needed or if the patient may be a candidate for discharge home. Another modern risk score, the *BISAP (bedside index of severity in acute pancreatitis) score*, is currently used to determine AP severity. Calculation of this score depends on five parameters that are easily attainable in the ED. The BISAP score is simple to use and is an accurate method for identifying patients at increased risk for in-hospital mortality. Several publications have compared the BISAP score with other risk scores in predicting the severity of AP and have noted its usefulness in determining AP severity earlier than other scoring systems. The BISAP score may be a useful tool to help divert appropriate patients to an EDOU. Exclusion criteria, management, and discharge criteria of AP for EDOU management are given in **Table 13**, and a summary of managing the AP is given in **Flowchart 5**.

TRANSIENT ISCHEMIC ATTACK/MINOR STROKE

Transient ischemic attack: Transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia without acute infarction. *Minor stroke*: Patients with neurological dysfunction presenting after 24–48 hours and able to perform their activities of daily living at home and being ambulated unassisted in the ED.

Transient ischemic attack presents without any residual deficit and patients appear clinically normal; most patients do not have any event during or after the TIA so these are the ideal candidates for OU workup. TIA is the risk factor for subsequent

TABLE 12: Risk scores used for initial evaluation of acute pancreatitis.

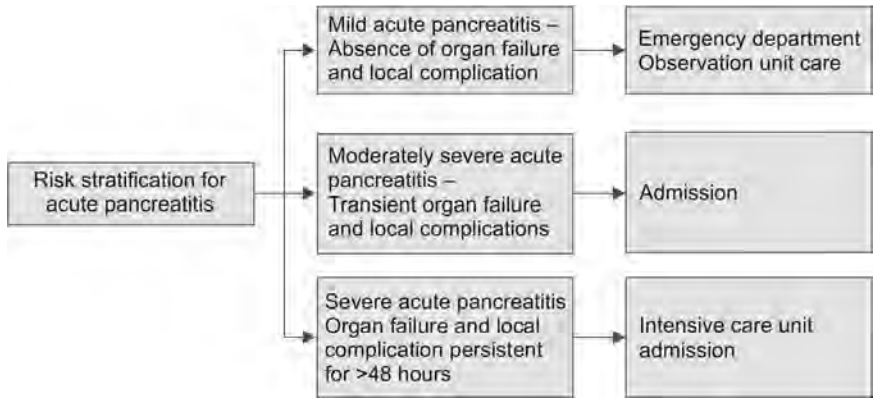
Risk score	*Clinical parameter*	*Scoring*	*Utility for EDOU*	*Purpose*
BISAP	• Obtained within first 24 h • BUN > 25 mg/dL • Impaired mental status • SIRS • Age > 60 years • Pleural effusion	• 1 point for each parameter Maximum score = 5 • Score = 0: 0.1% mortality • Score ≤ 2: 1.9% mortality	• Easily calculated before EDOU disposition • Could consider patients with BISAP score 2	Predicts mortality from acute pancreatitis
HAPS	• Initial evaluation • No rebound tenderness • Normal HCT Cr <2 mg/day	• 1 point for each parameter • Maximum score = 3 • Score = 0 not requiring hospitalization	• Easily calculated before EDOU disposition • Patients with a score of 0 could be discharged or placed in EDOU	Predicts mild course of acute pancreatitis

(BUN: blood urea nitrogen; BISAP: bedside index of severity in acute pancreatitis; EDOU: emergency department-based observation unit; HAPS: harmless acute pancreatitis score; HCT: hematocrit; SIRS: systemic inflammatory response syndrome)

TABLE 13: Exclusion criteria management and discharge criteria for acute pancreatitis in an observation unit.

Exclusion criteria for EDOU care	*EDOU management*	*Discharge criteria and advice*
• Gallstone pancreatitis • Blood urea nitrogen > 20 mg/dL • Hematocrit > 44% • Acute kidney injury • Pleural effusion • Pulmonary infiltrates • Extra pancreatic collections • Altered mental status	• Early aggressive hydration with IV Fluids (caution in elderly, cardiac, or renal patients) • Regular assessment of clinical status, vital signs, urine output, and laboratory values • Monitor for complications—fluid overload, abdominal compartment syndrome, etc. • Bowel rest with early oral feedings as appropriate beginning with clear liquids • Pain control with intravenous opioids • Antiemetics	• Stable vital signs • Tolerates solid diet and analgesics orally • Advice discontinuation of alcohol or medication which triggered the development of pancreatitis • Provide outpatient follow-up

(EDOU: emergency department-based observation unit)



Risk stratification for acute pancreatitis
Mild acute pancreatitis – Absence of organ failure and local complication
Emergency department Observation unit care
Moderately severe acute pancreatitis – Transient organ failure and local complications
Admission
Severe acute pancreatitis Organ failure and local complication persistent for >48 hours
Intensive care unit admission

FLOWCHART 5: Summary of management of acute pancreatitis in emergency department-based observation unit.

vascular events. The main objective of the initial evaluation of the management of TIA patients in EDOU are early detection and prevention of stroke, detection of causes of TIA, and prevention of future strokes. Causes of TIA may be vascular (extracranial or intracranial), cardioembolic, and cryptogenic. Evaluation of TIA includes a history of duration of symptoms assessing the vascular risk factors and other suspected etiology, and examination includes a structured stroke examination, such as the NIHSS (National Institutes of Health Stroke Score), to improve the clinical detection of small, subtle strokes. ECG and cardiac monitoring are important for the detection of atrial fibrillation. Laboratory testing should include a complete blood count, serum glucose, electrolytes, and prothrombin time. Brain imaging, with either CT or MRI, should be obtained if possible. Epilepsy, postictal paralysis, complex migraines, such as hemiplegic or ocular migraines, cervical disc disease, transient global amnesia, intracranial lesions, such as subdural hematomas and mass lesions, inner ear disease with vertigo, and metabolic derangement of the serum glucose, sodium, or calcium are the few conditions which commonly mimic the TIA.

There is no gold standard for diagnosing TIA. False-positive diagnostic rates range from 25% to 38%. To improve diagnostic performance, scores have been developed. The most common tool used for TIA risk stratification is ABCD2 score recommended by the American Heart Association (AHA). Admission or discharge of the patient is based on a total score more than or less than 3. However, further studies revealed that patients with ABCD2 less than 3 even detected high levels of carotid stenosis, atrial fibrillation, and other cardiac sources of embolism. Based on these studies, the American College of Emergency Physicians (ACEP) in 2016 recommends that physicians should not rely on the ABCD2 score for discharging the patient directly from the ED.

"Get up and Go" test: Objective measure is to assess the mobility of the patient in which the patient is asked to stand from a seated position, walk a short distance, turn around, walk back, and sit down. It is graded on a five-point scale in which a score of 1 indicates no need for assistance or risk of falling and a score of 5 indicates that the patient fell or almost fell during the test. A score of 3 indicates a risk of falling and should be given if the patient exhibits undue slowness, hesitancy, or stumbling. Although this test has not been validated in this population, the provider needs to perform some functional assessment on patients before selecting the patient for EDOU care. *ED goals*: Early detection and prevention of stroke, detection of alternate causes of TIA/stroke, *ED screening, bedside* dysphagia test, mobility test

These patients should be carefully selected on the basis of criteria given in **Table 14** for managing in OU and a stepwise approach should be followed as shown in **Flowchart 6**.

DIZZINESS/VERTIGO

Dizziness/vertigo is one of the common presenting waxing and waning symptoms in ED, with very broad differential and underlying etiology. It may involve many different organ systems as well as pharmacologic and environmental factors. Dizziness has peripheral, vestibular, or brainstem pathology. Evaluation of neurogenic dizziness focused on two main anatomic regions: (1) The cerebellum (central) or (2) The vestibular system (peripheral). An attempt should be made to determine if the cause is central or peripheral (**Table 15**). Patients with cerebellar dysfunction may present with ataxia or falls, and neurologic examination should include cerebellar and gait testing, whereas those with vestibular dysfunction may present with vertigo, and evaluation peripheral cause of vertigo should include Dix–Hallpike maneuver to test for nystagmus. Many patients may require laboratory testing and imaging.

A complete blood count and chemistry panel will screen for anemia, infection, or electrolyte abnormalities, such as hyponatremia, which can contribute to their symptoms. Consider serum vitamin B12 and folic acid levels in those presenting with ataxia of insidious onset, especially if they are at risk for malnutrition. A noncontrast head CT is indicated as the initial test for patients with a suspected central cause of neurogenic dizziness. This will rule out mass lesions, intracranial hemorrhage, subacute ischemic strokes, or cerebellar atrophy. Patients with vertigo that is clearly the result of a peripheral cause do not need imaging. ED treatment of peripheral causes of vertigo is mainly supportive and can include intravenous (IV) fluids, benzodiazepines, antiemetics, and antihistamines, such as meclizine. The Epley maneuver can resolve benign paroxysmal peripheral vertigo and may be performed by the ED provider or neurology consultant. The EDOU can be considered for continued diagnostic or therapeutic care of ED patients with vertigo (**Table 16**). Ideal patients for the EDOU are those whose symptoms are likely peripheral. Patients with concern for a central process based

TABLE 14: Patient selection for EDOU care—TIA minor stroke.

Exclusion criteria	*Inclusion criteria*	*EDOU intervention*
• Persistent acute neurologic deficit or crescendo TIAs • Disabling stroke (new gait disturbance, unable to perform ADLs, fails dysphagia screen and mobility test) • Nonfocal symptoms—confusion, weakness, seizure, transient global amnesia, depressed mental status • Known extracranial embolic source (history of atrial fibrillation, cardiomyopathy, prosthetic heart valve, mural thrombus, recent myocardial infarction, endocarditis) • Presence of active comorbidities • Poor social support • History of prior large stroke • Positive head CT/MRI • Known carotid stenosis (>50%)	• *Transient ischemic attack (TIA):* Resolved acute deficit • *Nondisabling stroke*: Will not require nursing home or inpatient rehabilitation on discharge • Independent with ADLs • Passes bedside dysphagia screen and mobility test (get up and go) • No high-risk conditions • CT brain negative for hemorrhage/mass lesion (unless prompt MRI planned) • Workup can be completed within 18 h	• Neuro checks every 2 h to detect stroke, crescendo TIA by trained nurses, emergency physicians • Neurology consult to detect occult stroke • Evaluate the size of stroke: MRI brain with and without contrast • Evaluate for embolic sources • MR angiography/CT angiography of head and neck vessels or Doppler of neck vessels • 2D echocardiography • Cardiac monitoring for at least 12 h for paroxysmal atrial fibrillation • Evaluate for contributing factors: Lipid panel, HbA1c level • Antiplatelet therapy: Aspirin ± clopidogrel • Stroke-preventive education (lipids, smoking, diabetes mellitus, hypertension, obesity, alcohol, stroke)

Disposition

Home	**Hospital**
• No recurrent deficits/Improved • Able to do daily routine work • Reassuring testing/negative workup • Clinically stable • Initiated on antiplatelet therapy	• Recurrent symptoms/need for rehabilitation • Evidence vascular disease stenosis of neck vessels • Evidence of embolic source requiring treatment (e.g., heparin/coumadin); for example, mural thrombus, paroxysmal atrial fibrillation • Unable to complete workup or safely discharge patient within the time frame • Physician/neurology judgment

Get up and go test

Score	**Description**
1	Normal: No assistance required; no evidence of falling
2	Very slightly abnormal
3	Mildly abnormal: fall risk; patient exhibited undue slowness, hesitancy, abnormal movements of the trunk or upper limbs, staggering or stumbling
4	Moderately abnormal
5	Severely abnormal: At risk of falling during the test

(ADLs: activities of daily living; HbA1c: glycated hemoglobin; TIA: transient ischemic attack)

Source: Mathias S, Nayak USL, Isaacs B. Balance in elderly patients: the get-up and go test. Arch Phys Med Rehabil 1986;67:387-9.

on history or physical examination should be admitted for further workup.

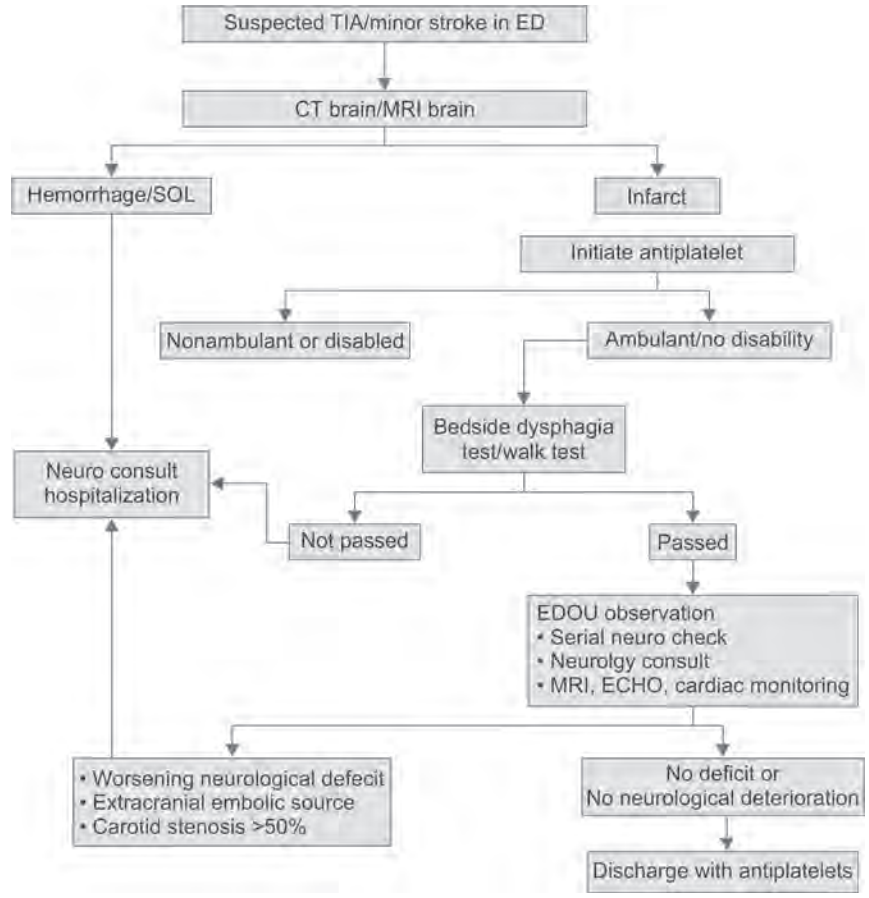
BACK PAIN

Back pain is the most common musculoskeletal complaint in the ED. Most of the patients presenting to the ED will have a benign cause for their back pain. But ED physicians must be aware of life-threatening causes of back pain as well as cases in which neurologic deficit exists while evaluating the patient. ED evaluation should focus on to rule in or rule out high-risk causes of back pain, such as abdominal aortic aneurysm, spinal cord compression, and pain management.

Patients should be assessed for neurologic deficit as well as for possible urinary or fecal incontinence, traumatic etiology, or IV drug use history. A careful examination must be performed to detect weakness and numbness as well as to determine if the weakness is due to pain or if it is a sensory change in a dermatomal distribution. Ancillary tests, such as laboratory tests or imaging, are only performed in patients with red flags on history or physical for malignancy, fracture, infection, or epidural compression syndrome. The goals of EDOU care (**Table 17**) for patients with acute back pain are to treat pain for patients with intractable symptoms in the ED and to obtain advanced neuroimaging for patients at mild to moderate risk for lumbar radiculopathy.

HEADACHE

Headache is also a common complaint in ED. Headache with benign conditions is usually discharged to home following ED treatment. A few patients will require additional



(ADLs: activities of daily living; ECHO: echocardiogram; ED: emergency department; EDOU: emergency department-based observation unit; HbA1c: glycated hemoglobin; SOL: space-occupying lesion; TIA: transient ischemic attack)

FLOWCHART 6: Approach to patients with TIA/stroke.

Treatment	Admission Neuro consult	EDOU management: • IV fluid • Benzodiazepines • Antiemetics • Antihistamines—meclizine • Epley maneuver

(IV: intravenous)

diagnostic and therapeutic interventions, making them ideal EDOU candidates. ED evaluation of patients with headache has two primary goals: (1) To rule out life-threatening causes of headache, such as SAH or meningitis, and (2) to start appropriate therapy. A thorough history and examination will be helpful in narrowing down the differential diagnosis and in giving a better understanding about the characteristics of the current headache, e.g., tension headache or migraine, which can be treated with oral analgesia and discharged after appropriate pain relief is obtained.

Patients who are vomiting or appear in distress may require IV fluids, analgesia, and antiemetics. Noncontrast head CT is not recommended for routine evaluation of patients with an headache but is a recommended initial step to rule out SAH or mass lesion.

There are two groups of patients with headache who may benefit from care in an EDOU (**Table 18**). Each of these conditions requires coordination with ancillary services, specifically neurology, before the initiation of an headache protocol to ensure efficient care. The first group is patients with benign headache who need better pain control and the second is patients in whom there is a concern for idiopathic intracranial hypertension (IIH), previously known as pseudotumor cerebri.

Patients with an established diagnosis of migraines can be chosen for EDOU management or whose current headache is similar to their previous episodes. Patients with fever, neurologic deficits, and other comorbidities should be excluded. EDOU care for patients with tension/migraine consists of continued supportive care, such as a quiet, dark room where they can rest, routine analgesia, and antiemetics. Usual medications are nonsteroidal anti-inflammatory medications (NSAIDs) or steroids. Neurology consultation may be necessary for headache that are difficult to abort, as they can recommend other abortifacient medications, such as valproic acid. Some patients may require further imaging, such as MRI/MRA. Disposition patients whose headache have been aborted and are at their neurologic baseline may be discharged home.

TABLE 16: Selection of patient for observation unit care—dizziness/vertigo.

Inclusion criteria for observation care	*Exclusion criteria*	*Potential interventions in EDOU*
• Likely peripheral vertigo • Normal CT/MRI of brain • Normal cerebellar and cranial nerve examination	• Acute hearing loss, double vision, fixed neurologic deficits • Severe headache, head injury • Hemodynamic instability • High clinical suspicion for central vertigo or stroke	• Symptomatic control • Rule out differential diagnosis—anemia, hyponatremia, B12/folate deficiency, sepsis • MRI and neurology consultation

Disposition	
Home	**Hospital**
• Stable vital signs • Able to ambulate and care for self safely • Able to take oral medications/food	• A positive finding on testing (MRI or laboratory) • Consultant recommendation • Persistent symptoms, inability to ambulate

(EDOU: emergency department-based observation unit)

TABLE 17: Selection of patient for observation unit—back pain.

Inclusion criteria for EDOU care	*Exclusion*	*EDOU intervention*
• Inability to control pain in the emergency department • No known malignancy or injection drug use • No history of trauma • No fracture seen on imaging	• Frequent visits for back pain • Bowel/bladder incontinence or saddle anesthesia • Inability to stand or walk due to neurologic deficit • Fever, suspected discitis, or spinal epidural abscess	• Pain management • MRI or CT to rule out spinal stenosis, malignancy • Frequent reassessment • Neurology or neurosurgery consultation

Disposition	
Home	**Hospital**
• Able to ambulate and care for self • Tolerates oral analgesics	• Worsening neurologic examination • Inability to walk, care for self • Intractable pain • Consultant recommendations • Abnormal imaging • Requires surgical intervention

(EDOU: emergency department-based observation unit)

TABLE 18: Selection of patient for observation unit care—headache.

Inclusion	*Exclusion*	*EDOU interventions*
• Tension headache • History of migraine—similar episodes in past • Drug-related headache • No focal neurologic signs • Normal CT brain scan	• Focal neurologic signs • Meningismus • Elevated intraocular pressure • Abnormal CT scan • Hypertensive emergency • Suspected temporal arteritis • Blocked ventriculoperitoneal shunt • Frequent ED visits	• Serial examinations including vital signs • Neurology checks: Level of alertness, speech, motor function • Analgesics • Neurology/ophthalmology consult as indicated • MRI with MR angiogram/venogram imaging if indicated

Disposition criteria
• Home—pain resolved • No clinical deterioration • The primary goal of ED evaluation of headache is to rule out life-threatening causes such as subarachnoid hemorrhage or meningitis and to begin appropriate therapy

(ED: emergency department; EDOU: emergency department-based observation unit)

TABLE 19: Selection of patient for observation unit care—seizure.

Inclusion criteria for EDOU care	*Exclusion*	*EDOU interventions*
• Known seizure disorder • No active seizure within past 2 h • New-onset seizures with a normal neurology examination, normal brain imaging, normal laboratory values (electrolytes, blood glucose)	• Ongoing seizures or postictal state • Persistent focal neurologic deficit • Suspected meningitis or stroke • Delirium due to other causes • Seizures due to toxic exposure of drugs, hypoxemia • Pregnancy beyond first trimester/eclampsia • New findings on neuroimaging • Cardiac arrhythmias	• Appropriate anticonvulsant therapy • Seizure precautions—position, NPO/oral intake with caution • Cardiac and oximetry monitoring • Serial (every 2–4 h) neurology checks and vital signs • Toxicologic testing as needed • EEG • Neurology consultation

Disposition	
Home	**Hospital**
• No clinical deterioration • Anticonvulsants initiated • Correction of abnormal lab parameters • Resolution of postictal or benzodiazepine-related sedation	• Clinical/neurological deterioration • Identification of other causes of seizure • Recurrent seizures or status epilepticus

(EDOU: emergency department-based observation unit; EEG: electroencephalogram; NPO: nil per oral)

Patients should be admitted if they have a change in their neurologic examination, unrelieved pain, or need further workup [e.g., electroencephalogram (EEG), lumbar puncture].

SEIZURES

Seizures are a common reason for patients to present to the ED. It can be difficult for the emergency physician to determine if the present episode is due to seizure or by conditions that mimic seizures, such as syncope or psychiatric conditions.

The initial ED management of active seizure is ensuring that the seizure has stopped and keeping the patient safe during the postictal period. Patients who receive benzodiazepines from prehospital providers or in the ED need to have their airway and cardiovascular status closely monitored. In patients with no history of seizures, ED workup is indicated. This should include a complete blood count and basic chemistry to screen for infectious or metabolic precipitants for the seizure. In addition, brain imaging should be obtained to rule out structural brain abnormality. For patients with epilepsy, there should still be an attempt to isolate the precipitant for the seizure. This can include infectious or metabolic conditions as well as noncompliance with anticonvulsant medications. Patients whose seizures followed their usual pattern and have returned to their baseline may not need any workup other than determination if drug levels are therapeutic in cases in which levels can be obtained in a timely manner. Patients with evidence of head trauma, fevers, or altered mental status likely need laboratory tests and imaging to ensure that another condition does not exist. Neurology consultation may be helpful for establishing the diagnosis of seizures and in deciding whether to start anticonvulsant medications. Occasionally, patients presenting after a seizure will need further workup or therapeutics beyond their ED visit. The EDOU is an ideal location for patients who need to be loaded with anticonvulsant medications, obtain an MRI or EEG, or have a formal evaluation by a neurologist (**Table 19**).

ASTHMA/CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The Global Initiative for Asthma defines asthma as "a heterogeneous disease, usually characterized by chronic airway inflammation. It is defined by the history of respiratory symptoms such as wheeze, shortness of breath, chest tightness, and cough that vary over time and in intensity, together with variable expiratory airflow limitation." Asthma is one of the most common conditions of all ages managed in an OU. The EDOU is an ideal place for asthma care and COPD care because this gives an extended period of observation of 24 hours (corticosteroids therapy may not reach full effect for up to 6 h), for patient teaching and preventative treatments that may lead to decreased recurrence, admissions, morbidity, and mortality. On the basis of vital signs and physical examination, asthma severity can be classified as mild, moderate, or severe. Patients selected for EDOU are those who have mild-to-moderate asthma and have not improved with initial therapy and hence cannot be discharged to home. Keeping the patient in EDOU under cardiac monitoring and pulse oximetry allows time for full medication effect, and final disposition can be done after repeated clinical assessment (**Table 20**). Various scoring systems are also used to assess the severity such as pediatric asthma severity score, pulmonary index score, and pediatric respiratory assessment measure (respiratory rate, accessory muscle use, decreased breath sounds) score. But no scoring system is a well-accepted and sufficiently validated scoring system. Chest radiograph as part of the workup is performed in the EDOU. Patients and caregivers should be educated about asthma medications, inhaler and peak flow meter use, and smoking cessation because patient education is helpful not only in the management and prevention of asthma but also in reducing the number of revisits.

TABLE 20: Patient selection for EDOU care asthma/chronic obstructive lung disease.

Inclusion criteria	*Exclusion criteria*	*EDOU interventions*
• Alert and oriented with stable vital signs • Intermediate response to β2 agonist nebulizers and steroid therapy in ED—improving but still wheezing • Chest X-ray—no significant acute findings	• Unstable vital signs • Clinically unstable—severe dyspnea, confusion, drowsiness • Poor response to initial ED treatment • Persistent use of accessory muscles, tachypnea (RR > 40), or excessive effort • ABG—respiratory acidosis, requires BiPAP • O_2 saturation < 92% on room air • Suspected acute coronary syndrome, congestive heart failure, or pneumonia • High-risk patient—prior intubation/admission in ICU • Frequent ED visits (>3/years) or hospitalizations (>2/years) • Recent steroid use or steroid dependence • Comorbidities such as cardiovascular disease, chronic lung disease, psychiatric disease	• Serial nebulization—β2 agonist and ipratropium • Systemic steroids • Frequent reassessment (every 2–4 h) of vital signs, response to therapy, and mental status • Pulse oximetry and cardiac monitoring

Discharge criteria	
Home	**Admit**
• Acceptable vital signs: HR < 100, RR < 20 after ambulation • Pulse oximetry > 93% on room air • Resolution of bronchospasm • Discharge on steroids, nebulizers • Follow-up in outpatient care • Smoking cessation counseling	• Progressive deterioration in clinical status or vital signs • Failure to resolve bronchospasm within 15 h • Hypoxic despite therapy

(ABG: arterial blood gases; BiPAP: bilevel positive airway pressure; ED: emergency department; EDOU: emergency department-based observation unit; HR: heart rate; ICU: intensive care unit; RR: respiratory rate)

COMMUNITY-ACQUIRED PNEUMONIA

Pneumonia, an infection of the lung parenchyma caused by bacteria, viruses, and fungi, is commonly seen in the ED. Pneumonia is frequently classified based on the location where it was presumed to have been acquired. Hospital-acquired (nosocomial) pneumonia is diagnosed after a minimum of 48 hours of hospital admission. Ventilator-associated pneumonia is defined by the development of pneumonia >48 hours after endotracheal intubation. Community-acquired pneumonia (CAP) is pneumonia that is neither hospital-acquired (nosocomial) pneumonia nor ventilator-associated pneumonia.

The British Thoracic Society developed the *CURB-65 (confusion, uremia, respiratory rate, BP, age ≥65 years) score*, a validated scoring system that assigns 1 point for the presence of each of the following variables: Confusion, uremia (blood urea nitrogen ≥ 19 mg/dL), respiratory rate ≥ 30 breaths per minute, blood pressure (systolic < 90 mm Hg or diastolic ≤ 60 mm Hg), and age 65 years or older. Patients with a score of 0 and 1 are low risk and have low mortality rates (0.6% and 2.7%, respectively).

The *SCAP (severe community acquired pneumonia) score* was developed in 2006 in an effort to develop a clinical prediction rule that could be calculated easily using only variables readily available in the ED. This system assigns various points for major (arterial pH < 7.3, systolic blood pressure <90 mm Hg) and minor [confusion, uremia (blood urea nitrogen > 30), respiratory rate > 30 breaths per minute, chest radiography (bilateral or multifocal infiltrates), PaO_2 < 54 mm Hg or PaO_2/FiO_2 < 250, age ≥80 years] variables and risk stratifies patients into low-, medium-, and high-risk groups. One drawback to this score is the use of arterial pH, which is not always measured.

In a prospective validation study of the three scoring systems—(1) PSI, (2) CURB-65, and (3) SCAP—patients considered low risk by all three had similar low risks of mortality. These scoring systems may underestimate illness severity, which should be taken into consideration when making disposition decisions. The ACEP's CAP clinical policy recommends the use of scoring systems in decisions for disposition.

The use of EDOU-specific protocols for the treatment of CAP ensures appropriate and timely administration of antibiotics and timely recognition of potential patient deterioration (**Table 21**). CAP protocols have been associated with improved overall quality. Management of CAP patients in the EDOU includes regular monitoring of vital signs with the assessment of pulse oximetry, respiratory status, and mentation. The patient should be reassessed serially for the need for parenteral antibiotics, IV fluids, and other potential interventions. Respiratory care may include suctioning of secretions with isolation measures. The patient should be counseled for smoking cessation.

INFECTIONS

An emergency physician commonly deals with infectious conditions in the ED. Managing infectious diseases in ED is very challenging with the emergence and spread of drug-resistant organisms, especially community-acquired

TABLE 21: Patient selection for EDOU care pneumonia.

Inclusion	*Exclusion (All features suggestive of Severe CAP)*	*Potential interventions*
• Pneumonia on chest radiograph or on CT scan or on clinical presentation • CURB-65 score 2–3 • Stable vital signs • Pulse oximetry > 90% on room air • Normal mental status	• Respiratory failure requiring positive-pressure ventilation • Severe respiratory distress—respiratory rate > 40, use of accessory muscles, severe intercostal retractions, cyanosis • Altered mental status—new-onset • Pulse oximetry < 90% on room air • Unstable vital signs • CURB-65 score of 4 or 5	• Serial vital signs, pulse oximetry • Serial clinical examinations—respiratory rate, use of accessory muscles, retractions, wheeze on auscultation, mental status assessment • Give supplemental oxygen • Initiate antibiotic therapy
CURB-65 score—1 point for the presence of each [confusion, uremia, respiratory rate > 30/min, blood pressure (systolic < 90 mm Hg or diastolic < 60 mm Hg)/age > 65 years]		
Discharge criteria		
Home: • Significant clinical improvement • Acceptable, stable vital signs • Pulse oximetry > 90% on room air • Able to tolerate oral intake and oral medications	*Admit:* • Deteriorating clinical condition: Worsening vital signs, alteration of mental status, respiratory distress, or respiratory failure • Hypoxia pulse oximetry < 90% on room air	
Antibiotic therapy for community-acquired pneumonia		
Outpatient treatment Previously healthy—macrolide, doxycycline Comorbidities: • Respiratory fluoroquinolone/β-lactam + macrolide/ amoxicillin-clavulanate • Ceftriaxone, cefpodoxime, cefuroxime + doxycycline/ macrolide Select an alternative antibiotic from a different antimicrobial drug class if antibiotic used within the prior 3 months	*Inpatient treatment* Non-ICU treatment—respiratory fluoroquinolone/β-lactam + macrolide/ doxycycline Preferred β-lactam agents—cefotaxime, ceftriaxone, ampicillin	

(CAP: community-acquired pneumonia; CURB-65: confusion, uremia, respiratory rate, BP, age ≥ 65 years; ICU: intensive care unit)

methicillin-resistant *staphylococcus aureus* (CA-MRSA). A recent challenge for the emergency physician is pandemic infection such as severe acute respiratory syndrome-2 (SARS CoV-2) or Covid-19 The choice of antibiotics and their response is not very straightforward and patient needs more time to stay in the ED (**Table 22**). So, OU in ED is a safe area for monitoring a patient with infection (**Flowchart 7**).

ACUTE TRAUMATIC CONDITIONS

Emergency department-based observation units are always used to manage trauma patients of various grades of severity which also reduce the hospital overcrowding and improve the outcome also. Various studies are also supportive for use of EDOU for all types of trauma. Trauma code trauma protocols are used to investigate and treat the patient in the OU, which is considered as a safe, cost-effective alternative to routine inpatient admission for the short-term management of injured patients (**Table 23**).

METABOLIC AND ENDOCRINE CONDITIONS

An observation unit is ideal for the care of many metabolic conditions, such as hypokalemia hyperkalemia, hyponatremia, hypoglycemia (**Table 24**), and hyperglycemia (**Table 25**). Electrolyte abnormality conditions can be best managed by therapeutic protocols with little or no diagnostic uncertainty. The care in the unit is often straightforward (**Box 3**). Carefully selected patients are included for OU care with the minor manifestation of their chronic condition.

ADDITIONAL CLINICAL CONDITIONS

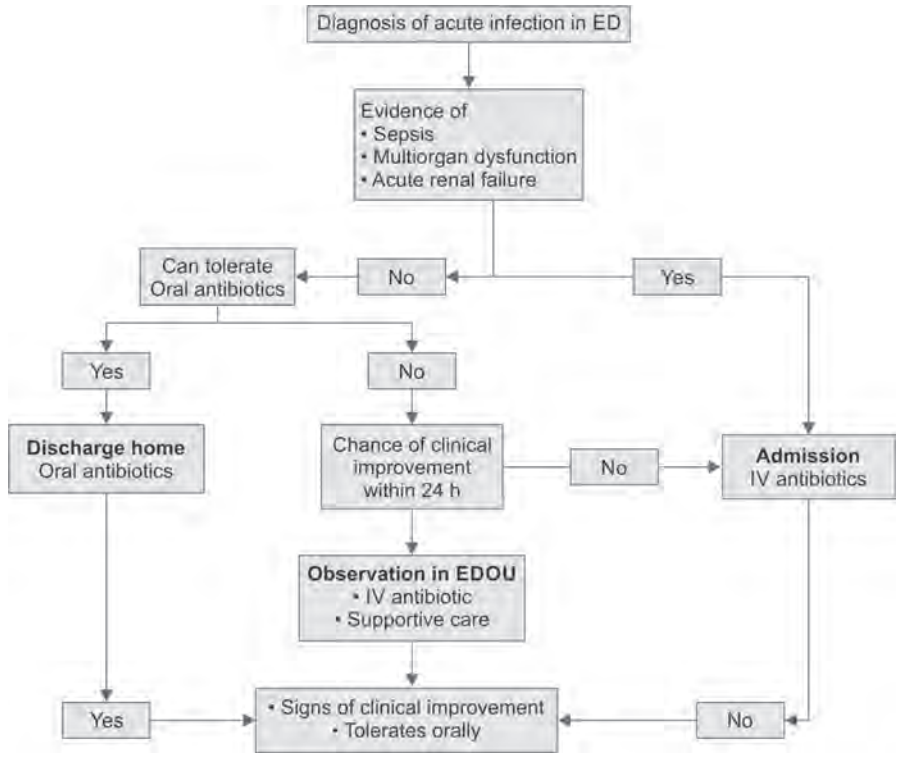
There are many conditions that do not fit into larger protocols that can be managed in the EDOU. The condition that complies with the definition of medical observation where the patient is 70–80% likely to be discharged in 15–18 hours is appropriate, e.g., abnormal uterine bleeding (**Table 26**), allergic reaction (**Table 27**), alcohol intoxication (**Table 28**).

TABLE 22: Management of infections in EDOU.

Infection	*Preferred antibiotic therapy*	*Nonpharmacological interventions*
Skin and soft-tissue infections		
Purulent infection Mild-to-moderate	Oral clindamycin, doxycycline	• Culture and sensitivity • I&D of abscess • Limb elevation
Severe	Intravenous vancomycin, linezolid	
Nonpurulent infection Mild-to-moderate	Oral cephalosporin, dicloxacillin, clindamycin	• Limb elevation
Severe	Intravenous cefazolin, clindamycin, oxacillin	
Hand and foot infections		
Superficial	Oral clindamycin, TMP-SMX	
Deep infections, necrotizing fasciitis	Intravenous vancomycin, piperacillin-tazobactam	• Surgical debridement • Splinting • Elevation
Animal bite wounds	Oral amoxicillin/clavulanate, IV ampicillin/sulbactam	• Irrigation • Vaccination
Peritonsillar abscess	*Intravenous:* • Ampicillin/sulbactam 3 g 6th hourly or • Clindamycin 900 mg 8th hourly • Oral • Amoxicillin/clavulanate 875 BD or • Clindamycin 300 mg 4 times/day	CT/oral US, ENT consult Needle drainage of abscess Look for complications: • Airway obstruction • Aspiration pneumonia • Septicemia • IJV thrombosis and thrombophlebitis • Carotid artery rupture and pseudoaneurysm • Mediastinitis • Necrotizing fasciitis
Pelvic inflammatory disease	Single-dose IM ceftriaxone or 3rd generation cephalosporin + oral doxycycline 100 mg BD ± metronidazole 500 mg BD for 2 weeks	• Pregnancy test • Radiological imaging with US/CT to rule out complications/peritonitis • Gynecology consult • Consider serologic testing for human immunodeficiency virus (HIV) and NAATs for gonorrhoeae/ trachomatis infection • STI counseling
Acute pyelonephritis	*Intravenous:* • Ciprofloxacin 400 mg BD • Levofloxacin 70 mg OD • Ampicillin/sulbactam 3 g 6th hourly • Piperacillin/tazobactam 4.5 g 8th hourly • Oral (for 1 week) • Ciprofloxacin 500 mg BD • Levofloxacin 750 mg OD	• Urinalysis and urine culture sensitivity before initiating antibiotics • Radiological imaging with CT/renal US in case of: ○ Immunosuppression ○ Persistent symptoms ○ Recurrent infections ○ Sepsis ○ Diabetes ○ Prior urogenital surgery
Suspected ESBL UTI	• IV meropenem 500 mg 8th hourly	

Disposition from EDOU	
Home • Clinical stable and improved • Able to take/tolerate the oral antibiotic	**Hospitalization** • Inability to take oral medication • Severe sepsis—hypotension, increased lactates, organ failure • No improvement/worsening of clinical condition • Inconclusive diagnostic workup • Need for surgical intervention • Presence of comorbidities/complications

(CAP: community-acquired pneumonia; CURB-65: confusion, uremia, respiratory rate, BP, age ≥ 65 years; ICU: intensive care unit)



(ED: emergency department; EDOU: emergency department-based observation unit)

FLOWCHART 7: Management of infection in observation unit.

TABLE 23: Managing trauma in observation unit.

Conditions	***Criteria for observation***	***EDOU management***
Mild traumatic brain injury	Neurologically intact with CT brain finding of: • Solitary contusion < 5 mm diameter • Localized subarachnoid hemorrhage < 1 mm thick • Isolated pneumocephaly • Closed depressed outer table skull fracture Anticoagulated patient with normal CT	Analgesics Neurological observation Neurosurgeon consult
Traumatic orthopedic conditions	Nonoperative orthopedic trauma and extremity fractures	Pain control Bracing
Compartment syndrome	Young men with fractures of: • Tibial diaphysis • Forearm diaphysis • Distal radius	Observe for development of compartment syndrome Emergent fasciotomy SOS
Trauma in pregnant patients	>20 weeks' gestation	Cardiotocographic monitoring (CTG) for 6 h
	High-risk conditions: • Uterine tenderness • Significant abdominal pain • Vaginal bleeding • Frequent contraction more than once per 10 minutes • Rupture of membranes • Fetal tachycardia, bradycardia • High-risk mechanism of injury	CTG for 24 h Obstetrics consultation
Other traumas	Rhabdomyolysis Rib fractures Abdominal contusions Minor burns Soft-tissue injuries	Pain management Hemodynamic monitoring Trauma surgeon consult

TABLE 24: Selection of patient for observation unit care—hypoglycemia.

Exclusion criteria for EDOU Care	*Management in OU*	*Disposition*
• Hypoglycemia secondary to drug overdosage as part of attempt at self-harm • Inability to tolerate oral intake • Blood glucose < 80 mg/dL after initial ED treatment • Underlying serious etiology • Nondiabetic	• Adequate dietary intake and hydration • Serial clinical examinations • Bedside glucose measurement 2nd hourly • Diabetic education	• Discharge • Resolution of symptoms • Bedside glucose > 80 mg/dL • Resolution of precipitating factor • Arrange follow-up with physician • Admission • Deterioration of clinical signs • Persistent neurological deficit • Bedside glucose consistently <80 mg/dL

(ED: emergency department; EDOU: emergency department-based observation unit; OU: observation unit)

TABLE 25: Selection of patient for observation unit care—hyperglycemia.

Inclusion	*Exclusion*	*Management in OU*
• Blood sugar > 300 mg/dL and <600 mg/dL after ED treatment • Normal pH and CO_2 level • Readily treatable cause (e.g., noncompliance, urinary tract infection, abscess)	• New-onset hyperglycemia • Diabetic ketoacidosis • Altered mental status	• IV hydration crystalloids at 150–250 mL/h • Bedside glucose monitoring 2nd hourly • Sliding-scale insulin • Treat precipitating causes • Diabetic counseling

Disposition

Home	**Admit**
• Blood glucose < 250 mg/dL • Symptoms resolved • Normal vital signs • Tolerating oral fluids • Primary care follow-up in 48 h • Patient education provided	• Worsening symptoms • Development of diabetic ketoacidosis or hyperosmolar hyperglycemic state • Inability to tolerate oral fluids

(ED: emergency department; OU: observation unit)

BOX 3: Selection of patient for observation unit care—electrolyte abnormalities.

- Minor electrolyte abnormalities with stable vitals and without any clinical complication can be corrected safely in EDOU
- Exclusion criteria for EDOU care
- Unstable vital signs of cardiovascular compromise
- Mental status changes
- Associated causes requiring long-term treatment
- Hyperkalemia level > 5.0 mEq/L with ECG changes
- Hypokalemia level < 2.5 mEq/L or >2.5 mEq/L with ventricular ectopy
- Hyponatremia level > 120 mEq/L with abnormal mentation <120 mEq/L SIADH
- Hypernatremia level >155 mEq/L, <155 mEq/L with altered mental status
- Hypercalcemia level >7.0 mEq/L (ionized calcium
- Hypocalcemia level <1.0 mEq/L (ionized calcium)
- Hypomagnesemia level <2.0 mEq/L associated with electrolyte abnormalities
- >2 acute electrolyte disturbances

(EDOU: emergency department-based observation unit; SIADH: syndrome of inappropriate antidiuretic hormone secretion)

TABLE 26: Patient selection for EDOU management—abnormal uterine bleeding.

Exclusion criteria	*EDOU intervention*	*Disposition*
• Hemodynamically unstable • Pregnant • Coagulopathy • Suspected malignancy • Heavy active bleeding • Needs >2 units PRBCs (Hb < 5 g/dL)	• Blood transfusion • Pain control • Gynecology evaluation • Initiation of hormone therapy • Pelvic ultrasound/imaging in new patients to investigate the cause of bleeding	• Home • Stable vital signs • Post-transfusion • Hemoglobin > 8 g/dL • Asymptomatic on exertion • Advise—gynecology follow-up • Hospital • Persistent heavy bleeding • Unstable vital signs • Orthostatic • Requires inpatient procedures

(EDOU: emergency department-based observation unit; PRBCs: packed red blood cells)

TABLE 27: Patient selection for EDOU management—allergic reaction.

Inclusion	*Exclusion*	*EDOU intervention*
• Erythroderma, urticaria, or angioedema not involving the airway • Stable and improved in ED for 2 h after treatment	• Hypotension (systolic blood pressure < 100 mm Hg) • Tachycardia > 110 bpm • SaO_2 < 94% on room air • Suspicion of acute coronary syndrome • Airway involvement—stridor, respiratory distress, hoarseness • Intravenous vasopressors required	• Symptomatic management: Antihistamines, corticosteroids, IV fluids • Periodic assessment for the evolution of rash, airway involvement, wheezing or hemodynamic compromised

Disposition	
Home	**Hospital**
• Improvement or resolution of symptoms • Stable vital signs • Advice—follow-up with allergist	• Progression of symptoms • Persistent/recurrent symptom • Airway involvement • New-onset hypotension • Epinephrine infusion required

TABLE 28: Patient selection for EDOU management—alcohol intoxication.

Alcohol intoxication believed to take 8 h or greater to resolve

Exclusion criteria	*EDOU interventions*	*Disposition*
• Signs/symptoms of alcohol withdrawal • Combative/delirious patients • Requires chemical sedation/restraints • Traumatic brain injury • Metabolic derangements such as alcoholic ketoacidosis • Polyingestion • Active comorbid condition	• IV or oral hydration as needed • Alcohol cessation education • Monitor for signs and symptoms of withdrawal	• Home • Clinically sober: Alert and oriented, able to ambulate unassisted and without difficulty • Stable vital signs • Hospital • Failure to achieve sobriety in 15–18 h • Development of signs and symptoms of withdrawal

SUMMARY

Over the past 50 years the history of observation medicine parallels the rise of emergency medicine to meet the needs of patients, EDs, hospitals, and the healthcare system. Protocol-driven observation units are best managed using basic principles. Observation patients need protocol-driven observation units, as in ED. Just like ED which becomes the safety net of the health system, observation units have become the safety net of ED—preventing inappropriate discharges or admissions while improving healthcare resource utilization. Observation medicine research evolved over the last one decade along with innovations in healthcare. Observation medicine research will continue to refine and improve this well-established

service to the benefit of ED patients and their health care system. Observation units have consistently proved to provide better outcomes than traditional care for selected patients. The growth of observation medicine has been driven by innovations in healthcare, ongoing shift of patients from inpatient to outpatient settings, and changes in health policy. To fully understand observation medicine, it is important to understand observation services payment policy, history, and ramifications.

Triaging

5
CHAPTER

Devendra Richhariya

INTRODUCTION

Triage is derived from the French word "*trier*" which means to sort out or to pick. This process was used in 18th-century Napoleonic wars where injured are removed rapidly from the battlefield to safe places for care. This process has become more refined and is used in the established healthcare setting. In modern medicine, this system is known as the triaging system. Nowadays, triaging area and triage process are important functions in the modern emergency department. The emergency department is a place where many patients may present simultaneously and the available resources become inadequate to provide quality care. Thus, it is both clinically and ethically important to identify those patients who need the most urgent emergency care. Mass casualty incident triaging has also evolved to achieve maximum good for the maximum number of patients.

EMERGENCY DEPARTMENT TRIAGING

With increasing awareness among the public about emergency care, the number of patients visiting the emergency department is increasing day by day. Various triaging strategies are used in the emergency department for clinical service development, patient safety, and clinical risk management. The purpose of the triage system is to deliver quality health services across the population rather than administrative or organizational compulsion.

REQUIREMENT FOR TRIAGING

- The triaging area must be easily approachable, well illuminated, and clearly signposted.
- All patients should enter through a single entry point so that they all go through a similar process.
- A special area for examination of the patient and privacy should be maintained.
- An appropriate communication system between entrance and triage area
- Emergency lifesaving equipment
- Universal protective facilities, e.g., hand washing and gloves
- Strategies to protect staff
- Trauma victim should be prioritized in a specific area.
- Document for recording the triage information
- The level of urgency must be noted at the entry point of the emergency department.
- Triaging should be based on clinical condition only and should not be influenced by any other factors.
- The primary triaging task consists of chief complaints and assessment of urgency.
- The secondary triaging task consists of diagnostic investigations, emergency care, and disposition.
- There should be a well-organized processing system from triage point to disposition.

TRIAGING SCALES

Various triaging scales (**Table 1**) are being used internationally. These include five-tier, four-tier, and three-tier scales. Five-tier triage (**Table 2**) scales are more reliable, valid, and internationally accepted. The valid and reliable scale should have the following characteristics:

- It should be easy to understand and simple to apply by emergency nurses and doctors.
- It should measure clinical urgency.
- The triage scale must be sensitive enough to register clinical urgency with accuracy.

TABLE 1: Types of triage scales.

Five-tier triage scales	*Four-tier triage scales*	*Three-tier scales*
• Australasian triage scale • Manchester triage scale • Canadian triage scale • Emergency severity index • Cape triage score	Hong Kong four-level field triage system	• Simple triaging and rapid treatment (START) • Field triaging, mass casualty triaging

TABLE 2: Five-tier triage scales.

Triage scale	*Level*	*Time to attend by the physician (min)*	*Color coding*
Australasian triage scale	1. Resuscitation 2. Emergency 3. Urgent 4. Semiurgent 5. Nonurgent	0 10 30 60 120	Red Orange Green Blue White
Manchester triage scale	1. Immediate 2. Very urgent 3. Urgent 4. Standard 5. Nonurgent	0 10 60 120 240	1. Red 2. Orange 3. Yellow 4. Green 5. Blue
Canadian triage scale	1. Resuscitation 2. Emergent 3. Urgent 4. Less urgent 5. Nonurgent	0 15 30 60 120	None

TABLE 3: Problems occurring during gestational age.

<20 weeks	*>20 weeks*	*Postnatal problems*
• Vaginal bleeding (common cause of miscarriage) • Abdominal pain (ruptured ectopic pregnancy, torsion, or ruptured cysts) • Domestic violence common in pregnancy	• Antepartum hemorrhage • Preeclampsia • Preterm rupture of membranes and labor	• Postpartum hemorrhage • Puerperal sepsis • Wound infection • Mastitis • Eclampsia • Postpartum cardiomyopathy • Postpartum psychosis

TRIAGING PROCESS

Assessment of Patient

All patients coming to the emergency department should be triaged on arrival by a trained nurse or physician. Diagnosis-making should not be the priority. Vitals measurement should be done to estimate the urgency. Other parameters that should be noted for estimation of urgency are general appearance, chief complaints, and physiological observation. Standing orders should be followed by the treatment nurse and immediate care needs should be fulfilled. As per the hospital protocol, initiate appropriate investigations and treatment.

Triage assessment should be completed within 3–5 minutes. Details that need to be documented in the patient assessment notes are: Patient name, age, sex, date and time of assessment, name of triage nurse and doctor, chief complaints, relevant history, relevant assessment findings (appearance of patient, airway breathing circulation disability), vital signs and random blood sugar, initial triage category, assessment of alertness [Glasgow Coma Scale/alert, verbal, painful, unresponsiveness (GCS/AVPU scale)], assessment of pain (various pain scale implementation), initiation of any treatment measures, care plan and discharge plan if the patient is discharged from emergency. Retriaging should be done if any vital parameter changes. A trauma record sheet should be used in the trauma patient. Other considerations such as pediatric age group, elderly group, and high-risk features (comorbidities, poisoning, severe pain, rashes) history of violence medicolegal cases, should also be considered in triaging.

Triaging in Pediatric Age Group

Children are usually uncooperative during the examination and give poor history, so it is very important to recognize markers of serious illness. Useful signs are drowsiness, hypotonia, respiratory grunt, wheeze, crepitation, stridor tachypnea, pallor, fever, signs of dehydration, abnormal posture, cold periphery, vomit or less urination, convulsion, and tender abdomen.

Assessment of Pain in Triage

Pain is one of the most common symptoms for which people visit to emergency and pain influences the triage category. Pain description and pain assessment should be included in triage assessment as the physiological and behavioral indicators. Description about factors influencing the pain, various pain assessment scales, and pain management strategies should be included in the triage document. Pain assessment should include location, intensity, time of onset, duration of pain, and aggravating and relieving factors. Heart rate, respiratory rate, blood pressure, facial expression, and body language should also be noted during pain assessment. Various pain scales used in triage setting are *verbal pain score, visual analog scale, numerical rating scale, Wong–Baker FACES rating scale, and Abbey pain scale.*

Triaging and Medicolegal Issues

Following documentation are required to fulfill the medico-legal requirements such as patient name, age, sex, address, name of accompanying person, date, time, and place of the event. Name of examining physician, documentation of injuries, details of clinical management are also required. It is the legal responsibility of a doctor to report the incident to relevant authorities and jurisdiction and also to preserve the forensic evidence (in case of poisoning, assault, rape).

Triage and Pregnancy

Pregnant women are at an increased risk of various conditions and may present with a variety of serious situations (**Table 3**). Triage nurses and physicians should be aware of normal physiological and adaptive changes during pregnancy. Pregnant women may present with any disease in the emergency department. Cerebral hemorrhage, cerebral thrombosis, severe pneumonia, venous thrombosis, and embolus pyelonephritis are more common in pregnant women than in nonpregnant women of childbearing age. Triaging should focus on the well-being of the mother and fetus.

BENEFITS OF TRIAGING

Life-threatening, limb-threatening, and time-critical emergencies (such as stroke and myocardial infarction) are treated on a priority basis. Triaging [early warning score (EWS)] is helpful in identifying the patient who is at a greater risk. Triaging improves the patient flow and patient satisfaction and decreases the overall length of hospital stay.

EARLY WARNING SCORE

In many triage systems, various warning scales are used to identify the patients who are at risk of clinical deterioration and who need hospitalization, so these warning scales are beneficial for quality improvement. EWS is based on vital signs: Respiratory rate, heart rate, blood pressure temperature, oxygen saturation, and level of consciousness [alert verbal painful unresponsiveness (AVPU)]. Various warning scores are developed according to the need, e.g., modified early warning score (MEWS), triage early warning score (TEWS), modified pediatric early warning score (MPEWS), and modified early obstetrics warning score (MEOWS). EWSs are an important tool for appropriate risk management and are also helpful in improving the safety and quality of a patient in the emergency department. Measurement of physiologic parameters and early recognition of warning signs and timely action would add value to patient care in the emergency department and can lead to improved quality of care and decreased morbidity and mortality.

Modified Early Warning Score and Triage Early Warning Score

Modified early warning score is based on blood pressure, heart rate, respiration, oxygen saturation, and alertness. In some triage scales, urine output and pain score are also taken into consideration. The patient's clinical deterioration can be anticipated by this score and the requirement of hospitalization can also be assessed. The MEWS score uses basic equipment and simple parameters, so it is easy to use by junior-most staff also. MEWS is useful for triaging of medical emergencies but not for trauma patient triaging. MEWS score >5 is considered as risk of clinical deterioration and need of hospitalization. The components and scoring of MEWS and TWES are described in **Tables 4** and **5**, respectively.

TRIAGE IN MASS CASUALTY INCIDENT

In a mass casualty situation, the number of patients and their severity are much more than the existing capability for management. Triage is the most important part of any disaster

TABLE 4: Modified early warning score (MEWS).

Vital signs	***3***	***2***	***1***	***0***	***1***	***2***	***3***
Systolic BP	<70	71–80	81–100			>200	
Heart rate		<40	41–50	51–100	101–110	111–129	>130
Respiratory rate		<9		9–14	15–20	21–29	>30
Temperature		<35		35–38.4		>38.5	
AVPU				Alert	React to voice	React to pain	No response
In some triaging systems, urine output and pain sore are also added in the early warning score.							

(AVPU: alert, verbal, painful, unresponsiveness)

TABLE 5: Triage early warning score (TEWS).

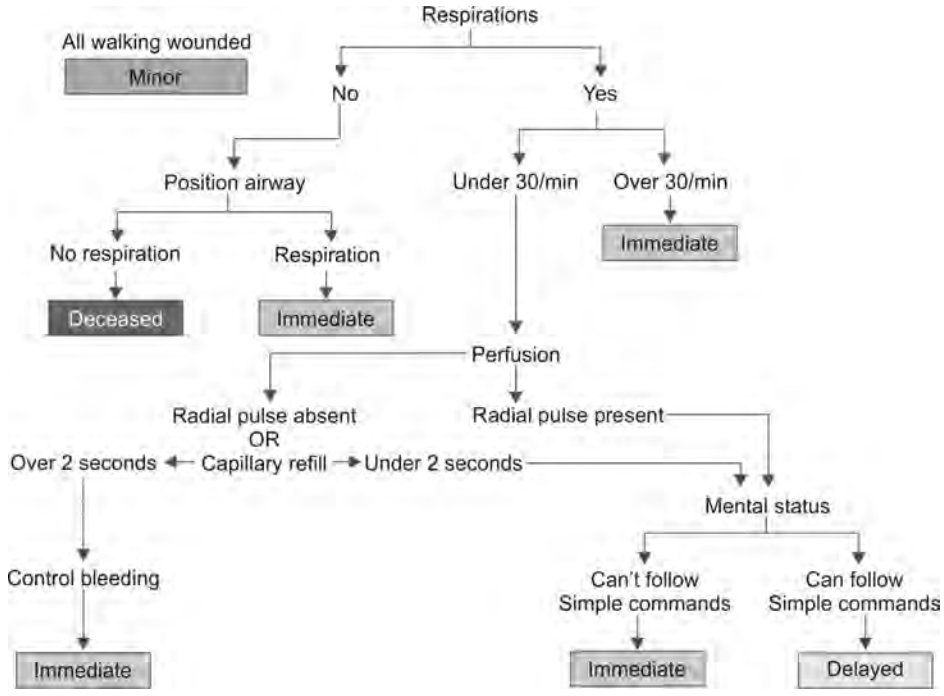
Parameters	***3***	***2***	***1***	***0***	***1***	***2***	***3***
Mobility				Walking	With help	Immobile	
Respiratory rate		<9		9–14	15-–20	21–29	>29
Heart rate		<40	41–50	51–100	101–110	111–129	>129
Systolic BP	<70	71–80	81–100	101–199		>199	
Temperature		<35		35–38.4		>38.5	
AVPU				Alert	React to voice	React to pain	No response
Trauma				No	Yes		
Correlating the triage early warning score with color code triaging							
Color	Red	Orange	Yellow	Green	Blue		
TEWS	7 or more	5–6	3–4	0–2			

(AVPU: alert, verbal, painful, unresponsiveness)

response. The main objective of mass casualty/disaster triage is to do the maximum help to the maximum number of people. Major incidents which cause mass casualties are road traffic accident, building collapse, earthquake, flood, major fire, train derailment, explosion, air crash, terrorist attack, and hazardous material release. The main objectives of triaging in disaster and mass casualty are to decompress the disaster area, to give the best care to the most critical casualty, and to provide special care for burn and crush injuries. In this critical situation, a simple triaging format [simple triaging and rapid treatment (START; **Flowchart 1**) and sort, assess, lifesaving interventions, treatment/transport (SALT; **Flowchart 2**)] should be used.

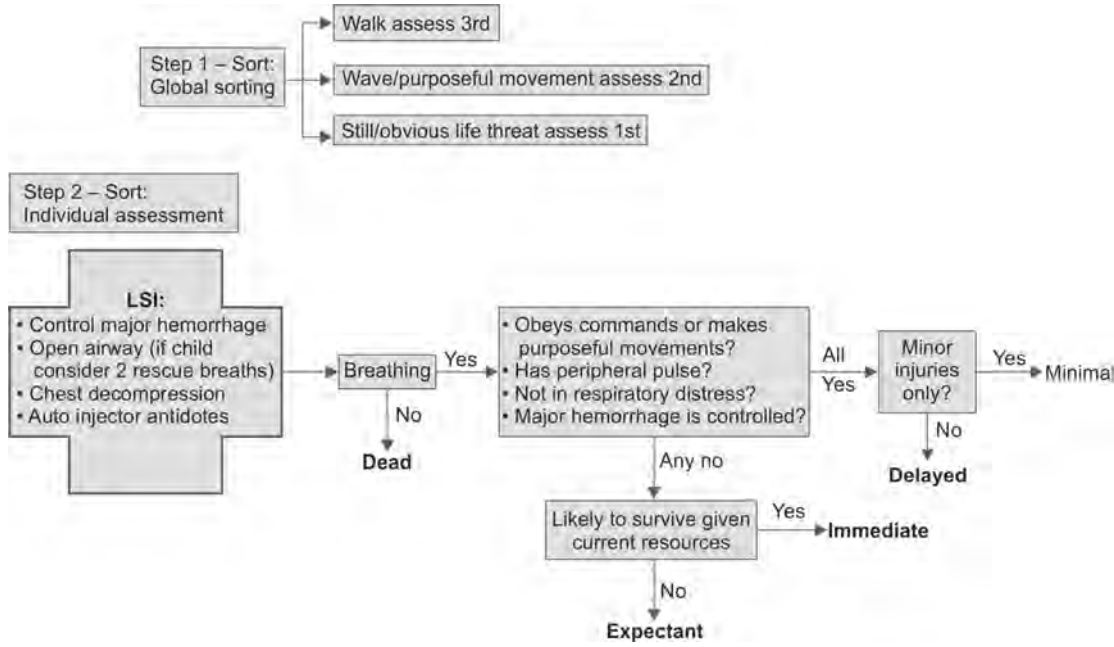
SUMMARY

Triaging is an essential first step in an efficient and effective emergency department. The use of a comprehensive triage tool along with the EWSs will help to save lives and reduce the mortality.



(START: simple triaging and rapid treatment)

FLOWCHART 1: START triaging (based on respiration, perfusion, mental status assessment).



(LSI: lifesaving interventions; SALT: sort, assess, lifesaving interventions, treatment/transport)

FLOWCHART 2: SALT triaging.

Rapid Assessment and Early Treatment

6
CHAPTER

Devendra Richhariya

INTRODUCTION

The emergency department has a challenging working environment; most of the patients present with acute illness, severe pain, and are in great discomfort and often these patients do not get appropriate privacy and empathy that they deserve. The emergency department system is not uniform across the country so different triaging scales are used by various emergency departments for assessing the severity of illness. The patient presents to emergency with a wide variety of complaints such as simple fever pain to severe sepsis shock, polytrauma stroke, exacerbation of asthma, and chronic obstructive lung disease and also as mass casualties. Various assessment tools such as the ABCDE (such as airway, breathing, circulation, disability, exposure) approach, START (simple triaging and rapid treatment for disaster), and various triage methods are based on time, thus making the patient wait according to categories and leading to delay in treatment and increase in errors, and expenditure of unnecessary tests. Since different disease presentations in emergency have different requirements so the superior method should be applied in which care plan (including investigation, treatment chart, admission requirement, and referral) is initiated only by an experienced qualified emergency team and instructions are followed by the rest of the team. Rapid assessment and treatment of a patient by an "experienced and qualified team" in emergency increases the patient safety and satisfaction as well as improves patient flow and also solves the problem of emergency department overcrowding.

BENEFITS OF RAPID ASSESSMENT

- Risk stratification can be done to identify patients for resuscitation.
- Early transfer to high dependency unit or ward; thus clinical risks are minimized
- Patient safety quality and outcome improve.
- Reduces overcrowding
- Provides a learning experience for junior doctors

STEPS FOR RAPID ASSESSMENT AND EARLY TREATMENT

A dedicated team consists of a senior doctor consultant, attending consultant, qualified nurse, social worker, and general duty attendant for this task. The team lead by a senior doctor attends the patient.

All patients are changed into gowns on arrival and given identification bands. A brief history (allergy history) and examination and documentation of management plan are given. Assessment and resuscitation of the patient as soon as he/she arrives in the emergency should be done by a senior doctor and nurse. On the basis of presenting complaints, investigations are decided. Point-of-care testing such as blood sugar, arterial blood gas analysis, and D-dimer is used. Medications are prescribed and delivered as per guidance. Necessary referral should be taken from the specialty if required. On-medical needs should be assessed by a social worker. The patient should be admitted or discharged on the basis of comprehensive assessment. The manager should arrange the bed and manage patient flow. The steps in rapid assessment and early treatment are summarized in **Figure 1**.

Initial Assessment and Resuscitation

Resuscitation should be started within minutes of the arrival of the patient. Assessment should start by acknowledging the patient by his name and by shake hands with the patient. This provides a lot of clinical information such as level of consciousness (LOC), airway patency, and peripheral perfusion of the patient and also provides confidence to the patient and attendant. Focused history and history of examination and investigations from the patient and attendant should be obtained.

Assessment of Airway

Complete airway obstruction leads to death within minutes, but partial airway obstruction is quite common and can be recognized by noisy breathing such as snoring or gurgling

FIG. 1: Summary of steps in rapid assessment and early treatment.

which causes reduced LOC (due to reduced airway muscular tone, loss of protective airway reflexes, principally the gag and cough reflexes, retention of oropharyngeal secretions, and tongue malposition). LOC can be rapidly assessed using the AVPU (i.e., alert, responds to voice, responds to pain, unresponsive) method. If the patient can talk, then it usually implies that the airway is safe. Simple maneuvers, such as jaw thrust or a chin lift, can relieve the partially obstructed airway. Airway adjuncts such as oropharyngeal or nasopharyngeal devices can also be useful.

Assessment of Breathing

Increased respiratory work is commonly associated with the severity of illness as a result of an increased metabolic rate and oxygen consumption. This may lead to respiratory distress, signs of which include: Inability to complete sentences, high respiratory rate, diaphoresis, accessory muscle use, and cyanosis. Focused clinical examination including tracheal palpation, percussion, and auscultation may pinpoint the diagnosis (tracheal deviation—tension pneumothorax, hyper-resonance—tension pneumothorax, dull percussion note—pleural effusion/empyema, wheeze, silent chest—acute severe asthma, left ventricular failure, diminished or bronchial breath sounds—pneumonia). High-flow oxygen should be administered to all acutely ill patients. The effects of therapy should be assessed using pulse oximetry and the target oxygen saturations should be 94–98%. An appropriate oxygen delivery device to use is a mask with a reservoir bag. It is vital that the reservoir be kept inflated at all times. This is usually achieved by setting the flow rate of oxygen to 15 L/min. This mask will usually deliver an inspired oxygen concentration (FiO_2) of 60–85%.

Assessment of Circulation

Assess the radial pulse, rate, rhythm, and character. Attach a cardiac monitor and note the blood pressure. Clinical signs that are common to hypovolemic, obstructive, and cardiogenic shockinclude: Confusion or agitation, cold extremities, reduced capillary refill, tachycardia, absent or small volume peripheral pulses, hypotension, and oliguria. The jugular venous pulse assessment is useful in distinguishing between hypovolemic states (low) and cardiogenic or obstructive shock (elevated). Circulatory features of septic shock include warm peripheries (vasodilatation) and a bounding pulse. Except for cardiogenic shock, complicated by pulmonary edema, the management of shock patients requires the administration of intravenous fluid. The peripheral cannula can usually be inserted into antecubital fossa or external jugular veins and central lines can be inserted into the internal jugular, subclavian, and femoral veins. The sizes of the peripheral cannula are determined by gauge (16 largest to 26 smallest). Two 16-gauge lines are recommended for resuscitation.

Assessment of Disability

Assessment of neurological status and relevant clinical examination would include level of consciousness, focal and localizing neurological signs, pupillary reflexes, and signs of meningism. Rapid assessment is done using the AVPU method.

Pain Management and Assessment of Patient Needs

Pain management is an important aspect in the emergency department and is described in Chapter 53 while assessment of the nonmedical needs of the patient is equally important and involvement of a social worker is helpful.

Investigations and Interventions

Important relevant investigations are carried out once the assessment part is over, e.g., blood tests, X-ray, ultrasound, and computed tomography (CT) scan, while point-of-care testing is helpful in the rapid assessment of a critically ill patient. Other interventions such as specialty reference should be taken on the basis of result of investigations for definitive care.

Diagnosis Definitive Treatment and Disposition

Once a diagnosis is certain or the causes understood, definitive treatment can be started. This may require the transfer of the patient to the operating theater, interventional cardiology laboratory, endoscopy suite, intensive care unit, or high-dependency unit. Proposed management should be carefully communicated to the patient and close relatives of the patient. If the patient is discharged to home medication prescription, the indicating diagnosis, follow-up test, and consultation should be clearly mentioned on the discharge summary.

CLINICAL QUALITY INDICATORS FOR RAPID ASSESSMENT

- Time to analgesia
- Time to delivering urgent medication, including antibiotics and bronchodilators
- Time to starting intravenous fluids
- Time to blood tests
- Time to imaging
- Time to specialty referral and assessment

IMPLEMENTATION OF RAPID ASSESSMENT AND EARLY TREATMENT (SEPSIS, STROKE, AND TRAUMA)

Sepsis

Timely recognition and intervention are important in reducing the morbidity and mortality due to sepsis and shock. Clinical suspicion, thorough physical examination, and laboratory screening using base deficit or lactate can improve outcomes. Rapid assessment and early treatment plan summary is given in **Table 1**.

Stroke

Stroke is time-bound emergency where an ischemic stroke patient needs thrombolysis within the window period. Early assessment of stroke and localization of pathology by stroke syndrome are summarized in **Table 2**. The early treatment plan is summarized in **Figure 2**.

Trauma

Implementation of a trauma system approach is important, which refers to the integration of all aspects of trauma care, to achieve the best outcome. Studies support that implementation of a trauma system approach improved the survival rate by 15–20% among seriously injured patients. **Table 3** summarizes the integrated trauma approach along with rapid assessment and early treatment improves the outcome for polytrauma patients.

SUMMARY

Rapid assessment and formulation of care of plan by a senior doctor ensure the patient's safety. Any important emergency or time-critical interventions are instituted (blood tests, X-rays, ultrasounds, CT scans, etc.). Initial clinical assessment and a clearly documented plan should be communicated with the nursing staff. This system improves the outcome of many critical illnesses such as sepsis trauma stroke.

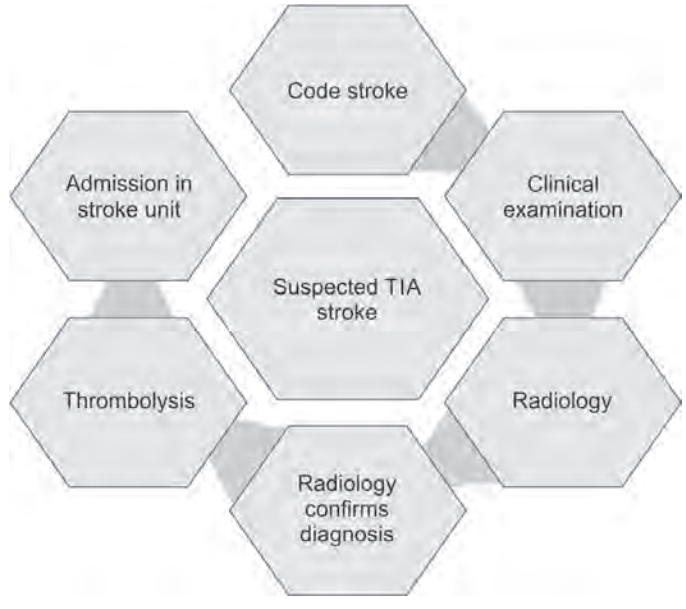
TABLE 1: Sepsis: Improving outcome through rapid assessment and early treatment.

Early recognition of sepsis	WBC high/low, temperature high/low, high heart rate, high respiratory rate, infection
Early recognition of shock	• Tachypnea, tachycardia, weak or bounding peripheral pulses, delayed capillary refill (>2 seconds) • Pale or cool skin, narrowed pulse pressure, oliguria • Lactic acidosis, elevated base deficit
Priorities in severe sepsis	Oxygenation and airway management, fluid resuscitation, hemodynamic stability, blood culture lactate levels, antibiotics, intensive care admission

(WBC: white blood cells)

TABLE 2: Early assessment in stroke patient (stroke syndrome).

• Aphasia (dominant hemisphere) or neglect (nondominant hemisphere) • Contralateral homonymous hemianopsia • Contralateral motor/sensory loss of face, arm, and leg • Conjugate ipsilateral eye deviation	Carotid territory
• Aphasia (dominant hemisphere) or neglect (nondominant hemisphere) • Contralateral homonymous hemianopsia • Contralateral motor/sensory loss face/arm > leg	Middle cerebral artery territory
• Apathy, abulia, disinhibition • Conjugate eye deviation • Contralateral motor/sensory loss leg > arm	Anterior cerebral artery territory
• Ipsilateral palatal weakness, Horner syndrome • Wallenberg syndrome • Ipsilateral limb ataxia • Decreased pain/temperature contralateral body	Posterior inferior cerebellar artery territory
• Ipsilateral deafness • Ipsilateral facial motor/sensory loss • Ipsilateral limb ataxia • Decreased pain/temperature contralateral body	Anterior inferior cerebellar artery territory
• Altered consciousness • Oculomotor difficulties, facial paresis • Ataxia, quadriparesis	Basilar artery territory



(TIA: transient ischemic attack)

FIG. 2: Rapid assessment and early treatment in stroke.

TABLE 3: Rapid assessment and early treatment in a trauma patient.

Trauma team	Emergency team, neurosurgery, orthopedics, surgery/GI surgery, critical care, thoracic surgery, vascular surgery
Criteria for trauma team activation	Blunt trauma, penetrating injury, gunshot wounds, stab wounds with SBP < 90 mm Hg, require endotracheal intubation, mechanically unstable pelvic injury, respiratory compromise, obstruction, or intubation with presumed thoracic, abdominal, or pelvic injury. GCS score < 8. Transfer patients receiving blood from other facilities to maintain vital signs or on the basis of a suspicion that the patient might require urgent operative intervention
Primary survey (ABCDE)	Check patency of airway and clear secretion Oropharyngeal airway, high concentration oxygen. Cervical spine stabilization (c-spine collar), two large-bore cannulas, simultaneously obtain blood for analysis, CBC blood grouping and typing, initial fluid therapy NS/RL, control bleeding, GCS score, pupil size, assess spinal injury, prevention of hypothermia, *Adjuncts*: ABG, cardiac monitoring, insertion of urinary and gastric catheters, consider need for X-ray, chest X-ray, pelvic X-ray, and FAST
Secondary survey	Detail history and examination, obtain history of injury-producing event and mechanism of injury. Reevaluation and detail examination of head, face, cervical spine, chest, abdomen, perineum, rectum, vagina, and musculoskeletal . Reevaluation of neurological status and GCS score
Management of hemorrhagic shock in trauma	Fluid therapy (crystalloid) in a hypotensive trauma patient, target SBP 80–90 mm Hg and urinary output 0.5 mL/kg/h in adult and 1.0 mL/kg/h in children, addition of vasopressors and inotropic agents if not responding to fluid therapy, norepinephrine is preferred, target hemoglobin is 7–9 g/dL, use of blood and blood products, type-specific blood is preferred, but type 0 –ve blood indicated in massive hemorrhage (which is available within 10 minutes in most of the blood bank), early use of RBCs and FFP improves the outcome (initial recommendations 10–15 mL/kg, additional dose depends on coagulation parameters PT or APTT 1.5 times the normal values), platelets transfusion is recommended when platelet counts are <5,000, tranexamic acid 1 g over 10 minutes and then 1 g over 8 hourly, rapid control of bleeding by local hemostatic procedures, packing, direct surgical bleeding control, angiographic embolization

(ABCDE: airway, breathing, circulation, disability, exposure; ABG: arterial blood gas; APTT: activated partial thromboplastin time; CBC: complete blood count; FAST: focused assessment with sonography in trauma; FFP: fresh frozen plasma; GI: gastrointestinal; GCS: Glasgow Coma Scale; NS: normal saline; PT: prothrombin time; RBCs: red blood cells; RL: Ringer's lactate; SBP: systolic blood pressure)

7
CHAPTER

Patient Safety and Quality in Emergency Department

Saravana Kumar

INTRODUCTION

The emergency department (ED) of any institution is an entry point for a significant number of patients to any healthcare organization (HCO). The department caters to various trauma and medical emergencies in both adults and children round the clock and is adequately staffed with emergency physicians and nursing to handle such emergencies at all times and days. The department also oversees operations of the prehospital emergency medical services (ambulance) and coordinates their services. The ED is considered particularly high risk for adverse events (AEs): About 60% of ED patients experienced medication error. Various studies suggests that prevalence of AEs related to ED is increasing and most of them are preventable.

Maintaining quality and developing error-free systems have been the focus of engineering over the last few decades. Consider the degree of variability of every individual human being compared to machine and also inputs from the engineering field, for an error-free system that guarantees good quality assistance should be defined a program reasonably simple, locally relevant, easily implementable, not resource intense, and have tangible outcomes which can be measured. The ED of any institution is an entry point for a significant number of patients to any HCO. It has to be conveniently located on the ground floor with direct access to the patients and ambulance. The entrance of the ED is always separate from the outpatient department (OPD) entrance. The department caters to various trauma and medical emergencies in both adults and children round the clock and is adequately staffed with emergency physicians and nursing staff to handle such emergencies at all times and days.

BACKGROUND OF EMERGENCY DEPARTMENT

The common medical emergencies handled in the ED include neurological emergencies such as seizures or stroke, respiratory emergencies such as asthma or any breathing difficulty, cardiac emergencies such as myocardial infarction or cardiac arrest or any acute arrhythmia, varied abdominal and gastrointestinal emergencies, and trauma emergencies that may include head injury, facial and oromaxillary injuries, chest injury, abdominal injury, musculoskeletal injuries, and fractures. Apart from this, the department also caters to patients with poisoning, drowning, hanging, acute allergy, and anaphylaxis and also handles any mass or multiple casualty events and medicolegal cases. During non-outpatient hours, the department also handles outpatient-based complaints and nonemergency cases who generally are triaged out to OPD during OPD hours. Unlike wards or intensive care unit (ICU), the beds in the ED are utilized on a continuous basis for different patients on a given day for initial stabilization and are eventually transferred to appropriate inpatient care areas of the HCO for continuity of care under different specialties (or) discharged from the emergency room (ER) after initial treatment with follow-up advice. There are no recommendations or scope for providing continuity of care in the ED/beds. The department also oversees operations of the prehospital emergency medical services (ambulance) and coordinates their services. More recently, quality issues have received much attention in the medical field and there has been some inputs from the airline industry, replicated to healthcare in error prevention by the introduction of safety checklists. There are, however, some fundamental differences between the medical and engineering field (man and machine).

The first aspect is dealing with uncertainties. One of the primary differences between man and machine is the degree of variability. Unlike machines that can be "cloned," every individual human being is different and each responds and reacts differently to illness and treatment. While there is a general pattern of presentation and response to illness, the uncertainties that one needs to be prepared for and deal with are more in the medical domain than in the engineering domain. In emergency medicine, the uncertainties are particularly enormous as the presenting illness is mostly not well defined by the patients and he/she is not fully coherent or conscious to give his symptoms, signs are not obviously evident, support documents or prior medical history are not available, there is a short therapeutic window, there is a delayed or denied consent, and affordability to emergency medical care is less.

The second aspect is paying attention to detail. Although on the surface there appears to be a similarity between the

medial and the engineering fields, there is a fundamental difference. Domain experts in the engineering field have made a remarkable difference for machines.

However, the domain experts in medicine need to start understanding the key performance metrics and measures for ensuring better outcomes and still need to have a holistic approach and expertise in order to be successful and have a low margin for error. There is also a lack of adequate expertise in emergency medicine available all over the world.

APPROACH TO QUALITY ISSUES IN THE EMERGENCY DEPARTMENT

The prerequisites of a good-quality assurance program are as follows:

- It should be reasonably simple.
- It should be locally relevant.
- It should be easily implementable.
- It should not be resource intense.
- It should have tangible outcomes which can be measured.

ADVERSE EVENTS IN THE EMERGENCY DEPARTMENT

The ED is considered particularly high risk for AEs.

Sixty percent of ED patients experienced medication error. *An AE is defined as "an injury caused by medical management rather than by the underlying disease or condition of the patient."*

It represents a significant threat to patient safety and public health. From a systematic review about AEs related to ED care, it appears that many studies conducted in multiple countries have reported a prevalence of AEs among hospitalized patients ranging from 2.9 to 16.6%, with 36.9–51% of events being considered preventable. Some studies indicate that AEs related to medical conditions such as myocardial infarction, asthma exacerbation, and joint dislocation reach up to 37%. They have also shown that 33% of the near misses were intercepted. About 29% of doctors reported AE or near miss of their ER patients due to poor hand-off. Only 12% of ED revisits within 7 days are due to AEs. Most frequent errors depend on the patient, provider, and system. The reasons behind this are as follows:

First is patient complexity, which depends on many issues such as age, extreme, communication barrier, vague complaints, undifferentiated presentation, mental status changes, cognitive impairment, complex medical condition, delayed presentation, myths and traditional beliefs, and lack of awareness/education or knowledge of a disease.

Second is care workers, who could risk making mistakes due to lack of knowledge and experience on diseases and procedural skills, fatigue (they disrupt sleep cycles for healthcare), prejudice, and risk-taking behavior (not use personal protective equipment during procedures).

Third is the relationship between patient and doctor. Many AEs depend on bad communication: At an average discharge, the verbal exchange between a doctor and patient lasts for 76 seconds. So, the incomplete information during an average discharge is 65%. Only 76% of the ED patients get a written diagnosis at discharge and only 34% of the ED patients get instructions on when and how to return to the hospital.

Fourth is the work environment that is characterized by time constraints, staff inadequacy, staff's lack of experience, team/communication problems, overcrowding, lack of equipment, or failures.

Last, there are *other emerging factors* such as multicultural/multilingual patient, relocation/migration of doctors to various countries and healthcare systems, and multielectronic health recorder (EHR) systems with poor integration for seamless flow.

SAFETY PRACTICE AND IMPLEMENTATION STRATEGY

To guarantee the safety practices and avoid AEs, we have to do an implementation strategy in many settings. The following points need to be addressed:

- Infrastructure requirements
- Basic clinical management process and protocols for quality emergency care
- Establishing a unit of quality department
- Measuring quality of performance (quality indicators)
- Sharing best practices
- Adapting to changing realities

Infrastructure Requirements

The factors which influence the ED size and design include a general scope of clinical services provided in the HCOs, average volume of ER visits, total number of beds in the HCOs, availability of other support services such as radiology and laboratory, total floor space, geographical location, demography of the patients who will be handled in the ER (pediatric, geriatric, trauma, and medical emergencies) or the maximum number of possible users in a given time. The ED design includes the following: *Entrance* which should be directly accessible from the road for ambulance and vehicles, Clearly marked. *Temporary parking space* for cars and other means of patient transport. *Ramp for wheelchair/stretcher*. Stretcher and wheelchair placing area should have a well-lit entrance with wide doors which can open both ways or one way into the ER. The doors should be wide enough to move a patient in an emergency trolley comfortably in and out. The ideal width would be a minimum of 6 feet when both the doors are wide open. The *waiting area* can be of a size that includes seating, telephones, display for literature, public toilets, and circulation space in total. *Triage area* it should be able to accommodate patients in wheelchair/emergency stretcher/walking in. The ideal space would depend on the volume of patients received in the department. There is a close operational relationship between triage and reception where the registration counter is located. *Resuscitation room (priority 1)*: Resuscitation room with at least one Resuscitation bed should be available in ER. Ideally, there should be an individual closed space with provision for an emergency stretcher bed, multiple monitors, defibrillator, crash cart, and ventilator in each room. The room should accommodate four to five staff members, including doctors, comfortably and be able to move around the patient. *Urgent care (priorities 2, 3):* The minimum recommended space between centers of two adjoining beds is 2 m. Each bed can be separated by a screen on all three sides for providing privacy. There should be a *consultation room (priority 4)* for examination and treatment of priority 4 patients. *Emergency short stay unit:* This facility may be provided either within or adjacent to the Emergency Unit for prolonged observation and

ongoing treatment of patients who are planned for subsequent discharge (directly from the ED). It is mostly applicable to high-volume ED. The types of patients planned to be admitted to this unit will determine the number and type of beds provided, and the design of associated monitoring and equipment. However, eight beds, are considered to be the minimum functional size. The configuration of the short stay unit should be a minimum of one bed per 4,000 attendances per year.

Nursing station: A staff room/utility storage room/security room/toilets/pharmacy sub store should also be there.

Patient Flow Management

The ED can have two types of patient: (1) Input-throughput and (2) Output flow based on the volume and space available in the healthcare institution.

For a large-volume department, it is advisable that the entry and exit points of the ED are separate. The triage room and registration can be done at the entry and there is also a facility for registering the patient at the entry point. After triage, the patients are moved to the appropriate preidentified bed space/area for further care. All *priority 1* patients are moved to the resuscitation room. *Priorities 2 and 3* are treated in the urgency care areas which can also be the observation area. *Priority 4* patients are triaged out to OPD or can be handled in ER in a predesignated fast track room or doctor consultation room (especially in non-OPD hours) in the ED and an emergency bed is not necessary for this category of patients. On disposition, the patients are moved into the hospital or discharged through an exit, away from the entry area. Billing counters can be situated at the exit. Bedside billing can also be done.

For low-volume ED*s* and HCOs with limited space, the entry and exit are through the same point and the registration and billing counter is essentially located at the entry/exit point. No separate triage room or space is provided and all the patients visiting ER are allotted a bed straight away and a bedside triaging is done. All *priority 1* patients are either moved to the bed identified for resuscitation purpose or resuscitation can happen in the same bed. *Priorities 2, 3*, and *4* are treated in emergency beds. *Priority 4* can also be treated in the ER doctor consultation room (if available). On disposition, the patients are moved into the hospital or discharged through the same entry/exit point. Billing counters can be situated here and bedside billing can also be done.

Clinical Management Process and Protocols for Quality Care

Each ED is unique as the patient profile varies with the locality of the hospital infrastructure within the same city and the level of acuity that the particular hospital can handle. Also, the disease profiles and healthcare systems vary across the globe.

Clinical management protocols are based on evidence-based recommendations and best practice recommendations, where clinical evidence is not possible.

Clinical protocols have to be region-based applicable to the population demography of the hospital and their health needs.

For example, a trauma center hospital may look into how efficiently it can manage a patient of polytrauma and process to better clinical outcome, such as initiating a massive transfusion versus a peripheral pediatric hospital where the nature of emergencies tends to be more medical in nature than surgical.

Irrespective of the locality: The protocols need to be tested and constantly upgraded based on recent updates.

Appropriate mock assessments conducted periodically and audits are a must to ensure that the policies and processes are implemented at the ground level.

Establishing a Unit of Quality Department

The establishment of a quality department is essential in order to examine the association between the scope of quality improvement (QI) implementation in hospitals and hospital performance on selected indicators of quality. Various key performance indicators (KPI) may be set by an identified champion from the ED, who may be certified through various national or international training programs to conduct an internal audit or program or quality implementation in hospital and with help from external accrediting agencies.

Reviews on various aspects of improving KPI must be taken up as a continuous process in order to reduce errors. Coordinate care among settings and practitioners and ensure that relevant, accurate information is available when needed as critical elements in providing a high level of care.

Achieving Quality Control of the Highest Standard in Medical Equipment

Periodic checks at least once a year are essential in achieving this goal. They can be done for a range of equipment including defibrillators, ventilators, pulse oximeters, infusion pumps, patient monitors, etc. This may be done as part of a set of national and international standards by trained engineers with help of specialized testing and calibrating equipment as per manufacturer recommendations. It should be concluded by documenting test results and issuing a calibration report. Any measuring equipment or device needs to be tested and checked for its accuracy and calibrated whenever the need arises. Testing is done as per domestic standards which imply in accordance with manufacturer specifications for both safety and performance tests. The results need to be formally documented.

Key parameters for testing and calibrating in the ED may include:

- *Defibrillators*: Electrical safety tests, biphasic energy measurements, electrocardiogram (ECG), performance and arrhythmia simulation, waveform simulation
- *Pulse oximeter*: Electrical safety, O_2 saturation, heart rate, pulse amplitude, selectable pigmentation, and ambient light condition
- *Infusion pumps*: Flow rates, occlusion alarm tests, pressure
- *Ventilators*: Modes, lung parameters, etc.

The entire activity must be subjected to appropriate methods of internal control and inspection.

Measuring Quality of Performance (Quality Indicators)

Institutions need to adapt appropriate quality indicators. The following quality indicators (**Tables 1A** and **B**) can represent the quality of EDs: Door to triage time, door to doctor time, door to needle time in stroke thrombolysis, pain score assessment, investigation return time, nurse/patient ratio, patient satisfaction level, time taken for discharge, mortality (adjusted), length of stay, left without been seen by the

TABLE 1A: Measuring quality of performance (quality indicators).

Door to triage time	*Door to doctor time*	*Door to needle time in stroke thrombolysis*	*Mortality parameter*	*Patient satisfaction (effective communication)*	*Patient fall rates*	*Medication errors*
Description: Time interval of patient's arrival to nurse triage *Type of parameter*: Outcome *Formula*: Time from patient arrival to time when triage is completed for a particular category of patients *Benchmark*: Does not exist *Action plan*: Ensure quality in design, conformance	*Description*: In case of emergency, the time shall begin from the time of the patient's arrival at the emergency till the time that the initial assessment is completed *Type of parameter*: Outcome *Formula*: Sum of the time taken for assessment/ total number of patients in emergency *Benchmark*: Does not exist *Action plan*: Ensure quality in design, conformance	*Description*: In case of acute-onset ischemic stroke in the window period *Type of parameter*: Morbidity in stroke *Formula*: Number of stroke patients thrombolysed/ number of eligible stroke patients for thrombolysis *Benchmark*: Does not exist *Action plan*: Ensure quality in design, conformance	*Description*: Standardized mortality rate (SMR) *Type of parameter*: Outcome *Formula*: Number of deaths/number of discharges and deaths × 100 *Benchmark*: None *Action plan*: Ensure quality in design and conformance	*Description*: Efficacy of communication *Type of parameter*: Process *Formula*: Quarterly average score/max score possible × 100 *Benchmark*: Not known *Action plan*: Through patient satisfaction	*Description*: Patient fall rate *Type of parameter*: Safety morbidity *Formula*: Number of falls/numbers of bed days *Benchmark*: 8.46/1,000 bed days *Action plan*: Ensure quality in design (beds) and conformance (sedation)	*Description*: Medication error *Type of parameter*: Safety *Formula*: (Number of errors/numbers of bed days) × 1,000 *Benchmark*: 1.2–9.47/1,000 bed days (reported) *Action plan*: Clinical pharmacists; process (2-people check)

TABLE 1B: Measuring quality of performance (quality indicators).

Compliance to hand-hygiene protocols	*Investigation return time*	*Length of stay in emergency department*	*Nurse–patient ratio in emergency department*	*Pain management in emergency department*	*Time taken for discharge*	*Left against medical advice*
Description: Compliance to hand hygiene *Type of parameter*: Infection, outcome, safety *Formula*: (Number adhered/total number of procedures) × 100 *Benchmark*: 90% adherence *Action plan*: Surveillance; health education	*Description*: Radiology CT investigation report *Type of parameter*: Adherence to protocol *Formula*: Time of order to time of reporting *Benchmark*: 60 minutes *Action plan*: Clinical audit	*Description*: Average length of stay *Type of parameter*: Adherence to protocol, safety *Formula*: Total length of stay of all patients in hours/total number of patients *Benchmark*: 240 minutes *Action plan*: Audit	*Description*: Nurse per bed per shift *Type of parameter*: Safety, mortality, morbidity *Formula*: Number of nurse/number of beds in each shift *Benchmark*: Does not exist *Action plan*: Audit	*Description*: Proportion of patients presenting with pain in whom validated pain score is documented *Type of parameter*: Key performance indicator *Formula*: Patients with pain assessment using validated score/total number of patients presented with pain × 100 *Benchmark*: Does not exist *Action plan*: Audit	*Description*: Discharge is the process by which a patient is shifted out from the ED with all concerned medical summaries after ensuring stability *Type of parameter*: Safety *Formula*: Sum of time taken for discharge/ number of patients discharged *Benchmark*: Does not exist *Action plan*: Audit	*Description*: Percent of patients who leave the ED before the examination *Type of parameter*: Safety *Formula*: Total number of patients who leave ER before seen by doctor/total number presented to ER during the time of study × 100 *Benchmark*: Does not exist *Action plan*: Audit

doctor, pain assessment/reassessment, safety—patient falls, medication error, failed intubation rate incident reporting and hand hygiene compliance.

Nonconformance Control and Management

Any nonconformance observed should be properly reported through the incident reporting system which will be reviewed by a multidisciplinary committee and the quality department of the hospital.

The nonconformances could be:

- Near miss
- Medical error
- Sentinel event

Configuration control and management under the quality of design: Any process changes in the hospital flow system or physical layout or functions related to the assignment pattern of doctors/staff need to be reported and discussed in the leadership team meet of the institution along with the justification of such a change and approval.

Adapting to Change Realities

Digitization

Opportunities for using data to improve the health system are partially driven by technological advances. New analytical methods, more efficient processing, and automation of routine analyses and analytics, for example, make it easier to draw insights from health data and to present the resulting information in an actionable format.

In the clinical setting, secondary use of health data can improve quality initiatives and the effectiveness of frontline care. For health system management, health data can be used to manage and improve the effectiveness and efficiency of the health system by informing program, policy, and funding decisions. For example, costs can be reduced by identifying ineffective interventions, missed opportunities, and duplication of services.

To facilitate health research, health data can be used to support research that gives information on clinical programs, health system management, and population and public health. Such research spans multiple fields.

Measuring Patient Feedback

Patient feedback systems are used to know their experiences when visiting the hospital, understanding of the services the hospitals offer, and opinions on changes you may have recently introduced or plan to make.

With a good feedback system, one can increase one's understanding of what patients think about a hospital, understand areas of concern, and take action to transform the experience for patients. One can make changes and use the system to monitor the patient reaction, gradually improving the practice based on accurate feedback.

Patient Experience Measures

- Should be developed with patient input to ensure that they are representative of their needs, values, and preferences
- Reveal critical information about the extent to which care is truly patient-centered
- Provide a rigorous, validated alternative to the subjective reviews that are posted on a large number of review sites

CLINICAL AUDIT

- The review of clinical performance against agreed standards, and the refining of clinical practice as a result: A cyclical process of QI in clinical care.
- The systematic critical analysis of the quality of healthcare, including the procedures used for diagnosis, treatment, and care; the use of resources; and the resulting outcome and quality of life for patients.
- Monitor the use of particular interventions, or the care received by patients, against agreed standards. Any deviation from "best practices" can then be examined in order to understand and act upon the causes.

There are different modalities with which we can do a clinical audit:

- *Standards-based audit (criteria-based audit)*: This is the recommended process. Current practice is compared against defined criteria, standards, or best practices, through the "audit cycle."
- *Peer review audit*: With the benefit of hindsight, the quality of services provided is assessed by a team, reviewing case notes and seeking ways to improve clinical care. This is especially applicable in "interesting" or "unusual" cases.
- *Significant event audit*: Adverse occurrences, critical incidents, unexpected outcomes, and problematic cases causing concern are reviewed systematically and solutions implemented.
- *Survey*: Opinion or suggestions from patient or special focus groups. Information gathered is then analyzed and change implemented as appropriate.

Stages of an Audit

- Prepare and plan for the project.
- Select an area to audit.
- Defining criteria and setting up standards
- Collection of data
- Analyze results.
- Identify solutions for improvement and implement changes.
- Reaudit to monitor the impact of changes (close audit loop).

This must be led by senior clinicians in the department and must be reported to the audit review boards and discussed with higher stakeholders for implementation and continuous improvement.

FISHBONE ANALYSIS FOR QUALITY IMPROVEMENT IN EMERGENCY DEPARTMENT

The fishbone analysis (diagram) is a visual tool used to explore the factors that influence or cause a given outcome to help to understand the problem more clearly. Quality improvement tool is named by its inventor Kaoru Ishikawa and its resemblance to a fish skeleton. Constructing the fishbone diagram helps to understand the multiple causal factors of the

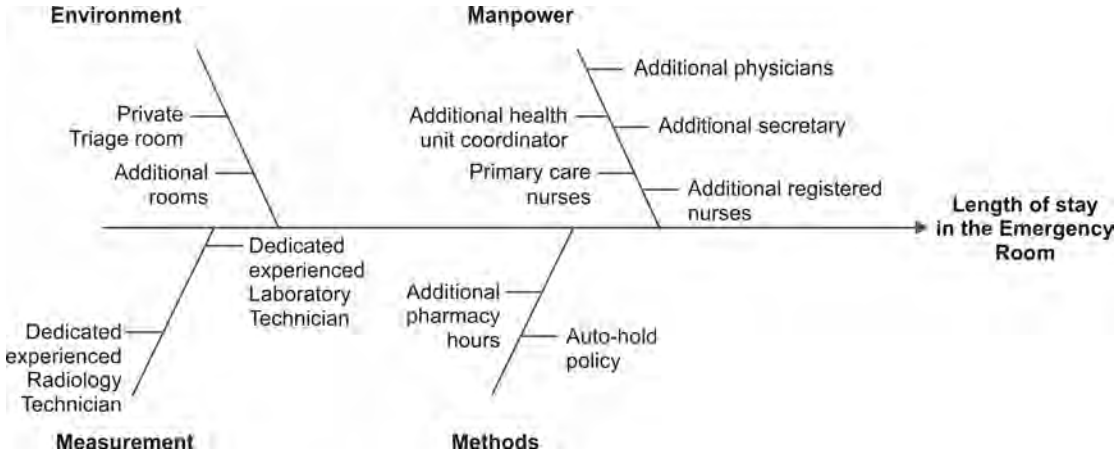

FIG. 1: Fishbone diagram showing the parameter to improve the length of stay in an emergency room.

particular problem and helps us to identify areas of further investigation (**Fig. 1**).

How to draw fishbone diagram/analysis:

- First write single statement in a box that describes the problem.
- Then identify major relevant categories of causes (people, place, policies, and procedures). Draw these main causes (bones) off the large arrow.
- For each main cause (bone) consider factors contribute to it (minor causes). We can use brainstorming for this step.
- Continue analyzing fishbone diagram until every possible contributing cause and influence has been identified.

SUMMARY

All EDs have to ensure that the patients, relatives, and primary physician are well informed about the clinical status of the patient through a structured communication protocol. A communication checklist to ensure that adequate communication has taken before disposition needs to be implemented in all EDs.

Promotion of reporting errors, teamwork, transparency with feedback, learning from errors, and administrative collaboration will be helpful in QI. Identify champions of quality and patient safety in ED.

Hazardous Material (HAZMAT) and Waste

8
CHAPTER

KV Sarma, Devendra Richhariya

INTRODUCTION

Biological, chemical, and radiologic materials that result in adverse effects on the health and safety of exposed individuals are termed hazardous materials (HAZMAT). Are there materials in your workplace that are hazardous? If so, then you must be aware of the following:

- Which ones are hazardous?
- What their hazards are?
- How you can work with them safely.

Hazardous material can be:

- Corrosive
- Explosive
- Flammable
- Radioactive
- Reactive
- Toxic

There are various routes from which they can enter the body. HAZMAT can enter your body by three routes: (1) Skin and eye contact (absorption), (2) inhalation (breathing), and (3) ingestion (eating). This chapter consists of information about the nature of HAZMAT and how they should be labeled, their usefulness in preplanning for HAZMAT emergencies, extinguishing tactics, and environmental protection aspects.

All accidents/spills must be reported to the Safety and Environmental department, and any other departments or persons as the situation requires (i.e., Radiation Safety Officer in case radiation is involved, Lab Safety Officer, Research Centre Chemical Safety Officer, Clinical Engineering, or others). All HAZMAT received in a department shall be handled by appropriate personnel and stored in an appropriate cabinet with proper ventilation, designated for chemical use only.

Hospital Plan

Hospital plan is a written program consistent with local and international regulations/standards to identify, determine control, implementation, and evaluation of all HAZMAT used or generated. The program covers HAZMAT inventory, selection, purchasing, storing, using/handling requirements, spill clean-up measures, and disposal methods.

Department Responsibilities

All HAZMAT received in a department should be handled by appropriate personnel and stored in an appropriate cabinet with proper ventilation, designated for chemical use only. HAZMAT Program is developed, in which departments are responsible for the following: Each department is responsible for identifying and labeling all HAZMAT within its department work area. All departments should inventory their HAZMAT and review them for appropriateness as part of the overall department's inventory program. It is the responsibility of each department to provide training for individual staff who handle HAZMAT; training records must be maintained. Emergency preparedness and spill clean-up procedures must be developed. Purchase of all chemicals including cleaning solutions, laundry chemicals, and chemicals routinely used for facility and grounds maintenance should follow the rules. Are there materials in your workplace that are hazardous? If so, you should know: All accidents/spills must be reported to the Safety and Environmental Section and any other departments or persons as the situation requires (i.e., Radiation Safety Officer in case radiation is involved, Lab Safety Officer, Research Centre Chemical Safety Officer, Clinical Engineering, or others).

CLASSIFICATION OF HAZARDOUS MATERIAL

Hazardous materials can be divided into three groups according to their effects: (1) Substances that affect health, (2) substances that affect fire, and (3) substances that may react violently. HAZMAT may have more than one of these effects, so it is critical to be aware of all the hazards associated with a substance.

Health Hazards

Materials that can affect health include poisons and other toxic substances that may enter the body through breathing (inspiration), swallowing (ingestion), or injecting through the skin (absorption).

Fire Hazards

Fire HAZMAT may be in liquid, solid, or gaseous form. All flammable liquids, by definition, are considered hazardous. A flammable liquid is a substance that has a flashpoint <100°F. The flashpoint of a liquid is the temperature at which the liquid releases vapors in sufficient concentration to support ignition by an external ignition source near the surface of the liquid. Flammable solids are solid materials that are easily ignited and that burn rapidly.

Reactive Hazards

Some materials are classified as hazardous because of the volatile way they react with other substances or with themselves. Explosives are materials that will detonate or will deflagrate. Oxidizing agents (which can be strong corrosives) give off oxygen and support combustion. The reaction of oxidizers with other substances frequently generates heat. Some substances will react violently, even explosively, when water or moisture is added to them. Other substances may react in the same way when they come in contact with air.

Classes of Hazardous Materials

There are nine classes of HAZMAT. Each class has a distinctive symbol for labeling containers. (1) Explosives, (2) gases, (3) flammable liquids, (4) flammable solids and materials that are dangerous when wet, (5) oxidizers and organic peroxides, (6) poisonous and etiologic materials, (7) radioactive materials, (8) corrosive, and (9) miscellaneous HAZMAT.

Combustion Byproducts

Examples: Carbon monoxide, nitrogen oxide, hydrogen sulfide, sulfur dioxide, acrolein, ammonia phosgene, phosphine, hydrogen. Byproducts of combustion are not new to firefighters. However, all of these products are highly toxic by inhalation. Therefore, breathing apparatus (BA) for protection must be worn. Some of these materials will damage the skin. In any event, protective clothing should be worn. Most of these materials are water-soluble, so water fog should be used to dilute and disperse the vapors.

Water-reactive Materials

Examples: Lithium, sodium, potassium, metal hydrides, carbides, organometallic compound. All of these materials will react with water to produce heat and a flammable gas, usually hydrogen. They are also highly corrosive and will react with all common extinguishing agents. Firefighters must wear protective clothing, BA, and evacuate the area. The special dry powder can be used, but this is only effective on small fires. These are highly toxic.

Pressurized and Liquefied Gases

Examples: Acetylene, hydrogen, oxygen, chlorine, carbon dioxide, compressed air, ammonia, butane, propane. Containers containing pressurized and liquefied gases are extremely dangerous under fire conditions. When heated, the excessive internal pressure will build up which is beyond the capability of relieving devices, and the container will rupture. When a rupture does occur, it is impossible to predict the direction of flying fragments. The decision to attack fires involving pressurized containers is a critical one. Containers can rupture in very short periods of time. Ample water must be applied to pressurized containers when exposed to heat. The flow of gas should be shut off and firefighters must wear BA and protective clothing.

Flammable Liquids (Nonpetroleum)

Examples: Alcohols, aldehydes, ketones, esters, ethers, amines. These are toxic and corrosive liquids, which react violently when decomposing under fire conditions. Foam, carbon dioxide, and dry chemical should be used to fight fires on soluble flammable liquids. Firefighters must wear BA and protective clothing.

Flammable Solids

Examples: Naphthalene, camphor, carbon phosphorous, sulfur. These solids present an explosive potential when in dust form and some are pyrophoric, i.e., they will ignite spontaneously in dry or moist air. Most produce highly toxic gases when burning. Large volumes of water should be used to extinguish fires. Protection against toxic gases is required and firefighters should wear BA and protective clothing.

Explosives

Examples: Azides, fulminates, nitro compounds [nitroglycerine, trinitrotoluene (TNT), dynamite, picric acid]. These materials present an extreme hazard due to their sensitivity to heat and shock, and fires should be fought from a distance. When it is not possible to fight the fire from a safe distance and an explosion is imminent, you must evacuate the area.

Poisons

Examples: Cyanides—hydrogen cyanide, sodium cyanide; fumigants—sulfur dioxide; heavy metals—mercury, arsenic, lead; pesticides—dichloro-diphenyl-trichloroethane (DDT), parathion, malathion. Poisons can enter the body in three ways: (1) Inhalation which causes asphyxiation and lung damage, (2) ingestion which causes internal organ damage, (3) skin contact which destroys tissue.

Toxicity is measured by threshold limits, which are assigned to each poison. These limits must be monitored and should not be exceeded. However, you must treat all poisons or chemicals as highly toxic and highly corrosive until reliable information is obtained. When poisons are involved in an emergency, protective clothing and decontamination processes all are required. Evacuation may be considered and required. Protective clothing is another important line of defense against infectious waste. Use every method available to protect yourself from hazardous medical waste.

Corrosives

Examples: Acids—sulfuric, nitric, acetic, carbolic, chlorosulfuric; alkalis—caustic soda, caustic potash, lime; halogens—fluorine, chlorine, promin, iodine. All corrosives destroy human tissue. Many react violently with water such as chlorosulfuric acid. Some are flammable and some react with other materials to start fires. All corrosives are highly toxic. Firefighters must wear BA and protective clothing in emergencies. Be sure that substances are not water-reactive before washing any spills. Tools, equipment, and personnel must be decontaminated any

time corrosives are encountered. Decontamination procedures must be followed.

Cryogenics

Examples: Liquid oxygen, liquid hydrogen, liquid nitrogen, liquid carbon monoxide, liquid natural gas. These substances have a temperature below –150°F (extremely cold) and can be both flammable and toxic. When released into the atmosphere, they expand in a very high vapor. In case of fire exposure, hose streams at sufficient volume and pressure should be employed to reduce the chance of rupture due to over-pressurization.

Oxidizing Agents

Examples: Nitrates, nitrites, chlorates, chlorites. These substances decompose when heated, giving off heat, toxic gases, and oxygen. When involved in fire, intense flame, heat and even explosions can result. Flood the area with deluge quantities of water from a safe distance when oxidizing agents are involved in a fire.

Unstable Materials

Examples: Organic peroxides, inorganic peroxides. These substances are highly flammable and toxic. They are also shock- and friction-sensitive, causing explosions. They decompose to give off heat and oxygen and form highly flammable mixtures and many materials. Evacuate the immediate area and concentrate on protecting exposures if peroxides are burning. You cannot predict what will happen with unstable materials and you must expect the worst possible conditions.

STORAGE AND TRANSPORTATION OF HAZARDOUS MATERIALS

Storage

Chemical storage parameters include temperature control, ventilation, segregation, isolation, ignition control, and regulatory considerations. Departments are responsible for ensuring that chemicals they use or are otherwise under their administrative control are stored safely. Material safety data sheets provide chemical-specific storage requirements. Observing the following general guidelines can minimize risks.

All chemicals shall be properly labeled with a description of the hazard. Materials which are toxic as stored or which can decompose into toxic components from contact with heat, moisture, and acid fumes shall be stored in a cool, well-ventilated place out of the direct rays of the sun. Incompatible toxic materials shall be isolated from each other. All flammable and combustible liquids should be kept in closed containers when they are not in use. Materials which ignite easily under normal conditions (flammable) shall be stored in a cool, dry, well-ventilated storage space. Store according to the hazardous nature of chemical using appropriate security when necessary. Store large bottles of acids on a low shelf or in acid cabinets. Segregate acids from bases and active metals. Segregate acids from chemicals which could generate toxic gases upon contact such as iron and sulfide. Acids and acid fume-sensitive materials shall be stored in cool, dry, well-ventilated areas. Use bottle carriers for transporting acid bottles. Have spill-control pillows and acid/caustic neutralizers available in case of acid or caustic spills. Store solutions of inorganic hydroxides in polyethylene containers. Store pyrophoric substances in a cool and dry place. Store water-reactive chemicals in a cool and dry place. Store oxidizers in a cool and dry place, and do not store close to liquid of low flashpoint. Segregate oxidizing agents from organic acids, flammable, and combustible materials. Keep oxidizers away from reducing agents such as zinc, alkaline, metals, and formic acid. Segregate flammable from oxidizing acids and oxidizers. Store flammable liquids in approved safety cans or cabinets. Keep away any source of ignition, flames, localized heat, or sparks. Corrosives shall be isolated from other materials and shall be stored in a cool, well-ventilated area. Safety cans containing flammable liquids should be grounded and bonded when being used. Firefighting equipment shall be readily available. An automatic firefighting system and smoke detection system shall be provided. Have spill clean-up materials handy. Store highly volatile flammable liquids in a specially equipped refrigerator. In case of fire involving water-reactive chemicals, keep water away. The personal protective equipment (PPE) shall be available for use when handling chemicals. Do routine inspections. Hazardous waste should not be stored outside a building. Compressed gas cylinders shall be handled, stored, and used in a manner that will prevent damage to the valve. Secure them when in an upright position or on hand trucks or lay them flat. Always have cylinder caps securely in place whenever the cylinder, regardless if full or empty, is not in service. Oxygen and oil make an explosive mixture. Never use any petroleum in or near any oxygen system component or equipment. Restrict access to the building where the chemical is being stored. *HAZARDOUS– KEEP AWAY* signs shall be posted in all flammable gas or chemical cabinets. The cabinet shall be operated at negative pressure. It is true that many hazardous chemicals are unpredictable under certain conditions such as when mixed with another chemical. However, even if you are unable to predict exactly what a HAZMAT will do, you must have guidelines to assist you.

Transportation

Chemicals must be transported safely to minimize the potential for spills, releases, or accidental exposures. The following general guidelines should be followed: Chemicals should be transported in sealed and labeled primary containers. Primary containers should be transported in secondary containers. Only manageable quantities of chemicals should be hand-carried. Heavier quantities should be placed on a cart. Only persons knowledgeable about the chemicals' hazards should transport the chemical.

SAFE USE OF HAZARDOUS MATERIAL

To avoid problems, be prepared and read the label which usually tells you the following at a glance:

- What is in the container
- What the hazard could be (health, fire reactivity, etc.)
- Special instructions
- How to protect yourself
- Basic first-aid

Before using HAZMAT:

- Remove things that could burn, explode, or react dangerously with nearby materials.

- Know where emergency showers and eyewashes are located.
- Make sure that the correct type of fire safety equipment is nearby and ready for use.
- Check for adequate ventilation.
- Know what to do in an emergency.
- Assemble PPE that might be required, such as:
  - Safety glasses, goggles, or face shields
  - Gloves
  - Rubber boots or special shoes
  - Respirators

Laboratory Chemicals

Laboratories have a specially written plan to keep the employee safe. The Chemical Hygiene Plan covers the specific operating procedures and safety concerns of the individual laboratory. Always follow the procedures in your laboratory's plan. The Chemical Hygiene Plan is designed to protect from the health hazards associated with hazardous chemicals in the laboratory.

Chemical Hygiene Plan

It outlines the specific work practices and procedures covering: (1) Procedures to follow when working with hazardous chemicals, (2) details on how your chemical exposure will be monitored and limited, (3) ensures that you have the right protective equipment such as a fume hood and that it works properly, (4) specifies that some hazardous tasks be approved in advance by your supervisor, (5) assumes that any unfamiliar chemical is hazardous, (6) considers a mixture to be at least as hazardous as its most hazardous component, (7) do not use any unlabeled substance, (8) strictly follow all chemical safety instructions and procedures, and (9) use common sense and be cautious around all laboratory equipment.

CHEMICAL SPILL AND DECONTAMINATION

Chemical Spills

The range and quantity of hazardous substances require preplanning to safely respond to chemical spills. Only knowledgeable and experienced personnel should clean up a minor chemical spill. Spill response kits or materials with instructions, absorbents, reactants, and protective equipment should be available. A "minor" (few drops) chemical spill is one that staff is capable of handling safely if the following criteria are satisfied: Staff should have access to and wear appropriate PPE. They should have access to and use appropriate spill clean-up equipment. They should have a way to dispose of waste generated from spill clean-up activities. They should be trained. They feel comfortable cleaning up the spill. All other spills are considered "major" (>10 mL) and must be cleaned up by trained Hazmat Chemical Spill Response Team members. The safety department is responsible for investigating significant hazardous chemical spills and unplanned releases. Department heads and other staff are included in the investigation to help identify causative factors and develop strategies to prevent reoccurrence. Spills and exposures are reported by any of the following methods: Physicians report of occupational injury/illness from human resources.

All workers who are likely to discover a HAZMAT spill/release should be trained to notify the proper personnel. All workers at the operation level are trained to contain a spill/release from a safe distance and keep it from spreading and stop the release of HAZMAT. On-site cooperation and knowledge of specific chemicals should be given to government officials. The workers should know how to control an incident scene during an emergency response.

If a chemical spill happens:

- Immediately inform housekeeping.
- Proper protective clothing must be worn. This includes solvent-resistant gloves and respiratory protection.
- In case of a large spill, follow steps set out in the "Chemical Hygiene Plan."
- Small spills can be cleaned up easily by using a chemical spill kit which is available in the laboratory.

Decontamination

Decontamination neutralizes harmful contaminants and removes them from personnel and equipment. It also reduces the chance that contaminants will be carried out of the release area. There are two major methods of decontamination: (1) Physical and (2) chemical. Physical is done by diluting with water or blowing with air jets. Chemical is done by neutralizing HAZMAT with chemicals.

Chemical exposure staff, visitors, and patients can become contaminated with a hazardous substance in a variety of ways, including contact with airborne contaminants, splash walking through a spill on the floor, and contact with contaminated equipment. General guidance regarding decontamination methods and techniques is presented below. The exact procedure is determined after evaluating a number of factors related to the incident and consulting material-specific literature such as the material safety data sheet.

- Eliminate further contact with the material.
- Identify the material.
- Decontaminate with a copious amount of water or other appropriate material.
- Remove contaminated clothes and other material in contact with the victim.
- Assess the amount and concentration.
- Obtain medical assistance.
- Notify supervisor.

HAZARDOUS WASTE AND SEGREGATION

Segregation of Waste System

The waste classification system is effective to sort and handle the various types of waste generated by the hospital and protect our staff and the community from contamination. General objectives regarding the waste classification, with respect to hazardous medical waste including infectious waste and radioactive waste, are to provide technical guidance in hazardous waste segregation, collection, packaging, storage, transporting, treating, and finally proper safe disposal of the waste separation and packaging of different colors that are part of the hospital policies and requirements that everyone must comply with which are actually part of the existing contract. Waste is sorted as follows: *Red bags* for isolation biological/contaminated waste, *yellow bags* for radioactive waste, *orange bags* for toxic waste, *blue bags* for general waste, and *black bags* for regular trash. *General waste*: Not considered infectious;

Infectious waste: Potentially infectious or hazardous, generated in the diagnosis, treatment, or immunization of human beings or animals. The categorization of hospital waste is given in the following text.

General Waste

It consists of all waste materials that are not regulated or defined as hazardous and do not require special handling and disposal. These wastes are sometimes referred to as nonregulated medical waste. General waste is generated by almost every aspect of the hospital including administration, support services, utilities and maintenance, patient rooms, nursing stations, food services (even this type of waste has some special disposal considerations), and many areas throughout the hospital. Although the above waste is not considered hazardous, such waste can pollute the environment. Therefore, in reducing solid waste by establishing recycling programs, all departments should be encouraged to reduce their waste and great effort is requested from all managers to plan for recycling or reusing, and if necessary modify the process in contribution to the reduction in waste.

Medical Waste

It is defined as all waste generated from healthcare facilities. The type of waste classified as medical waste may vary according to the institution in which it is generated. This type of waste is regulated and requires special handling and disposal. The different types of medical waste generated by hospitals are chemical, radioactive, and infectious.

Chemical Waste

Chemical waste includes substances such as:

- Germicides
- Cleaning solvents
- Pharmaceuticals
- Chemicals that have expired or are no longer used.

Chemical waste can create hazardous situations such as fire or explosion. It can harm health. Information on how to handle and store the chemical safely and its specific disposal is important. Always place materials and waste in the right bag and color-coded system. Do not pour chemicals down the drain. If you are not sure about chemical disposal, ask the Laboratory Hygiene Officer, Laboratory Safety Officer, Environmental Officer, or Safety Officer.

Radioactive Waste

Radioactive waste has dramatically increased with the recent advances in nuclear medicine and is found in:

- Iodine 123
- Iodine 131
- Thallium 201

Although radioactive materials and waste are the responsibility of the research center and all radioactive materials are disposed of in accordance with the Nuclear Regulatory Commission. We should mention that radioactive waste is any waste that contains or is contaminated with liquid or solid radioactive material. It is not generated by X-rays or other external beam therapy procedures. It is important to ensure that all disposing wastes are placed with the radiation sign in a yellow bag. Always keep radioactive waste separate from other types of waste.

Infectious Waste

Infectious waste is a very important part of the medical waste disposal because more employees and departments are directly involved with infectious waste than any other type of HAZMAT present in the hospital. Infectious materials are handled every day and include:

- Laboratory cultures
- Blood and blood products from emergency rooms, operating rooms, pathology laboratories, patient rooms, laboratories, clinics, dental clinics, autopsy, and blood bank
- Sharps
- Renal dialysis waste
- Contaminated animal carcasses, body parts, and bedding.

Infectious waste means any waste material that has the potential to carry disease. This includes the following.

Sharp Infectious Waste

Medical items such as scalpel blades and hypodermic needles require careful disposal into rigid, puncture-proof containers called *sharps boxes*. The broken or unbroken glass used in animal or patient care including items such as blood vials are sharps or potential sharps designated for incineration. Other glass and plastic material may be disposed of as solid waste in rigid containers designated for glass disposal. *Never* recap needles. *Do not* bend or break needles. *Always* dispose of used needles in *yellow puncture*-resistant containers. *Change* needle disposal containers when three fourth full. *Submit* an incident report if you are injured by a needle stick/sharp object/instrument. Objects must be labeled in leak-proof, puncture-resistant containers.

- The most effective method of protecting yourself is the implementation of universal precautions.
- Dispose of sharps properly.
- Never bend, shear, recap, or resheath by hand.
- Use a broom and dustpan to pick up broken glass.
- Follow the safety guidelines established for the use of protective clothing and equipment on the job.
- The incineration method is recommended for infectious waste as part of the contract. Incinerators must have the ability to destroy pathogens.

Chemotherapy Waste

It results from the production or use of an antineoplastic agent.

Radioactive Waste

It is related to the use of radioactive supplies, containers, and radioactive iodine.

DEGREE OF HAZARD IDENTIFICATION FOR HAZARDOUS MATERIALS

Below is a system for marking the degree of HAZMAT, which provides a simple and easily understood system. It also provides a general idea of the hazard of the materials and the severity of their hazards (**Table 1**).

HAZARDOUS MATERIAL SAFETY BOOKLET

Also known as material safety data sheet (MSDS), it is the cornerstone of the hazard communication guidelines. They provide information about the chemical substances within a product, safe handling procedures, first-aid measures, and

TABLE 1: Degree of hazard identification.

	Identification of health hazard (type of possible injury) Color code: Blue	*Identification of flammability (susceptibility of materials to burning) Color code: Red*	*Identification of reactivity (susceptibility to release of energy signal) Color code: Yellow*
Signal			
4	Materials that on very short exposure could cause death or major residual injury	Materials which will rapidly or completely vaporize at atmospheric pressure and normal ambient temperature or that are readily dispersed in air and that will burn readily	Materials that in themselves are readily capable of detonation or of explosive decomposition or reaction at normal temperatures and pressures
3	Materials that on short exposure could cause serious temporary or residual injury	Liquids and solids that can be ignited under almost all ambient temperature conditions	Materials that in themselves are capable of detonation or explosive decomposition or reaction but require a strong initiating source or which react explosively with water
2	Materials that on intense or continued but not chronic exposure could cause temporary incapacitation or possible residual injury	Materials that must be moderately heated or exposed to relatively high ambient temperatures before ignition can occur	Materials that readily undergo a violent chemical change at elevated temperatures and pressures or which react violently with water or which may form explosive mixtures with water
1	Materials that on exposure under fire conditions would offer no hazard beyond that of ordinary combustible material	Materials that must be preheated before ignition can occur	Materials that in themselves are normally stable, but which can become unstable at elevated temperatures and pressures
0	Materials that on exposure under fire conditions would offer no hazard beyond that of ordinary combustible material	Materials that will not burn	Materials that in themselves are normally stable, even under fire exposure conditions, and which are not reactive with water

procedures to be taken when a product is accidentally spilt. They must be provided from chemical distributors. All new information regarding certain chemical substances must be provided by the distributor. It is required that all departments using chemicals must maintain copies of the booklet and ensure that they are readily accessible to employees during all work shifts.

PERFORMANCE STANDARDS AND PERFORMANCE IMPROVEMENT

Safety Committee is responsible for monitoring the performance, tracking the events, and monitoring HAZMAT, and waste. Data and significant events, findings, and trends are reported to the committee at least annually to identify potential risk and possible opportunities for improvement. Upon approval, the reports become part of the committee's minutes and are submitted to the administration for review. Other HAZMAT and waste can also be monitors and may be tracked by the safety department. Annual evaluation of the Hazardous Materials and Waste Management Plan is reviewed and evaluated annually by the safety department. The purpose of this evaluation is to determine the degree to which actions taken during the previous year were effective in meeting the goals and objectives of the plan. Plans and policies are also evaluated after events that involve HAZMAT. Plan and policy improvements reflect institutional experiences, regulatory changes, or routine reviews of response protocol. The evaluation also provides a mechanism to determine opportunities for improvement for the next year. This determination forms the basis for setting goals and performance improvement standards for the future. The actions taken to achieve these goals are reviewed to assess their effectiveness. The data for this analysis derives from information supplied to the committee as part of its information collection and evaluation function, along with discussions with staff and record reviews. Opportunities to improve the effectiveness of the plan are identified during the review and evaluation process. Goals are then established for the coming year, along with recommendations for implementing processes necessary to achieve those goals. Performance monitors are reviewed to determine if modifications are necessary in response to the evaluation and established goals.

PERSONAL PROTECTIVE EQUIPMENT IN HAZARDOUS MATERIAL INCIDENTS

Biological, chemical, and radiologic materials that result in adverse effects on the health and safety of exposed individuals are termed HAZMAT. These substances represent significant risks to healthcare workers when hospitals receive patients contaminated with these materials. Therefore, hospitals and their workforce must be prepared to use PPE to protect themselves when these situations arise. There are four key issues, which must be fully understood whenever PPE is required: (1) Various types of PPE, (2) basics of a "hazard assessment," (3) how to select appropriate PPE, and (4) training in the proper use of PPE. It is only after these four key issues

have been adequately addressed that a properly equipped and well-trained healthcare staff facility can provide a safe and effective response.

Types of Personal Protective Equipment

Personal protective equipment are articles worn or equipment used to protect the user from harmful contaminants released into the environment. In this chapter, this means the PPE used by hospital personnel when decontaminating and caring for the patient(s) involved in a HAZMAT incident. The main function of PPE is to provide a barrier between the user and respiratory or skin exposure to the contaminant in the environment or on the skin/clothing of contaminated patients.

Personal protective equipment can be listed in the following categories:

- Respiratory protection
- Eye and face protection
- Hand protection
- Foot protection
- Body protection

A specific combination of PPE from each of these categories is normally needed to properly protect the wearer from each specific contaminant.

There are two primary types of respirators: (1) Air-purifying and (2) supplied air respirators. (1) *Air-purifying respirators (APRs)* have filters, cartridges, or canisters that trap contaminants from the air. APRs are the most common protection method for particulates and vapors and are used in environments where there is no chance of an oxygen-deficient state. Available filters should protect against, at a minimum, organic vapors and also contain a high-efficiency particulate air cartridge for particulates. (2) *Supplied air respirators* are used for oxygen-deficient atmospheres, provide breathable air from a clean source such as an air tank or air compressor located outside the contaminated area, and are suitable for use in an oxygen-deficient environment. Half-face pieces allow workers to wear any appropriate eyewear that does not interfere with the respirator seal, but they provide no eye protection themselves, and contaminated air can enter the mask if the seal is broken. Full-face pieces provide eye protection and a tight-fitting facepiece may be able to pull filtered air into the facepiece if the battery fails on a powered air-purifying respirators (PAPR). Various levels of PPE used in HAZMAT are summarized in **Table 2**.

SUMMARY

Various hazardous materials (HAZMAT), biological, chemical, and radiologic materials are present in and around the workplace that result in adverse effects to the health and safety of exposed individuals. Through the development of policies and procedures the health and safety of staff, patients, and visitors are protected and risks are minimized associated with hazardous materials. Policies and procedures are laid down regarding the selection, handling, storage, use and disposal of hazardous materials, and waste. Hazardous materials and hazardous waste streams include, but are not limited to: Chemical, biological, radioactive, pharmaceutical, chemotherapeutic, hazardous gases and mixed waste. Hazardous materials and waste are identified in and around the workplace, appropriately labeled, evaluated, inventoried, handled, managed, and monitored in compliance with applicable regulations to minimize

TABLE 2: Level of personal protective equipment for HAZMAT.

Level A protection	***Level B protection***	***Level C protection***	***Level D protection***
Highest level of protection for eye skin respiratory system from liquid vapors and gases (**Fig. 1A**)	Level B protection provides adequate skin protection but is not vapor impervious like Level A (**Fig. 1B**)	Level C protection should be used when the atmospheric contaminants, liquid splashes, or other direct contact absorbed through any exposed skin (**Fig. 1C**)	Level D protection is used when the atmosphere contains no known hazard, and hardly any possibilities of splashes, unexpected inhalation of or contact with hazardous levels of any chemicals (**Fig. 1D**)
Components of level A protection	*Components of level B protection*	*Components of level C protection*	*Components of level D protection*
• Positive-pressure, full-face piece, self-contained breathing apparatus (SCBA), or • Positive-pressure supplied-air respirator with escape SCBA • Totally encapsulating chemical-protective suit • Gloves, outer, chemical resistant • Gloves, inner, chemical resistant • Boots, chemical resistant, steel toe, and shank • The disposable protective suit, gloves, and boots	• Positive-pressure, full-face piece SCBA, or positive-pressure supplied-air respirator with escape SCBA • Hooded chemical-resistant clothing (one- or two-piece chemical splash suit; disposable chemical-resistant overalls). Gloves, outer, chemical resistant. Gloves, inner, chemical resistant. • Boots, outer, chemical-resistant steel toe and shank • Boot-covers, outer, chemical-resistant (disposable) • Face shield	• Full-face or half-mask, air-purifying respirators • Hooded chemical-resistant clothing (chemical splash suit) • Gloves, outer, chemical resistant • Gloves, inner, chemical resistant • Boots, outer, chemical-resistant steel toe and shank • Boot covers, outer, chemical-resistant (disposable)	• A work uniform affording minimal protection • Gloves • Boots/Shoes • Chemical-resistant steel toe and shank • Safety glasses or chemical splash goggles • Face shield

(PPE: personal protective equipment)

risk to staff, patients and visitors, and their impact on the environment. In response to hazardous materials spills, releases and exposures appropriate protocol should be implemented for reporting and investigating hazardous materials spills, releases, and exposures in order to provide the appropriate and effective response, and to prevent reoccurrences. During the emergency procedures to contain the spills specific precautions, equipment, and protective equipment to be used. Apart from this we need to ensure that employees are oriented to, and educated about the proper procedures to follow in order to protect themselves from exposure to hazardous materials. Environmental air monitoring surveys and work procedure analyses required to confirm the effectiveness of engineering and administrative controls. Administration needs to ensure that mandated licenses and permits are maintained in compliance with applicable law and regulations and the granting regulatory agency requirements. Mechanism needs to be established for the review, development, and dissemination of hazardous materials policies and procedures.

9 CHAPTER

Infection Prevention in Emergency Department

Josephine Cyrill, Angelika Masih

INTRODUCTION

Emergency departments (EDs) are the frontline providers for all the patients with disease and injuries, including infectious disease conditions. Sometimes, healthcare workers (HCWs) and other patients are often predisposed for the development of secondary infections. HCWs in emergency requires competency not only in the diagnosis and management of disease conditions but also in the control and prevention of the same. Infection control and prevention focus on reducing communicable and infectious disease transmission and preventing healthcare-associated infections.

It is highly recommended to practice measures such as standard infection control precautions (SICPs), transmission-based precautions (TBPs), and the prevention of healthcare-associated infections in the ED.

ADHERENCE TO STANDARD INFECTION CONTROL PRECAUTIONS

Adherences to SICPs, formerly known as "standard precautions," are an important part of the healthcare setting and are designed to offer protection against infections to both HCWs and patients. n SICP includes certain components which are shown in **Figure 1**.

Hand Hygiene

Hand hygiene is the foremost element of SICPs and one of the most effective approaches to prevent transmission of microorganisms. Hand hygiene refers to any action of hand cleansing, such as hand washing or hand rubbing.

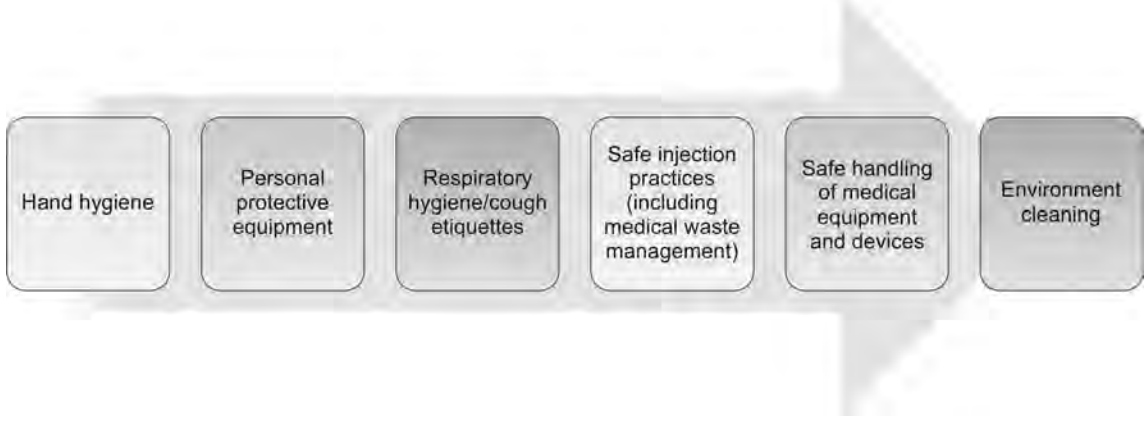
The Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) recommend hand hygiene before and/or after key actions while dealing with patients and have named it as *"five moments for hand hygiene"*: (1) Before touching the patient, (2) before the aseptic procedure, (3) after body fluid exposure or risk, (4) after touching the patient, and (5) after touching the patient's surroundings.

Personal Protective Equipment

Personal protective equipment (PPE) are wearable equipment that is designed to protect HCWs from exposure to or contact with infectious agents. Common PPE includes gloves, gown, face mask/respirator, goggles/eye shield, shoe cover, and cap.

Respiratory Hygiene/Cough Etiquettes

Respiratory hygiene/cough etiquette is integrated into infection control practices as a new element of standard precautions. This strategy targets all the patients and attendants with



Hand hygiene
Personal protective equipment
Respiratory hygiene/cough etiquettes
Safe injection practices (including medical waste management)
Safe handling of medical equipment and devices
Environment cleaning

FIG. 1: Standard infection control precautions.

Yellow	Red	White	Blue
• Human anatomical waste • Animal anatomical waste • Soiled waste items • Discarded or expired medicine • Chemical waste chemicals • Discarded linen, mattresses, beddings contaminated with blood or body fluid, routine mask and gown	• Wastes generated from disposable items such as tubing, bottles, intravenous tubes and sets, catheters, urine bags, syringes without needles, fixed needle syringes with their needles cut, vaccutainers, and gloves	• Waste Sharps including metals needles, syringes with fixed needles, needles from needle tip cutter or burner, scalpels, blades, or any other contaminated sharp object that may cause puncture and cuts This includes used, discarded and contaminated metal sharps	• Broken or discarded and contaminated glass including medicine vials and ampoules except those contaminated with cytotoxic wastes

FIG. 2: Biomedical waste management.

undiagnosed contagious respiratory infections and applies to any person with signs of illness while arriving to a healthcare facility.

Safety in Injection Practices (Including Medical Waste Management)

Injection safety practices focus on preventing the spread of transmissible infections from one patient to another or between a patient and healthcare worker in the course of preparation and administration of parenteral medications.

Bio Medical Waste Management Rules, 2016, sorts the biomedical waste generated from the healthcare facility into four kinds based on the color code and segregation process (**Fig. 2**).

Safe Handling of Medical Equipment and Devices

Safe handling of medical equipment/devices targets:

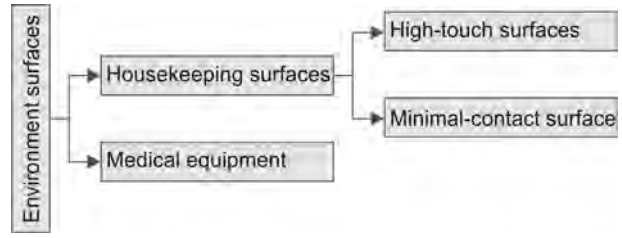
- To prevent the spread of microorganisms to HCWs and patients
- To minimalize inappropriate handling and further damage to medical equipment/devices from extraneous material (e.g., blood, body fluids, saline, and medications)

Environment Cleaning

Environmental cleaning plays a crucial role in the prevention of healthcare-associated infections. The Healthcare Infection Control Practices Advisory Committee (HICPAC) has divided environmental surfaces into two categories (**Flowchart 1**): (1) Medical equipment surfaces and housekeeping surfaces (e.g., floors, walls, tabletops) and (2) housekeeping surfaces which are further divided into "high-touch" surfaces (e.g., door handles, bedside rails, light switches) and minimal-contact surfaces (e.g., floors, ceilings). The cleaning of these surfaces highly depends on the possibility for direct patient contact, the degree and frequency of hand contact, and the risk of contamination with body materials or environmental sources of microorganisms (e.g., soil, dust, water).

PREDETECTION AND TRIAGE MANAGEMENT

Predetection and triage point areas should be equipped with sufficient and appropriate nontouch thermal scanning, hand hygiene products and supplies, PPE and disinfection facilities,



FLOWCHART 1: Categories of environmental surfaces.

etc. ED should have well-developed protocols for early detection and management of potentially infectious patients. HCWs should be well trained and strictly implement SICP protocols whenever necessary.

TRANSMISSION-BASED PRECAUTIONS

Transmission-based precautions are the infection control and prevention approaches which use a combination of PPE and patient isolation. TBPs in ED entirely depend on the patient's clinical presentation and diagnosis of the disease condition.

Transmission-based precautions include specific precautions—airborne, droplet, and contact—and generally require patient isolation (**Table 1**).

Airborne Spread

The particles, in the airborne spread, are smaller (≤5 μm) and remain suspended in the air for long periods. They tend to stay longer in the air and are transported by air during breathing, talking, coughing, and sneezing. Organisms spread via the airborne mode, e.g., measles, varicella, smallpox, highly pathogenic influenza, severe acute respiratory syndrome (SARS), and the Middle East respiratory syndrome (MERS) corona virus.

Droplet Spread

The droplets are usually large particles that are >5 μm. Droplet spread occurs via the upper respiratory tract (nose, nasal passages, and pharynx). Individuals in ED should practice distancing of at least 1 m to prevent the spread of infections from one to another. Droplet infectious agents include mumps, influenza, Neisseria meningitides (meningitis), and COVID-19.

Contact Precautions

Contact spread happens via direct contact with the infected person, the immediate environment, and/or the equipment

TABLE 1: Transmission-based precaution for selected microorganism.

Airborne	*Droplet*	*Contact*
• Tuberculosis • Varicella-zoster virus (chickenpox, disseminated zoster) • Measles • Smallpox	• Meningococcus • Seasonal influenza Rhinovirus, respiratory syncytial virus, German, measles, mumps, pertussis, diphtheria, pneumonic plague • SARS CoV-2, COVID-19	• MRSA • Vancomycin-resistant Enterococcus. Multidrug-resistant gram-negative bacteria (e.g., carbapenem-resistant Enterobacteriaceae, extended-spectrum β-lactamase producing bacteria) • *Clostridium difficile* • Norovirus • Lice, scabies
Highly pathogenic influenza Severe acute respiratory syndrome (SARS) Middle-east respiratory syndrome (MERS)		

(MRSA: Methicillin-resistant *Staphylococcus* aureus)

being used for the patient. It is the most common form of transmission and there are two types: (1) Direct and (2) indirect (**Fig. 3**). Examples of infections and organisms spread by the contact route are COVID-19, MRSA (methicillin-resistant *Staphylococcus aureus*), *Escherichia coli*, and *Clostridium difficile*.

High-consequence Infectious Diseases

High-consequence infectious diseases (HCIDs) may be transmitted by contact, droplet, or an airborne route or by a combination of any of these. HCID is an acute infectious disease which:

- Typically has a high case-fatality rate
- May not have effective prophylaxis or treatment
- Is often difficult to recognize and detect rapidly
- Is able to spread in the community and within healthcare settings
- Requires an enhanced individual, population, and system response to manage effectively, efficiently, and safely

Transmission-based Precautions in Practice

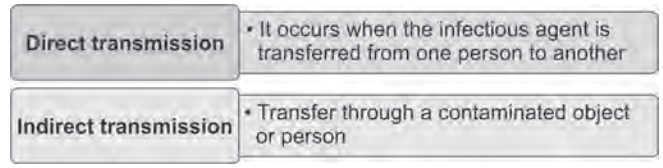
Contact precautions are the most common type of TBPs. Use of N95 masks, single-room isolation with negative pressure (≥12 air exchanges per hour), and airborne precautions by clinicians and other healthcare staff in the ED is mandatory. Continuous audit, training, and adherence to protocols are needed. In case of nonavailability of a negative-pressure room, a well-ventilated single room is required specially to prevent transmission during aerosol-generating procedures (AGPs).

Aerosol-generating procedures:

- Intubation, extubation, and other procedures
- Tracheostomy
- Manual ventilation
- Open suctioning
- Bronchoscopy
- Noninvasive ventilation
- High-frequency oscillating ventilation
- High-flow nasal oxygen

Points to remember:

- Training
- Cleaning and disinfection of high-risk areas such as isolation room
- PPE usage, donning/doffing



Direct transmission
• It occurs when the infectious agent is transferred from one person to another
Indirect transmission
• Transfer through a contaminated object or person

FIG. 3: Direct and indirect contact transmission.

- Biomedical waste (BMW) practice
- Hand hygiene compliance
- Healthcare personnel vaccinations

The CDC recommends annual influenza vaccination for healthcare teams. Immunization programs ensure immunity to most of the vaccine-preventable diseases.

DISINFECTION AND STERILIZATION OF REUSABLE MEDICAL DEVICES

It is done as per the organization's protocols and policy. In most of the hospitals, cleaning, disinfection, and sterilization are done centrally in central sterile services department (CSSD). The ED has many equipment which are mainly categorized as critical and noncritical devices according to the *Spaulding classification system* (**Fig. 4**).

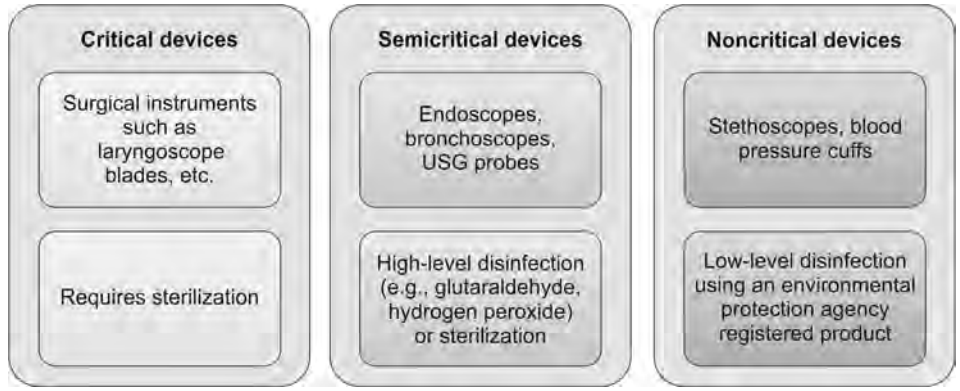
The following steps have to carefully be monitored:

- Precleaning of surgical instruments before sending them for sterilization
- Use of recommended disinfectants and their dilution
- Training by the infection control team and regular audits
- Awareness on material safety data sheet (MSDS) of chemicals to prevent occupational hazards

Routine cleaning and high- and low-level disinfection ensure patient safety and adherence to infection control recommendations.

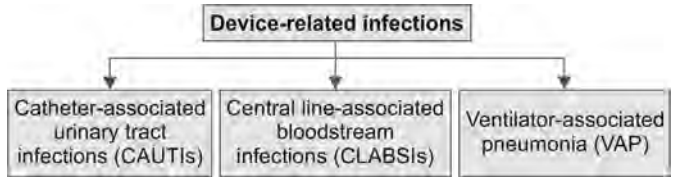
DEVICE-ASSOCIATED INFECTIONS

Device-associated infections are one of the largely preventable sources of healthcare-associated infections (HCAIs). Device-related infections can be categorized into catheter-associated urinary tract infections, central line-associated bloodstream infections, and ventilator-associated pneumonia (**Flowchart 2**).



Critical devices
Surgical instruments such as laryngoscope blades, etc.
Requires sterilization
Semicritical devices
Endoscopes, bronchoscopes, USG probes
High-level disinfection (e.g., glutaraldehyde, hydrogen peroxide) or sterilization
Noncritical devices
Stethoscopes, blood pressure cuffs
Low-level disinfection using an environmental protection agency registered product

FIG. 4: Spaulding classification system for medical devices.



FLOWCHART 2: Device-associated infections.

Care bundles have been formulated based on evidence-based research work and best considered practice. Bundles are a powerful weapon against hospital-acquired infections. The EDs require thorough knowledge of the care bundles to prevent HCAI and deliver optimal patient care.

Catheter-associated Urinary Catheter Infections

Although urinary catheter insertion is necessary for emergency care, catheter-associated urinary catheter infections (CAUTIs) are one of the common infections attributing to HCAI. The CDC and the Society for Healthcare Epidemiology of America (SHEA) recommend limited usage of urinary catheterization for managing acute urinary retention and bladder outlet obstruction and accuracy in urine output measurement in critically ill patients, clinical situations, patients who require prolonged immobilization (e.g., pelvic fracture, spine trauma), and selected surgical procedures. The CAUTI maintenance bundle is to enhance the patient care requiring urinary catheterization during acute care and to make certain that urinary catheters are removed as soon as clinically indicated.

Central Line-associated Bloodstream Infections

Central line-associated bloodstream infections (CLABSIs) are a critical infection causing prolongation of hospital stay and increased expense and risk of mortality. CLABSIs are prevented through proper insertion skills and management of the central line catheters. Insertion and maintenance bundles are implemented for reducing the risks for CLABSIs. Multiple organizations in collaboration have given guidelines that comprise education, procedure checklists, a standardized catheter cart or kit, hand hygiene, use of maximal sterile barrier precautions (sterile surgical gown, sterile gloves, mask, cap, and sterile drape), chlorhexidine-alcohol skin antisepsis, and use of ultrasound guidance.

Ventilator-associated Pneumonia

Emergency airway management and resuscitation necessitate endotracheal intubation and mechanical ventilation. Ventilator-associated pneumonia (VAP) is defined as the diagnosis of a new pneumonia after >48 hours of mechanical ventilation, not present at the time of intubation. Endotracheal intubation in the ED and prolonged ED stay have also been related to high VAP rates in comparison with the intensive care unit (ICU). The CDC guidelines provide a basic framework for VAP prevention strategies, including:

- Head elevation of the bed to 30–45°
- Oral care with chlorhexidine
- Daily sedation and vacation
- Subglottic suctioning
- Pressure ulcer prophylaxis
- Deep vein thrombosis (DVT) prophylaxis

Nursing engagement is vital for successful implementation of these bundles.

EDUCATION AND TRAINING

Staff training and education play an essential role in improving compliance with infection control practices measures in the ED. Continuing nursing education help staffs to develop the ability to identify patients with transmissible indications during triage and thereby swiftly implement the required prevention and control methods. Ongoing in-service education and competency-based training of HCWs are necessary to ensure that infection prevention policies and procedures are well understood and followed.

SUMMARY

Healthcare workers should practice infection control and prevention practices as a part of our basic responsibility toward the patients. Hand hygiene remains the vanguard for the prevention of HCAI spread. SICPs, TBPs, environmental cleaning, and care bundles provide additional levels of protection to patients and HCWs. Moreover, staff training and education regarding infection control practices play an essential role. Healthcare facilities are encouraged to refer and further augment their own system and implement in clinical practice.

10
CHAPTER

Personal Protective Equipment

TV Ramakrishnan, Akilan Elangovan

INTRODUCTION

Healthcare-associated infections (HCAIs) can occur in any healthcare setting. It is the responsibility of every healthcare worker (HCW) to follow the basic principles of infection prevention and control (IPC). The goal is to improve the safety and well-being of health personnel and to avoid transmission of HCAI by following standard precautions.

STANDARD PRECAUTIONS

Standard precautions are a group of IPC practices applied to all patients, at every patient encounter, irrespective of their suspected or confirmed infection status. The basic principle is that all blood, body fluids, secretions, and excretions contain transmissible infectious agents. Hence, the implementation of standard precautions helps to maintain a physical, mechanical, or chemical barrier between microorganisms, the environment, and an individual, thus breaking the disease transmission cycle. These precautions include hand hygiene, use of personal protective equipment (PPE) (gloves, gown, mask, protective eyewear), respiratory hygiene/cough etiquette by patients or HCWs, safe injection practices with proper disposal of sharps, device sterilization, environmental cleaning, and disinfection. Wearing PPE is one such standard precaution, which creates a two-way protective barrier between the HCW and the patient by reducing the risk of transmitting microorganisms, which in turn prevents hospital-acquired infections (HAIs).

PERSONAL PROTECTIVE EQUIPMENT

Personal protective equipment, as defined by the Centers for Disease Control and Prevention (CDC), refers to a variety of protective barriers and respirators used alone or in combination by the HCW to protect the airway, mucous membrane, skin, and clothing from contact with infectious agents. Various PPE used in healthcare include gloves (nonsterile or sterile), mask, respirator, protective eyewear (face shield, goggles, or safety glasses), gown, apron, and other items (headcover, hood, closed-toe shoes, and shoe covers). The most crucial step that one should follow before wearing PPE is hand hygiene. PPE prevent the spread of pathogens (**Table 1**).

HAND HYGIENE

Hand hygiene is the single most crucial method in standard precautions of IPC. It provides the first line of defense in the prevention of transmission of microorganisms in healthcare facilities. The World Health Organization (WHO) recommends *"my five moments for hand hygiene"* which include: (1) Before direct contact or touching the patient; (2) Before performing clean/aseptic procedures on the patient; (3) After contact with blood, body fluids, mucous membranes, nonintact skin, wound dressings, or visibly contaminated; (4) After direct contact or touching the patient; and (5) After touching the patient's surroundings or inanimate objects (including medical equipment) in the immediate vicinity.

To facilitate effective hand hygiene, always perform with sleeves "rolled up" above the elbow, remove any hand or wrist jewelry, keep nails short, use water and liquid soap (if hands are soiled), or an alcohol-based hand rub (ABHR) (if not soiled). ABHR is an effective, inexpensive, and practical alternative to soap and water. ABHR is faster and easier to perform than handwashing with soap and water. It should be performed at every room entry and exit and before any procedure. The use of ABHR has been associated with improved hand hygiene compliance rates and reductions in nosocomial infections. The technique for hand hygiene is summarized by the WHO, which recommends a six-step sequence with liquid soap and ABHR.

TYPES OF PERSONAL PROTECTIVE EQUIPMENT USED IN HEALTHCARE SETTINGS

For PPE to be effective, they must be readily available, provide adequate protection, and be utilized correctly in the appropriate situations and settings. Various types of PPE are used in combination depending on the suspected or known infectious pathogen and its route of transmission.

Gloves

Gloves are the most common and crucial type of PPE used. They serve as a physical barrier, which protects the hands of HCW from contamination with infectious materials and

TABLE 1: Role of personal protective equipment in preventing the spread of pathogens.

Source for pathogen		*Mode of transmission*	*Protective barrier*	*Protection offered*
From healthcare workers	Hands	Touching	Hand hygiene and gloves	Patients, HCW
	Body and skin	Touching	Scrub suit, uniform, gown, apron	
	Nose and mouth	Coughing, talking	Surgical mask, N95 respirator	
	Hair	Shedding scalp hair or facial hair	Headcover, facial hair cover	
From patients	Mucous membranes and nonintact skin	Touching	Hand hygiene and gloves	HCW, patients
	Blood and body fluids	Touching (surface and instruments)	Utility gloves, environmental cleaning, instrument sterilizing and decontaminating reusables	
		Splashing or spraying	Gloves, protective eyewear, mask, gown, apron, head, and shoe cover	HCW
		Infectious waste	Utility gloves, protective eyewear, mask, apron, plastic bags, and appropriate disposal.	HCW, community
	Respiratory secretions	Splashing or spraying	Surgical mask, N95 respirator (for HCW)	HCW, patients, community
Hospital environment		Touching	Hand hygiene and environmental cleaning	HCW, patients

(HCW: healthcare worker)

Sources: 1. Modified from Melanie S. Curless, Bria S. Graham-Glover, Reprolineplus.org, Jhpiego. [online] Available from http://reprolineplus.org/system/files/resources/IPC_M3_PPE.pdf [Last accessed June, 2021].

2. Tietjen LG, Bossemeyer D, McIntosh N. Infection Prevention: Guidelines for Healthcare Facilities with Limited Resources. Baltimore, MD: Jhpiego; 2003.

reduces the likelihood of colonization with microorganisms from the patient. They are worn by HCW when anticipating contact with infectious materials, namely blood, bodily fluids, secretions from mucous membranes, nonintact skin, or potentially contaminated intact skin and when handling equipment that may have been in contact with these. The gloves must be removed correctly and should be followed by complete hand hygiene to prevent the risk of transmission of infections to vulnerable patients.

Selection of Glove

Sterile gloves are worn by surgeons and other healthcare personnel when performing sterile or aseptic procedures, namely surgical, invasive radiological, or vascular procedures. Nonsterile gloves are single-use, disposable ones worn by most HCWs when performing routine patient care activities. They are made of latex, vinyl, or nitrile and their choice should be determined by the degree of risk of exposure to blood or potentially infected body fluids, length of time required for the procedure, and the possibility of allergy (to latex) for HCWs.

Dos and Don'ts for Gloves

Gloves should fit the user's hands correctly to avoid limitations in performing the task. They may be damaged more easily if they are not of the correct size. Gloves should be changed between patient encounters and when they get torn or visibly contaminated, namely between each patient and between different procedures on the same patient to prevent cross-contamination of body sites or contamination of medical equipment. The HCW should not touch their face or environmental surfaces or adjust PPE with contaminated gloves. Gloves are single-use and should never be decontaminated, washed, reused, or shared with another user. They must be discarded into the appropriate waste container immediately after use. They are not an alternative to hand hygiene. Hands should be decontaminated thoroughly with soap and water or ABHR.

Gown/Apron

Gown provides a fluid-resistant barrier that protects the HCW's skin from splashes and spills. It avoids soiling or contamination of clothing during procedures and patient-care activities, when there may be possible contact with blood, body fluids, secretions, excretions, or objects. There are three types of protective gowns used in healthcare facilities: (1) Isolation gowns, (2) Surgical gowns, and (3) Coverall suits with hood. The gown should fully cover the torso, fit comfortably over the body, and have long sleeves that fit snuggly at the wrist, thus providing 360° protection. They are of single-use and preferably disposable. Plastic aprons provide a waterproof barrier along the front of the body (i.e., front torso), protecting the skin of the HCW from contamination with blood and other body fluids during patient care or handling soiled items.

Selection of Gown

Selecting the appropriate gown is based on the type of patient interaction, including the anticipated degree of contact with infective material, the potential for blood and body fluid penetration of the barrier, and the kind of task or procedure to be performed by the HCWs.

Plastic aprons are the preferred PPE for standard precautions. Sterile gowns are necessary for a sterile procedure such as central line insertion or a surgical procedure in an operating room to protect the sterile field. During standard precautions, an isolation gown is worn if blood or body fluid contact, spills, or splashes onto clothing is anticipated.

During contact and droplet precautions, an isolation gown is used to prevent transmission of an infectious agent that cannot be prevented by standard precautions alone. Isolation gowns should be worn in combination with gloves and other PPE depending on the various routes of transmission of the pathogen, as recommended.

Dos and Don'ts for Gown

Gowns should be changed routinely during shifts and between patients or between different procedures on the same patient when visibly soiled. Remove the gowns carefully using ties and be careful not to touch the outer surface and always decontaminate hands thoroughly after removal of gown and gloves.

Protective Eyewear

The mucous membrane of the eyes is a susceptible portal of entry for infectious agents (e.g., respiratory tract and bloodborne pathogens) from exposure to respiratory or aerosolized droplets and splashes of blood, body fluids, secretions, or excretions. Hence, protective eyewear is used to shield eyes and the surrounding skin from potential risks of transmission, while performing procedures of close proximity (e.g., aerosol-generating procedures or invasive vascular procedures). Goggles, safety glasses, masks with an attached shield, and full-face shields are used according to the need anticipated during procedures and patient-care activity.

Selection of Protective Eyewear

Eyes can be protected either by wearing goggles or by a visor, but these do not protect from splashes or sprays to other parts of the face. Face shields can be used as an alternative to goggles, as they extend from the chin to the crown of the head and wrap around the sides and hence provide better face and eye protection from splashes and sprays. The choice of eyewear for a specific work situation depends upon the type of exposure, other PPEs used, and the HCW's vision needs.

- As part of standard precautions (if the risk of spraying or splashing is anticipated)
- As part of droplet precautions to protect from respiratory secretions
- As part of contact precautions during procedures that involve spraying or splashing of blood and body fluids
- During specimen collection or aerosol-generating procedures in patients with specific respiratory tract pathogens

Dos and Don'ts for Protective Eyewear

Personal eyeglasses and contact lenses are not an alternative to eyewear. The eyewear should fit comfortably over and around the eyes and allow sufficient peripheral vision. It should fit over personal prescription lenses and provide antifog features to help maintain clarity of vision. It is of single-use and preferably disposable. If reusable, it should be placed separately after use and decontaminated. Hand hygiene should be performed after removing the eyewear.

Masks and Respirators

Masks cover the mouth and nose to protect the respiratory tract from inhalation of respiratory droplets, transmitted by coughs or sneezes from patients with infected or suspected respiratory tract pathogens via droplet or airborne transmission.

The choice of particulate respirators is selected based on the natural fit and the protective factor expected. The filtering efficiency of the N95/ FFP2 respirator is at least 95% and that of N99/FFP3 respirator is at least 99% of tiny test particles (0.3 μm).

Powered air-purifying respirators (PAPRs) are an alternative to particulate respirators that use high-efficiency particulate air filters (HEPA) and a battery-powered blower to provide filtered air to a hood. PAPRs are more expensive than particulate respirators and require electricity to charge the battery. A comparison of surgical mask and respirator is given in **Table 2**.

Headcover/Hood

Headcovers or hoods are most often worn during surgery and in procedure areas where a sterile field is required. They are not necessary for most other regions of the healthcare facility. Headcovers are not part of routine PPE for contact, droplet, or airborne precautions unless used during pandemic outbreaks. These are used to protect the HCW's hair and scalp from the spread of infectious pathogens by droplet or airborne transmission.

Footwear/Shoe Cover

Sturdy shoes with closed toes are recommended for all clinical areas, as these decrease the risk of exposure to blood, body fluids, or other potentially infectious materials and avoids injuries by sharps. Open-toe slippers and flip flops are not appropriate footwear for safety concerns in healthcare settings. Shoe covers are not part of routine PPE for contact, droplet, or airborne precautions unless used during pandemic outbreaks. This is because they do not prevent transmission of the pathogen from the floor but rather prevent contamination of shoes with blood and body fluids. If shoe covers are used, dispose them properly and perform hand hygiene immediately after removing them.

DONNING AND DOFFING PERSONAL PROTECTIVE EQUIPMENT

Personal protective equipment are used as a part of standard precautions, transmission-based precautions in an operating room, isolation rooms, and during disease outbreaks (e.g., novel respiratory disease). The sequence of donning and doffing PPE depends upon the purpose for which the PPE is being used. Failure to properly don and doff PPE in the correct sequence could lead to exposure to infectious agents.

Key Points About How to Safely Use Personal Protective Equipment

Carefully wear them before you have any contact with the patient, generally before entering the room. Once you have PPE on, check for proper fit and use them carefully. Avoid touching the face and unwanted surfaces to prevent contamination. Change, when torn or heavily contaminated. After completing your tasks, remove the PPE carefully and discard it in the containers provided. Perform hand hygiene either by hand rub or by handwash before moving on to the next patient.

TABLE 2: Comparison of surgical mask and respirator.

	Surgical mask	*Respirator*
Testing and approval	• Approved by the US Food and Drug Administration (FDA)	• Evaluated, tested, and approved by the US National Institute for Occupational Safety and Health (NIOSH)
Intended use and purpose	• Fluid resistant and protects from inhalation of large droplets of >5 µm in size transmitted by splashes or sprays of bodily or other hazardous fluids. Also, it protects the patient from the wearer's respiratory emissions • Do not filter or block tiny particles in the air that may be transmitted by coughs, sneezes, or specific aerosol-generating procedures	• Protects from inhalation of tiny droplet particles <5 µm or less in size transmitted by cough, sneeze, talk, or undergo aerosol-generating procedures (nebulization, suctioning, intubation, and resuscitation)
Indication for usage at work	• Patients with respiratory secretions, to protect healthcare workers from patients' infectious material (such as aerosols containing blood or body fluids) • Patients undergoing sterile procedures (including central line insertion, invasive spinal procedures), to protect patients from respiratory aerosols generated by healthcare personnel performing the procedure • Besides, masks should be worn by patients with respiratory secretions who are coughing to limit the spread of infectious secretions to other patients and healthcare workers	• As part of droplet precautions to protect from respiratory secretions during invasive respiratory procedures of close proximity (sputum collection, endotracheal suctioning, intubation) • As a part of airborne precautions to protect from infectious pathogens transmitted by airborne particles • During aerosol-generating procedures (nebulization, intubation, and resuscitation) on patients with specific respiratory tract pathogens (TB, SARS-CoV-2, novel respiratory viruses) that can spread via droplet or airborne route
Face seal fit	• Loose-fitting mask as they are not designed to form a tight seal around the nose and mouth	• Tight-fitting, hence usually challenging to breathe through. One must undergo medical evaluation to determine that it is safe to wear a respirator, fit test for the appropriate respirator size and type, and training on how and when to use a respirator. Facial hair interferes with the proper fit of masks
Fit testing requirement	• Not required as they are loose-fitting by design	• Required every time the respirator is donned and with any change in physical characteristics affecting the fit
Seal check requirement		
Filtration	• Does not provide the wearer with a reliable level of protection from inhaling smaller airborne particles and is not considered respiratory protection	• Filters out at least 95% of airborne particles, including large and small particles
Leakage	• Leakage occurs around the edge of the mask when the user inhales, hence does not provide complete protection from contaminants	• When properly fitted and donned, minimal leakage occurs around the edges of the respirator when the user inhales
Use limitations	• Single-use, disposable. Not to be shared or reused. Discard after each patient encounter	• Ideally should be discarded after each patient encounter and after aerosol-generating procedures. It should also be discarded when it becomes damaged or deformed, no longer forms an effective seal to the face becomes wet or visibly dirty, breathing becomes difficult, or becomes contaminated with blood, respiratory or nasal secretions, or other bodily fluids from patients

(SARS-CoV-2: severe acute respiratory syndrome coronavirus disease-2; TB: tuberculosis)

Source: Modified from Centers for Disease Control and Prevention National Institute for Occupational Safety and Health. Difference between the surgical mask and N95 respirator. [online] Available from https://www.cdc.gov/niosh/npptl/pdfs/UnderstandDifferenceInfographic-508.pdf [Last accessed June, 2021].

How to Don a Gown

Perform hand hygiene. Select the gown of the right size and appropriate type for the task. Unfold the gown and insert both hands in the sleeves of the gown, one after the other. Completely cover the torso from neck to knees, arms to the end of the wrists, and wrap around the back. Ensure that the opening of the gown is in the back. Secure both sides using the tie at the neck and the waist (seek help if needed). Make sure that you tie the waist knot on the side so that it is easy to untie at the time of removal (**Fig. 1**).

How to Don a Mask

Masks are fastened either with ties or with an elastic band. If the mask has ties, place the mask over your mouth, nose, and chin. Fit the flexible nosepiece to the form of your nose bridge; tie the upper set at the back of your head and the lower set at the base of your neck. If a mask has elastic bands, pull and place behind the ears and secure them comfortably. Adjust the mask to ensure that it is secure and fit snuggly around your face, so there are no gaps (**Fig. 2**).

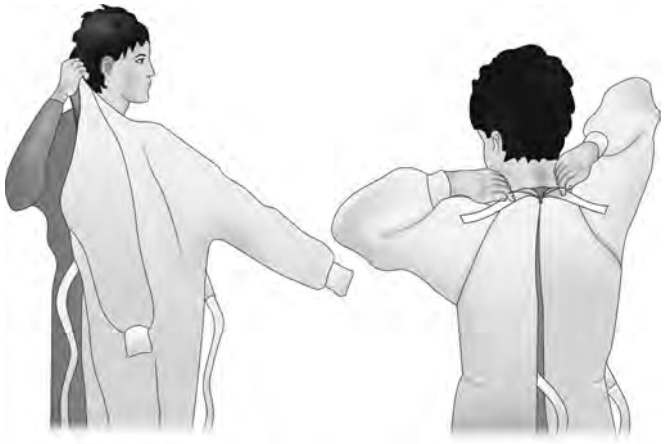

FIG. 1: Donning a gown.

FIG. 2: Donning a mask.

How to Don a Particulate Respirator

Donning a particulate respirator is similar to a mask with elastic bands. Cup the respirator in one hand and the nosepiece at the fingertips, allowing the headbands to hang freely below your hand. Position the respirator under the chin first with the nosepiece up. Pull off the top strap over your head, resting it high at the top back of your head. Pull off the bottom strap over your head and position it around the base of the neck, below the ears. Perform "fit test" to verify that the respirator is both comfortable and its size fits correctly. Now place two fingertips from both hands at the top of the metal nose clip. Slide fingertips down both sides of the metal strip to mold the nose area to the shape of your nose. Perform "seal check test" to verify that the particulate respirator is properly sealed without leakage. A successful negative pressure check is when while inhaling the respirator collapses slightly under the negative pressure that is created, and a positive pressure check is when while exhaling the respirator is somewhat pressurized before increased pressure causes outward leakage (**Figs. 3A** to **C**).

How to Don Goggles or Face Shield

Put on protective eyewear after putting on the gown and mask. Either goggles or a face shield must be worn over the face and eyes and secured to the head using the attached earpieces or headband. Adjust to fit comfortably and assess the field of vision. Goggles should feel snug but not tight (**Figs. 4A** to **C**).

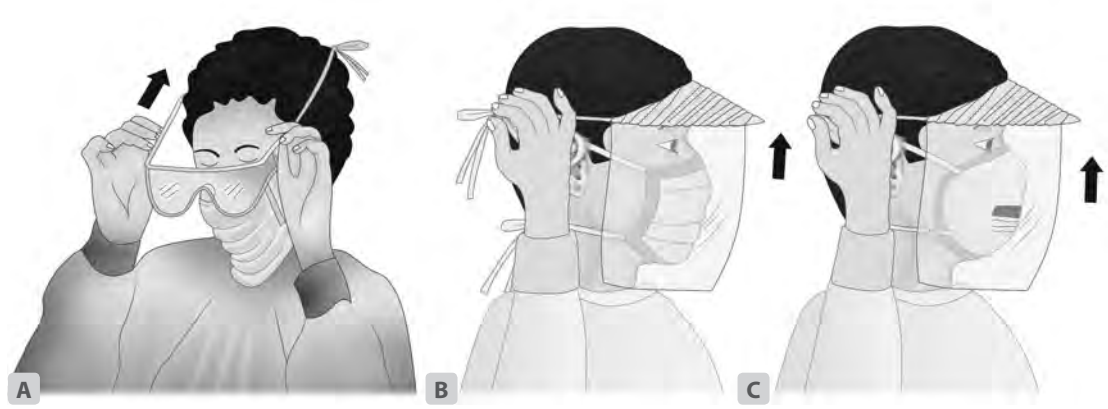
How to Don Gloves

The last PPE to be donned is the gloves. Select the appropriate type of glove needed for the task, in the size that best fits you. Insert each hand into the suitable glove and adjust as needed for comfort and fit. If you are wearing an isolation gown, secure the end of the gloves over the gown cuffs. This offers continuous barrier protection for your skin. Once gloved, hands should not touch anything else that is not defined by indication for glove use (**Fig. 5**). Check for complete coverage and proper fit of the PPE before approaching the patient (**Fig. 6**).

Key Points About How to Safely Doff Personal Protective Equipment

Personal protective equipment should be removed promptly and disposed of properly. To remove PPE safely, first, identify the sides which are considered clean or contaminated.

FIGS. 3A TO C: Donning particulate respirator. (A) Wearing; (B) Fit test; (C) Seal check.



FIGS. 4A TO C: Donning eye and face. (A) Goggles with mask; (B) Face shield with mask; (C) Face shield with N95.

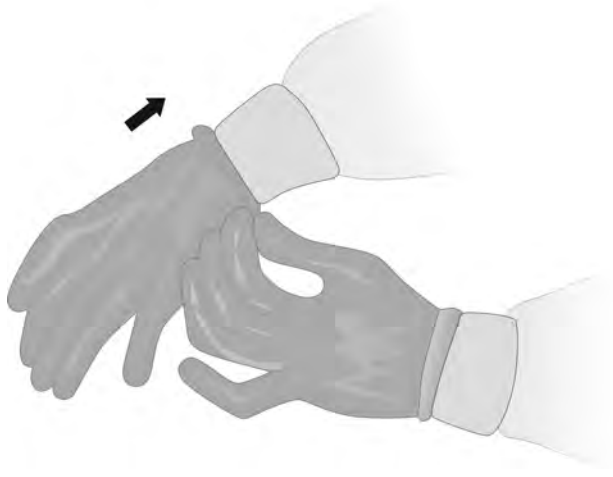


FIG. 5: Donning gloves.

(PPE: personal protective equipment)

FIG. 6: Full PPE.
Courtesy: Srinath Senthil.

Generally, the outside front and sleeves of the gown and the outer aspect of the goggles, gloves, mask, and face shield are considered contaminated, regardless of whether it is visibly soiled. The sites that are considered clean are the parts that will be touched when removing PPE, namely inside the gloves, inside and back of the gown, including its ties, and the ties or elastic bands of the mask, goggles, and face shield. The sequence for removing PPE is gloves, face shield or goggles, gown, and mask or respirator.

How to Doff Gloves

Using one gloved hand, carefully hold the outer part of the opposite glove near the wrist. Pull and peel off the glove away from the hand. The glove must now be turned inside-out, with the contaminated side on the inside. Remain to hold the removed glove in the opposite gloved hand; now slide one or two fingers of the ungloved hand beneath the wrist of the remaining glove. Peel gloves off from the inside, making a bag for both gloves. Discard in the appropriate container (**Fig. 7**).

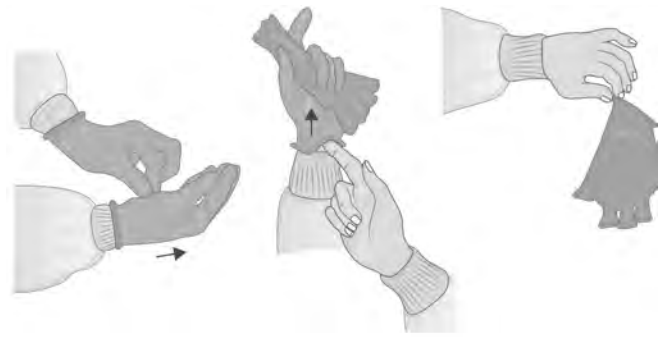

FIG. 7: Doffing gloves.

How to Doff Goggles or Face Shield

Do not grab the front of goggles or face shields as they are contaminated. Using ungloved hands, grasp the clean earpiece or headpiece and lift away from the face. If the goggle or face shield is reusable, place it in a designated container for subsequent reprocessing. Otherwise, discard it in the appropriate container (**Figs. 8A** to **C**).

How to Doff a Gown

The front and sleeves of the gown are contaminated. Unfasten the gown ties by first releasing the neck knot, being sure not to

FIGS. 8A TO C: Doff goggles or face shield. (A) Goggles with mask; (B) Face shield with mask; (C) Face shield with N95.

contaminate the neck, followed by the side knot. Slip hands beneath the gown at the neck and shoulder and peel away from the shoulders. Slip the fingers of one hand beneath the cuff of the opposite arm. Now pull the hand into the sleeve, grasping the gown from inside. Then reach across and push the sleeve of the opposite arm. Fold the gown inside out and roll into a bundle, ensuring that you avoid touching the gown's outer surface. Dispose of the gown in a contaminated-waste container (**Fig. 9**).

How to Doff a Mask

The respirator or mask should be removed last and outside the patient room or in an anteroom after removing all other PPE, including gloves. Do not touch the front of the mask, as it is considered most contaminated. Remove by handling the bottom ties or elastic bands first, followed by the top tie or band. Move the mask away from the face and discard it into the designated waste container (**Fig. 10**).

How to Doff a Respirator

Pull off the bottom elastic strap around the neck first and then pull off the top strap over your head. This must be performed slowly to prevent the respirator from snapping off the face. Remove it without touching the front of the respirator, which may be contaminated. Discard the respirator immediately.

Perform Hand Hygiene

Hand hygiene is a crucial infection control practice to protect patients, healthcare personnel, and visitors and is required for both standard and transmission-based precautions. Hand hygiene must be performed immediately before and after removing PPE, even during PPE changes, and between patient contacts. Wash your hands methodically with soap and warm water or, if hands are not visibly soiled, use an ABHR (**Fig. 11**).

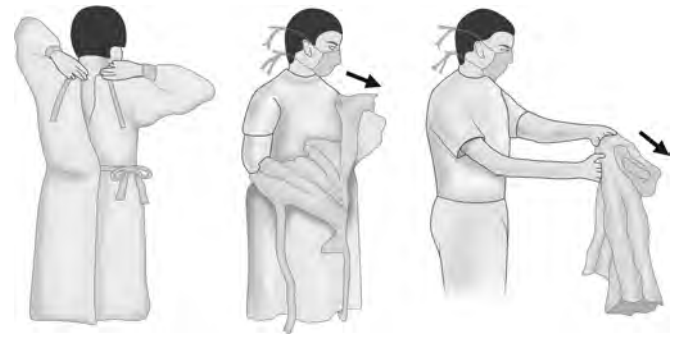

FIG. 9: Doff isolation gown.

FIG. 10: Doff a mask and respirator.
Courtesy: Srinath Senthil.

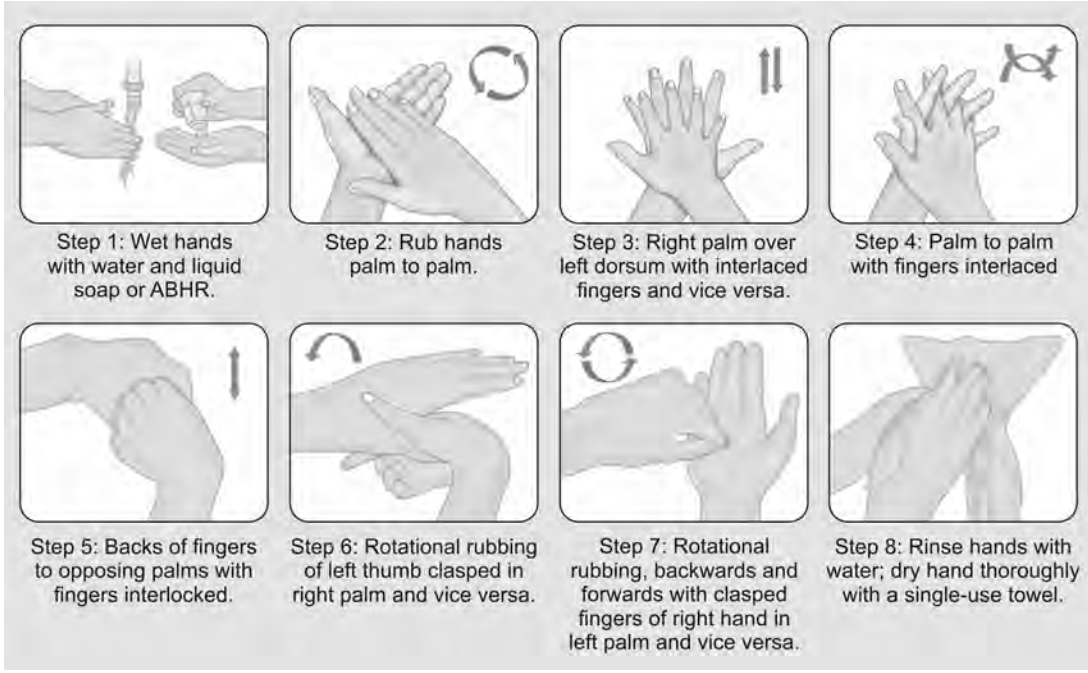
SELECTING THE APPROPRIATE PERSONAL PROTECTIVE EQUIPMENT FOR HEALTHCARE WORKERS

The decision made regarding the selection of PPE is determined by CDC recommendations for standard precautions and transmission-based precautions (i.e., exposure to blood, body fluids, infectious agents, and the likely mode of transmission).

The HCW must select appropriate PPE according to the risk assessment done, which is not based on the clinical presentation or diagnosis of the patient but rather on the potential of the HCW coming into contact with infectious materials, namely blood, body fluids, mucous membranes, or respiratory droplets, during each task and procedures undertaken. Decisions should be based on the suspected or identified infectious agent, transmission route of the infectious agent, patient care setting, and tasks or procedures performed.

TRANSMISSION-BASED PRECAUTIONS

Transmission-based precautions are used additionally for patients who are known or suspected to be infected or colonized with those infectious agents that require additional control measures to prevent transmission of infection in



Step 1: Wet hands with water and liquid soap or ABHR.
Step 2: Rub hands palm to palm.
Step 3: Right palm over left dorsum with interlaced fingers and vice versa.
Step 4: Palm to palm with fingers interlaced
Step 5: Backs of fingers to opposing palms with fingers interlocked.
Step 6: Rotational rubbing of left thumb clasped in right palm and vice versa.
Step 7: Rotational rubbing, backwards and forwards with clasped fingers of right hand in left palm and vice versa.
Step 8: Rinse hands with water; dry hand thoroughly with a single-use towel.

(ABHR: alcohol-based hand rub)

FIG. 11: Steps of hand hygiene.

Courtesy: Srinath Senthil.

health care facilities effectively. They are intended to decrease the risk of contact, droplet, and airborne transmission among hospitalized patients and the HCWs, when the disease transmission cycle is not entirely interrupted using standard precautions. They are used empirically, according to the clinical syndrome and the likely etiologic agents at the time of admission, and then modified when the pathogen is identified or a transmissible infectious etiology is ruled out. They are categorized according to the route of transmission of the infectious agent, namely contact precautions, droplet precautions, and airborne precautions.

LEVELS OF PERSONAL PROTECTIVE EQUIPMENT AND TYPES OF PRECAUTIONS FOR INFECTION CONTROL

Table 3 outlines the recommended PPE to minimize the risk of cross-transmission of infection to self and others when providing patient care.

OPTIMIZING PERSONAL PROTECTIVE EQUIPMENT USAGE DURING CRISIS

The CDC offers guidance on optimizing PPE supply during a crisis, when sudden increases in patient volume affect the existing infrastructure and resource capacity. These strategies include:

- Cancelling nonurgent surgical procedures
- Implementing standard precautions at all healthcare facilities for all patients at all times
- Using appropriate PPE based on the suspected route of transmission
- Prioritizing the use of specific PPE for only the highest risk of interventions on patients
- Minimizing face-to-face encounters with the patient by designating entire units within a facility, to care for infected or suspected patients in isolation (i.e., cohorting), limiting the number of people who examine the patient, using medications with extended intervals to reduce nursing encounters, and allowing patients to convey needs to providers using tablets or other electronic interfaces.
- Limiting visitors and nonessential staff contact with patients
- Limiting patient's movements outside of the designated areas
- Disinfecting patient care environments and reusable equipment between each patient
- Cautious extended use or decontamination of PPE for reuse may be reasonable.

DECONTAMINATION OF PERSONAL PROTECTIVE EQUIPMENT FOR REUSE

In general, most PPE are single-use, disposable, and designed to be used only one time and by one person; it cannot be washed, or reused, or shared. Washing PPE changes its protective barrier capabilities, and it may no longer be effective, if reused. Sharing PPE that is proposed for single use may expose another person to infectious materials. Disposable PPE should be removed promptly, using proper removal and disposal procedures. The CDC and WHO have highlighted few exceptions for some types of respirators such as elastomeric respirator masks, N95 respirators, and protective wear such as goggles, visor, face shield for reuse with appropriate decontamination when supplies are critically low. Decontamination with ultraviolet

light, hydrogen peroxide vapor, moist heat, and ethylene oxide has been shown to reduce the viability of single-stranded ribonucleic acid (RNA) viruses, such as H1N1 influenza and novel coronavirus (SARS-CoV-2), on N95 respirator and other environmental surfaces.

LIMITATIONS OF PERSONAL PROTECTIVE EQUIPMENT

Personal protective equipment will protect HCWs only from exposure to infectious agents or penetration of substances such as solid, liquid, or airborne particles but will not protect them from a specific disease. The other limitations are:

- Restricted movement due to its weight
- Decreased vision due to visual field limitations
- Difficulty in communication due to face protection
- Psychological stress resulting from the confining nature of full suits
- Heat stress and the risk of dehydration

REGULATIONS AND EFFICIENCY OF PERSONAL PROTECTIVE EQUIPMENT USAGE

The Occupational Safety and Health Administration (OSHA) focuses on workplace health and safety, which require effective use of PPE in healthcare settings to protect HCWs from exposure to bloodborne and airborne pathogens. Employers must provide the appropriate PPE to protect employees and provide training sessions on the proper use of PPE and their

TABLE 3: Levels of PPE and types of precautions for infection control.

Level of protection and types of precaution	*Recommended PPE*	*Suspected or known infectious agent*	*Major specifications*
Level 1 • Standard infection control precautions (SICPs)	• Disposable gloves • If the risk of spraying or splashing of blood/body fluids is anticipated: ○ Disposable surgical mask ○ Goggles or a full-face visor ○ Disposable apron	• No suspected or known infectious agent • Use as standard for all patients at all times	• Perform hand hygiene before and after every patient contact* • Anticipate exposure to blood and other body fluids • Safe disposal or cleaning of instruments and linen • Cough etiquette: Patients and visitors should cover their nose or mouth when coughing, promptly dispose of used tissues, and practice hand hygiene after contact with respiratory secretions
Level 2 • Contact precaution • Patients are placed on contact precautions when they have a known or suspected infection transmitted directly or indirectly from an infected or colonized individual by touch or contact with the patient or the patient's environment (surfaces and equipment). Contact is a common way that germs spread in healthcare facilities	• Disposable gloves • Disposable apron, consider fluid-resistant disposable gown if apron provides inadequate cover for the procedure or task being performed. • If the risk of spraying or splashing of blood/body fluids is anticipated: ○ Disposable surgical mask ○ Goggles or full-face visor ○ Disposable headcover/hood ○ Disposable shoe covers over surgical boots or closed shoes	• Colonization of any bodily site with multidrug-resistant bacteria (MRSA, VRE, drug-resistant gram-negative organisms) • Enteric infections (Norovirus, *Clostridium difficile**, *Escherichia coli*) • Viral infections [HSV, VZV, RSV†, parainfluenza, enterovirus, Rhinovirus‡, certain coronaviruses (SARS-CoV-2, MERS-CoV)], scabies, impetigo, noncontained abscesses or decubitus ulcers (especially for *Staphylococcus aureus* and group A *Streptococcus*)§	In addition to standard precautions: • Place the patient in a single room; cohorting is allowed if necessary • Gloves required upon entering the room • Change gloves after contact with contaminated secretions • Clean, nonsterile gown required if clothing may come into contact with the patient or environmental surfaces or if the patient has diarrhea • Discard PPE before exiting the room. Perform hand hygiene immediately after removing PPE • Do not wear the same PPE for the care of more than one patient • Use new PPE before coming in contact with another patient or patient environment • Noncritical items must be dedicated to use for a single patient if possible • Use disposable or dedicated patient care equipment (e.g., blood pressure cuffs) • Clean and disinfect reusable equipment before use on another person • Minimize the risk of environmental contamination during patient transport (e.g., the patient can be placed in a gown)

Continued

Continued

Level of protection and types of precaution	*Recommended PPE*	*Suspected or known infectious agent*	*Major specifications*
Level 2 • Droplet precaution • Patients are placed on droplet Precautions when they have known or suspected infections transmitted by large respiratory droplets (>5 µm in size) generated by coughing, sneezing, talking, or during the performance of aerosol-generating procedures. Droplet transmission requires close proximity or contact between the source and the susceptible host. These remain in the air briefly and can travel about 1 m (3 feet) or less. These may also land on surfaces later and be transferred by contact transmission	• Disposable gloves • Disposable apron, consider fluid-resistant disposable gown if apron provides inadequate cover for the procedure or task being performed • Disposable surgical mask with goggles or full-face visor • If high risk of direct physical or close contact is anticipated: ○ N95 respirator with goggles or full-face visor ○ Disposable headcover/ hood ○ Disposable shoe covers over surgical boots or closed shoes	• *Neisseria meningitidis, Haemophilus influenzae* type B, *Mycoplasma pneumoniae, Bordetella pertussis* • Group A *Streptococcus*[§], Diphtheria, Pneumonic plague, Influenza, Rubella, Mumps, Adenovirus, Parvovirus B19 • Rhinovirus[‡], Certain coronaviruses (SARS-CoV-2, MERS-CoV, and SARS)	In addition to standard precautions: • Place the patient in a single room • Cohorting is allowed if necessary, provided a distance of at least 1 m (3 feet) is maintained between patients along with a physical barrier such as a curtain or divider • Make sure eyes, nose, and mouth are fully covered before entering the room • Discard PPE before exiting the room • Perform hand hygiene immediately after removing PPE. (If PPE is to be reused, it must be cleaned and disinfected before each reuse) • Always wear a mask when within 1 m (3 feet) of the patient • Patients should wear a mask in the room and during transport in order to minimize the risk of environmental contamination. • Cough etiquette: Patients and visitors should cover their nose or mouth when coughing, promptly dispose of used tissues, and practice hand hygiene after contact with respiratory secretions
Level 2 • Airborne precaution • Patients are placed on airborne precautions when they have known or suspected infection transmitted by tiny droplet nuclei (<5 µm in size). Due to their tiny size, these particles can be suspended in the air for extended hours and can spread widely within a room or over longer distances on air currents	• N99/FFP3 respirator or PAPR • Goggles or full-face visor. • If high risk of exposure during a task or close contact is anticipated: ○ Disposable gloves ○ Disposable apron, consider fluid-resistant disposable gown if apron provides inadequate cover for the procedure or task being performed ○ Disposable headcover/ hood ○ Disposable shoe covers over surgical boots or closed shoes	• Tuberculosis, varicella, measles, smallpox, certain coronaviruses (SARS-CoV-2, MERS-CoV, and SARS), Ebola	In addition to standard precautions: • Place the patient in an AIIR— Monitored negative-pressure room with at least 6–12 air exchanges per hour • Room exhaust must be appropriately discharged outdoors or passed through a HEPA filter before recirculation within the hospital • A fit-tested certified N99/FFP3 respirator or PAPR must be worn before entering the room • Discard all PPEs except the respirator before exiting the room • Remove respirator always after exiting the room • Perform hand hygiene immediately after removing PPE • Restrict susceptible HCWs or individuals visiting or entering the room • Doors must always remain closed and avoid frequent movements of HCWs caring for the patient • Transport of the patient should be minimized; the patient should wear a mask, if transport within the hospital is unavoidable • Cough etiquette: Patients and visitors should cover their nose or mouth when coughing, promptly dispose of used tissues, and practice hand hygiene after contact with respiratory secretions

Continued

Continued

Level of protection and types of precaution	*Recommended PPE*	*Suspected or known infectious agent*	*Major specifications*
Level 3 • Enhanced precaution • Suspected or confirmed infectious agent spread by multiple modes of transmission and more than one transmission-based precautions category may be used	• Disposable gloves (two sets) • Reinforced fluid-resistant long-sleeved surgical gown (or) full-length disposable plastic apron additionally over the gown (or) 360° fluid-resistant coverall-suit with the hood • N99/FFP3 respirator or PAPR • Disposable goggles or full-face visor additionally over the goggles • Disposable fluid-resistant hood (if wearing a gown without an attached hood) • Disposable shoe covers over surgical boots or closed shoes (if wearing a gown)	• For suspected or confirmed infectious diseases of high consequence (IDHC) which spread by direct/indirect contact, droplet, airborne route	• Along with standard precautions to consider precautions required for multiple routes of transmission anticipated • All PPE except gloves need not be changed in between confirmed patients or cohorting unless they are visibly soiled or contaminated. Gloves should always be changed in between patients irrespectively • Ideally, all PPE including gloves should be changed in between suspected patients irrespective to being visibly soiled or contaminated. If not possible, at least gloves and plastic apron worn in addition to gown or coverall should be changed between patients
For all aerosol-generating procedures (AGP) use Level 3 PPE at any circumstances. (Nebulization, tracheal intubation, noninvasive ventilation, tracheotomy, cardiopulmonary resuscitation, manual ventilation before intubation, bronchoscopy)	• Fluid-resistant coverall-suit with the hood plus: ○ N99/FFP3 respirator or PAPR ○ Disposable goggles ○ Disposable gloves (two sets) • Fluid-resistant long-sleeved surgical gown plus: ○ N99/FFP3 respirator or PAPR ○ Full-length disposable plastic apron additionally over the gown ○ Full-face visor additionally over the goggles ○ Disposable hood/headcover ○ Disposable shoe covers over surgical boots or closed shoes ○ Disposable gloves (two sets)		• Place the patient in an AIIR (airborne infection isolation room) – Monitored negative-pressure room with at least 6–12 air exchanges per hour • Room exhaust must be appropriately discharged outdoors or passed through a HEPA filter before recirculation within the hospital • All PPE should be changed after an aerosol-generating procedure irrespective to being visibly soiled or contaminated • Remove respirator always after exiting the room • Reusable PPE should be placed separately for decontamination

* Alcohol-based hand disinfectant is an acceptable alternative to soap and water in all situations except in the setting of norovirus and *Clostridium difficile* infection, for which soap and water should be used.

† RSV may be transmitted by the droplet route but is primarily spread by direct contact with infectious respiratory secretions. Droplet precautions are not routinely warranted but are appropriate if the infecting agent is not known, if the patient may be coinfected with other pathogens that require droplet precautions, and if there is a chance of exposure to aerosols of infectious respiratory secretions.

‡ The most important route of transmission for rhinovirus is via droplets; contact precautions should be added if copious moist secretions and close contact are likely to occur (e.g., young infants).

§ Patients with invasive group A streptococcal infection associated with soft-tissue involvement warrant both droplet precautions and contact precautions. Droplet precautions alone are warranted for patients with streptococcal toxic shock or streptococcal pneumonia as well as for infants and young children in the setting of pharyngitis or scarlet fever. Droplet and contact precautions may be discontinued after the first 24 hours of antimicrobial therapy.

Note: NHS Sheffield – NIPCM – HPS are aware of the high consequence infectious diseases (HCID) consensus PPE model drafted by Public Health England's HCID Programme (article in press) and will review this aide-memoire following an evidence appraisal. Adapted from original work produced by Public Health England and NHS Sheffield. https://hpspubsrepo.blob.core.windows.net/hps-website/nss/3037/documents/1_nipcm-appendix-16.pdf

(AGP: aerosol-generating procedures; AIIR: airborne infection isolation room; FFP3: filtering facepiece 3; HSV: Herpes simplex virus; HEPA: high-efficiency particulate aerator; MERS-CoV: Middle East respiratory syndrome coronavirus; MRSA: methicillin-resistant *Staphylococcus aureus*; PAPR: powered air purifying respirator; PPE: personal protective equipment; RSV: respiratory syncytial virus; SARS: severe acute respiratory syndrome; SARS-CoV-2: severe acute respiratory syndrome coronavirus disease-2; VRE: vancomycin-resistant enterococci; VZV: varicella-zoster virus)

competency should be assessed. Employers should have a management program that ensures effective use of PPE by HCWs. Employees must ensure that they wear the appropriate PPE to protect themselves from possible exposure to infectious agents. Employees should attend mandatory IPC training to perform all tasks related to wearing PPE which include how to select appropriate PPE, properly check for fit, don and doff in the correct sequence and safe disposal of PPE, know the limitations of PPE, and proper care and maintenance of PPE.

SUMMARY

- The goal must be to improve the safety of health personnel and to avoid transmission of HCAI by following standard precautions.
- Hand hygiene is the single most crucial method to reduce the incidence of HCAI.
- PPE is a two-way protective barrier between the HCW and the patient and reduces the risk of transmission, thus preventing HAI.
- For PPE to be effective, they must be readily available, provide adequate protection, and utilized correctly.
- Gloves should be changed between patient encounters and when they get torn or visibly contaminated.
- Gowns provide a fluid-resistant barrier that protects the HCW from soiling or contamination. Plastic aprons are the preferred PPE for standard precautions. Sterile gowns are necessary for a sterile procedure such as central line insertion or a surgical procedure in an operating room.
- Protective eyewear is used to shield eyes from potential risks of transmission while performing procedures of close proximity.
- Masks offer protection from inhalation of respiratory droplets. For all aerosol-generating procedures, use an N95 respirator. Always perform "fit test" and "seal check test" to verify that the N95 respirator fits comfortably and is properly sealed without leakage. Masks should be discarded when they become damaged, no longer form an effective seal to the face, or become wet or contaminated with blood, respiratory, or nasal secretions from the patient and after aerosol-generating procedures.
- Failure to properly don and doff PPE in the correct sequence could lead to exposure to infectious agents.
- Appropriate PPE is selected according to the risk assessment done, which is not based on the clinical presentation or diagnosis of the patient but rather on the suspected or identified infectious agent, transmission route of the infectious agent, patient care setting, and tasks or procedures undertaken.
- Transmission-based precautions are used additionally for patients who are known or suspected to be infected or colonized with those infectious agents that require additional control measures to prevent transmission of infection in healthcare facilities effectively.
- Employees should attend mandatory IPC training to perform all tasks related to wearing PPE.

Section 2: Recent Concepts in Emergency Medicine

11 CHAPTER

Research Methodology

Padam Singh, Pooja Sharma, Manish K Singh

INTRODUCTION

This chapter provides all the systems and tools used for dissertation and also gives a broad overview of the research methodology, empirical methods of the approach, and particular techniques to approach objectives of the research. Research in emergency medicine aims at generating evidence for new therapeutic interventions to provide appropriate health care in emergency settings. Research requires sound planning and systematic implementation through a sequence of steps. *The sequence of steps in research are as follows*:

- Rationale for the study—identification of research problem through extensive research review
- Objectives, research hypothesis, and statistical hypothesis
- Study design
- Sample size
- Sample selection—inclusion/exclusion criteria
- Method of data collection and study tools
- Data management and analysis including use of software
- Summarization of data and statistical inference
- Interpretation

LITERATURE REVIEW

The literature review is the first step in undertaking any research as it is through this only that the gap in knowledge is identified which would justify and provide the rationale for carrying out the research. There are different search engines that might be used to locate relevant material which are summarized in **Table 1**.

FORMULATING A RESEARCH QUESTION

Based on the literature review, the next step in any research study is to clearly define the research question. An ideal research question is one that is relevant and doable within the specific time frame. A well-built research question should include four elements, referred to as patient, intervention, comparison, and outcomes (PICO) concept.

1. *P*: Patient or characteristics. The first step in the PICO process is to describe characteristics patients of under study such as age, gender, disease status, or any other patient's related characteristic.
2. *I*: Intervention. The second step in the PICO process is to identify the intervention or the exposure intended to be studies in the research. This may include the use of a specific diagnostic test, treatment, adjunctive therapy, medication, etc.
3. *C*: Comparison. It is the alternative exposure or control to which the intervention will be compared, which might be the standard of care or a placebo. The comparison component is the only optional one in the PICO question, since the researcher might study the intervention alone either due to no interest in comparison or due to lack of a comparable group.
4. *O*: Outcome. It is for the evaluation of the interventions effect. This may include cure or level of control of a disease, efficacy of a diagnostic test, etc.

Examples of research questions are given in **Box 1**.

ESSENTIALS OF BIOSTATISTICS

While undertaking any research, an understanding of the basics of statistics is necessary for scientific planning, appropriate analysis, and valid interpretation of findings. Importantly, statistics deals with variables which are broadly categorized as quantitative and qualitative variables. The parameter of interest in a research study could be either a proportion (for a categorical response) or an average (for a quantitative outcome). Quantitative variables are those which are measurable and are always a number which can be either continuous or discrete. On the other hand, qualitative variables are nonnumerical which can be either ordinal or nominal. Qualitative variables, also called "categorical variables," classify or divide individuals into classes/groups, so that quantitative variables may be compared among the classes. All research hypotheses are related to claim for the improved outcome and superior drug/diagnostics. This claim

TABLE 1: Search engine for literature review.

Search engine	*Website/Characteristics*
PubMed	www.pubmedcentral.nih.gov. The National Library of Medicine's free search service. Available through the World Wide Web
MEDLINE	www.nlm.nih.gov. Contains abstracts and references from 1966 to the present. Combines more than 3,900 medical and nursing journals into a single database
Ovid	Ovid is a comparable search engine to PubMed. Its advantage over PubMed is that it searches more databases in addition to MEDLINE, including EMBASE and the Cochrane Database of Systematic Reviews (CDSR). This means that your search will expand to include more results giving you more evidence to use for your research/writing
Web of Science	Web of Science uses a large database of 8,700 international scientific journals from Thomson Reuters. The database includes a large number of international publications from Asia and requires a subscription to access the articles. Web of Science has a useful database to search for scholarly research data on emerging trends. It is useful for writing protocols or guidelines. It covers over 250 disciplines in science, social science, arts, and humanities
Science Direct	• Science Direct is a very familiar search engine for researchers. It is a full-text scientific database • The search engine allows to find articles in over 3,800 science, technology, and medicine journals owned by the academic publisher Elsevier. Another similar portal is Springer Link that has access to over five million articles in journals operated by the publisher Springer
Scopus	Scopus is a large database of over 60 million peer-reviewed literature also owned by Elsevier. Scopus interfaces with the EMBASE and MEDLINE databases to search records for journal articles. It gives access to the full-text articles from >4,200 full-text journals
Cochrane Library	For systematic reviews or meta-analyses, the Cochrane Library is the best source. In addition to results obtained from the Cochrane Database of Systematic Reviews (CDSR), Cochrane library search results can also include control trials in MEDLINE and EMBASE, Cochrane protocols, and editorials. Cochrane Library is a subscription-based search platform. However, some open-access articles may be retrieved, depending on when the article is published
Google Scholar	Google Scholar is a free medical journal search engine indexing journal; however, login may be required via a subscription for some full-text journal articles

BOX 1: Example of a research question.

1. Does smoking among men older than 35 years increase the risk of asthma compared to nonsmokers?
   - *Broad topic of interest*: Men's health
   - *Narrowed topic*: Men and asthma
   - *Focused topic*: Men smokers and asthma

   PICO: P = men (age > 35 years); I = bidi/cigarette smoking; C = no smoking; O = asthma
2. Serum enzymes and CT severity score for assessing the severity of pancreatitis in the patient presenting to the emergency:
   - *Broad topic of interest*: Emergency patients
   - *Narrowed topic*: Pancreatitis in patients presenting to emergency
   - *Focused topic*: Severity of pancreatitis in patients

   PICO: P = emergency patient; I = serum enzymes; C = CT severity score; O = comparison of serum enzymes and CT severity score for assessing the severity of pancreatitis
3. Predictive values of mREMS and RAPS in determining the outcome (mortality and morbidity) in trauma patients reaching the emergency and trauma care, assessing the morbidity score by Glasgow outcome scale:
   - *Broad topic of interest*: Trauma patients
   - *Narrowed topic*: Mortality and morbidity among trauma patients
   - *Focused topic*: Glasgow outcome scale for assessing morbidity

   PICO: P = trauma patients; I = Glasgow outcome scale; C = mREMS and RAPS; O = predictive value of mREMS and RAPS
4. Glasgow Coma Scale (GCS) versus Full Outline of Unresponsiveness (FOUR) score as predictors of mortality in traumatic brain injury patients:
   - *Broad topic of interest*: Trauma patients
   - *Narrowed topic*: Traumatic brain injury patients
   - *Focused topic*: Predictors of mortality in traumatic brain injury patients

   PICO: P = brain injury patient; I = full outline of unresponsiveness score; C = Glasgow Coma Scale; O = predictive value of GCS

(CT: computed tomography; mREMS: modified rapid emergency medicine score; RAPS: rapid acute physiology score)

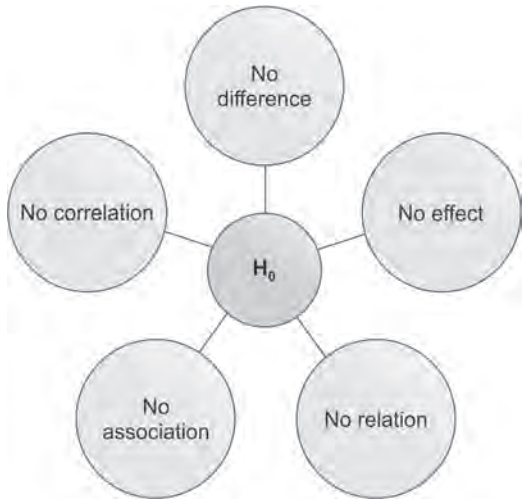

FIG. 1: Commonly used null hypothesis.

is required to be tested against a null hypothesis negating the claim by indicating that the effect of interest is zero. In most of the situations, the statistical null hypothesis is the negation of the research hypothesis. The commonly used null hypothesis is shown in **Figure 1**. The null hypothesis is evaluated against a competing hypothesis (alternative hypothesis) in which the effect of interest is considered as nonzero. Hypotheses are always stated in terms of a population parameter, such as the mean "μ" or proportion "*P.*" An alternative hypothesis may be one sided or two sided. A one-sided hypothesis claims that the parameter under the alternative hypothesis is either larger or smaller than the value given by the null hypothesis. A two-sided hypothesis claims that the parameter is not equal to the value given by the null hypothesis—the direction does not matter and could be either side.

Errors in Testing of Hypothesis

In the testing of hypothesis, there are probabilities of committing two kinds of errors: (1) False rejection (type I error); and (2) False acceptance (type II error) of the null hypothesis (**Table 2**).

In order to explain these concepts, let us consider the possible errors in clinical practice as follows:

- Diagnosing a person wrongly as suffering from the disease when he/she is not
- Missing the diagnosis and declaring the person as free from the disease when he/she is actually suffering from the disease

The null hypothesis in the present case is "person is not suffering from the disease" (**Table 3**).

The probabilities of type I error and type II error are denoted by α and β, respectively.

There are two terms: (1) Confidence level; and (2) Power, which are complement to these errors as follows:

Confidence level = Probability of accepting the null hypothesis when it is true
= 1 – Probability of type I error
= 1 – α

Power = Probability of rejecting the null hypothesis when it is false
= 1 – Probability of type II error
= 1 – β

TABLE 2: Type of errors in null hypothesis.

Type I error	False rejection	Reject H_0 when H_0 is true
Type II error	False acceptance	Accept H_0 when H_0 is false

TABLE 3: Null hypothesis—person is not suffering from the disease.

Type I error	Diagnosing a person who is not suffering from the disease as suffering from the disease would imply rejecting null hypothesis when it is true
Type II error	Declaring a person free from the disease when he/she is actually suffering from the disease would imply accepting the null hypothesis when it is false

TABLE 4: *p*-value and related inferences.

Values of p	***Inferences***
$p > 0.10$	No evidence against the null hypothesis
$0.05 < p < 0.10$	Weak evidence against the null hypothesis
$0.01 < p < 0.05$	Good evidence against null hypothesis
$0.05 < p < 0.001$	Strong evidence against the null hypothesis
$p < 0.001$	Very strong evidence against the null hypothesis
Notes: Conventionally, $p < 0.05$ is referred to as statistically significant and $p < 0.001$ as statistically highly significant. When presenting *p* values, it is a common practice to use the asterisk rating system.	

Importantly, α is commonly referred to as the level of significance. The implication of type I error in the context of a clinical research is that the new regimen, although not effective, is adopted and prescribed, i.e., an ineffective drug is allowed to be marketed. In a trial on a new regimen, type II error would imply that the new regimen is not approved when it is actually effective. Thus, the medical profession and the society are deprived of the benefits of this new regimen.

p-value: The *p*-value is calculated based on the null distribution, which is a distribution of the test statistic when the null hypothesis is true. The *p*-value indicates how probable the results are due to chance. Statistical inferences indicating the strength of the evidence corresponding to different values of *p* are given in **Table 4**.

RESEARCH DESIGNS

The research designs are broadly categorized as observational or interventional. The commonly used situations of observational and interventional studies specific to emergency medicine are given in the following text.

Observational Studies

In an observational study, the natural history of treatments (standard of care) is studied, i.e., there is no intervention. Some examples are as follows:

- Profiling of patients attending an emergency clinic for different conditions such as stroke and accidents

- The pattern of antibiotic use for patients admitted in an intensive care unit (ICU) with sepsis
- The birth outcome of pregnant women in advanced shock from uncontrolled postpartum hemorrhage (PPH)

In observational studies, the study design could be cross-sectional, cohort, or longitudinal, which are discussed in brief in the following text.

Cross-sectional Design

In cross-sectional studies, data are collected only at one point in time. Such studies are better suited for estimating the prevalence of an outcome of interest. As a cross-sectional study assesses both the exposure and the outcome concurrently, it cannot be utilized to establish cause and effect relationships.

Longitudinal Design

A longitudinal study follows the same sample over time and makes repeated observations. Longitudinal research designs describe patterns of change. Measurements are taken on each variable over two or more distinct time periods. *Example*: Study of growth of children from birth till 5 years.

Cohort Design

A cohort study generally refers to a study in which a defined group of people (the cohort) is followed over time. In this, subjects under study have some commonality or similarity. Examples are victims of calamities such as methyl isocyanate (MIC) gas leak, earthquake, and fire.

Interventional/Experimental Studies

In these studies, there is an active intervention (drug, diagnostic, procedure, etc.) for a desirable change in the outcome. Examples are as follows:

- Clinical studies evaluating the response of specific treatment to patients of a disease, i.e., pre versus post
- Clinical trials comparing the outcome of an intervention (experimental) with that of control (standard of care)

Experimental designs comparing two groups relate to (1) an experimental group (that receives the new intervention) and (2) a control group (placebo or standard of care). Both groups are measured on the same dependent/outcome variable. Observations are made before and after the implementation of the intervention.

In such situations, *randomized control trials (RCTs)* are conducted. The common study designs employed in RCTs include parallel-group design, matched pairs, and cross-over designs. In parallel-group design, the patients are enrolled, followed, and observed for outcomes on a parallel basis. In matched pairs, patients are matched for different variables and those matching the required variables are then randomized to various treatment groups. This type of study design overcomes the influence of variables on outcomes. Cross-over design is particularly used when the effect of a drug is reversible and transient. In a cross-over design, the patients are given more than one treatment but in sequence, i.e., one after another when the effect of the previous treatment is washed out. Cross-over design, thus, requires less number of patients. *Randomization* is a prerequisite for such studies and *blinding* is desirable. These are discussed in the following text.

Randomization

Randomization is a scientific method of allocation of subjects between the treatment and the control groups. This method ensures that there is no bias or preference in selecting specific treatment for any subjects. Further, randomization provides equal chance/probability to subjects for allocation into different groups. Importantly a prerequisite, all statistical tests of significance assume that the sample drawn is random, which is met through randomization.

Randomization techniques used in RCTs are simple randomization or stratified randomization. In simple randomization, subjects are allocated to different groups without any matching. On the other hand, in the stratified randomization technique, subjects are classified into groups, i.e., strata, and then within a group, they are randomized to various treatment groups. This ensures matching of subjects for confounding factors that might influence the outcome and thus helps in drawing valid conclusions netting out the effects of confounders. For allocation of subjects in different groups, the random numbers are generated through the computer using appropriate mathematical algorithms. In the case of two groups generally, odd numbers correspond to group I and even numbers to group II.

As an example, in the case of two groups with a sample size of 30 each, a sequence of 60 two-digit random numbers are generated of which 30 are odd and 30 even. The sequence of random numbers will be kept in opaque-sealed envelopes. In this, the serial numbers will be written on the envelopes and the group to which the subject at that serial number has been allocated will be kept inside the envelope. After recruitment of the subjects and taking their consents, the allocation of the subjects to two groups will be based on the sequence of random numbers kept in opaque envelopes. The envelopes will be kept with a biostatistician and will be opened after recruitment of the subjects and obtaining the consent.

Blinding

To avoid any bias in the study, blinding is resorted which means concealing or masking of the subject's assignment to a study group (control or treatment) from those participating in the study."

The blinding could be single-blinded, double-blinded, or triple-blinded as given in **Table 5**:

- *Single-blinded*: The study subjects will not know whether they would receive the treatment (test intervention) or control (placebo).
- *Double-blinded*: Neither the study subjects nor the experimenter will know which of the subjects are in the treatment (test intervention) or control (placebo) group.

TABLE 5: Type of blinding studies.

	Concealment about the allocation of subjects to a group (√: Yes; X: No)		
Type of blinding	***Subjects***	***Experimenter***	***Observer***
Single	√	X	X
Double	√	√	X
Triple	√	√	√

- *Triple-blinded*: Neither of the study subjects, experimenter, and observer will know which of the subjects are in the treatment (test intervention) or control (placebo) group.

The non-blinded study is referred to as an open-label study. In this type of study, all three—subjects, experimenter, and researcher, are aware of the treatment allocation.

SAMPLE SIZE

Background

"How big a sample do I require to get a reliable estimate and valid inference in my research study?" is one of the most frequently asked questions by researchers. For answering this question, the sample size should be determined on the basis of scientific statistical criteria, which take into account the objective of the study, outcome parameter, and study design along with certain assumptions. The criteria will vary according to whether the study design is observational or interventional/experimental and also whether the parameter is "a proportion" or an average. The determination of sample size in different situations is discussed as in the following text.

Situation A: Observational studies for proportions: In this situation, the formula to be used for computation of sample size is as follows:

$$n = \frac{Z_\alpha^2 PQ}{d^2}$$

where P = Likely value of the parameter
Q = 1 – P
d = Permissible margin of error—a measure of precision
Z_α = Value of standard normal deviate corresponding to the desired confidence level

In view of this, the information needed in determining the sample size is as follows:

- *Likely value of the parameter*: Speculating about the parameter may be tricky. The investigator may get some idea about this from the review of literature, from the studies with similar study designs, and from the reference population. From the reviews, one may get an idea about the parameter in terms of range, say for instance, 60–65%, 40–50%, 20–35%, etc. In such situations, the value of P in the range which gives a higher sample size may be considered.
- *Confidence level*: In most studies, a 95% confidence level is considered. However, in some situations, it can be relaxed to 90% and there could be situations where it should be as high as 99%. The values of Z_α, the standard normal variate corresponding to the desired confidence level α, are given in **Table 6**.
- *Level of precision:* The permissible margin of error, a measure of precision (d), is often expressed in percentage points, ±5%, ±10%, etc. The thumb rule in deciding the appropriate precision in prevalence studies is as follows:
  - If the likely prevalence is around 50%, d may be taken as 10%.
  - If the likely prevalence is <20% or >80%, d may be taken as 5%.
  - Alternatively, d can be taken as a fixed percentage of P, i.e., $d = e \times P$. In such cases, e is relative precision.

TABLE 6: Z_α and confidence level.

Confidence level	Z_α
99%	2.576
95%	1.960
90%	1.645
80%	1.282

Example: Consider an example for a study of compliance of a clinical care pathway for patients undergoing gastrectomy, where the likely/anticipated value of parameter P to be estimated is 90%. What would be the sample size if this parameter is desired to be estimated with precision of ±5% and confidence level of 95%. In this case, P = 0.9, Q = 0.1, d = 0.05, and Z_α = 1.96.

Substituting these in the formula, the sample size is computed as:

$$n = \frac{Z_\alpha^2 PQ}{d^2} = \frac{(1.96)^2 \times 0.90 \times 0.10}{0.05 \times 0.05} = 138$$

Thus, a sample of 138 patients undergoing gastrectomy will be required to be followed to find out the proportion of compliance of the clinical care pathway.

Example: Consider another example for estimation of complications among patients following pancreaticoduodenectomy, where the likely/anticipated value of parameter P is 20%. What would be the appropriate sample size if this is to be estimated with a precision of ±5% and the confidence level of 95%. In this example, P = 0.20, Q = 0.80, d = 0.05, and Z_α = 1.96. Substituting the value in the formula, the sample size is determined as:

$$n = \frac{Z_\alpha^2 PQ}{d^2} = \frac{(1.96)^2 \times 0.20 \times 0.80}{0.05 \times 0.05} = 245$$

A sample of 245 patients of pancreaticoduodenectomy will be required for this study.

Alternative formula for determination of sample size: Considering "d" in terms of relative precision $d = e \times P$, the formula for sample size reduces to the form as:

$$n = \frac{Z_\alpha^2 Q}{Pe^2}$$

where e = relative precision.

Following are the implications of P, d, and α on sample size:

- "n" is inversely proportional to "P". A small sample size may suffice for high prevalence, but we need a large sample size for lower values of P. This is the case with rare diseases.
- "n" is inversely proportional to e^2. Thus, for higher precision (i.e., lower relative margin of error), a larger sample size will be required.
- "n" is directly proportional to the confidence level. Thus, a larger sample size will be needed for a higher confidence level.

Sample sizes for some typical values of "P" are given in **Table 7** for α = 0.05 and 10% relative margin of error.

TABLE 7: Sample size in relation to prevalence.	
Likely value of "P"	***Sample size "n"***
0.50	400
0.10	3,600
0.05	7,600
0.005	80,000
0.0005	8,00,000

It is seen that sample sizes increase rapidly with the decline in prevalence rates, i.e., rare situations/diseases. The commonly encountered rare situations are the prevalence of cancer, infant mortality rate, maternal mortality rate, serious adverse effects, etc.

Situation B: Observational studies for average: In dealing with averages, the formula for estimating sample size is given by

$$n = \frac{Z_\alpha^2 \sigma^2}{d^2}$$

where σ = Likely value of standard deviation.

Importantly, though the average does not feature in the formula, *d* is taken as some fraction of the likely value of average.

Example: Consider an example of estimation of the average hemoglobin level among adolescents with

d = ±0.5 g/dL and 95% confidence level, where the likely value of standard deviation σ = 5 g/dL.

Here, σ = 5, *d* = 0.5, and Z_α = 1.96. Substituting these values, the sample size is calculated as:

$$n = \frac{Z_\alpha^2 \sigma^2}{d^2} = \frac{1.96^2 \times 1.96 \times 5 \times 5}{0.05 \times 0.05} = 400$$

Thus, a sample of 400 subjects will be needed for this study.

Situation C: Sample size for paired comparison (pre vs. post): In many studies, the impact of a medical intervention may be desired to be evaluated. An example of an intervention is when a metformin drug leads to a change in the glycated hemoglobin (HbA1c) level for type 2 diabetic patients. In such situations, the estimates of baseline (pre) and end line (post) are compared for statistical significance of a change of the desired magnitude. In planning such studies proper sample size needs to be considered. The formula for calculation of sample size in such situation is given by:

$$n = [(Z\alpha + Z\beta)^2 \times \sigma_\Delta^2]/\Delta^2$$

where Δ = Change in value of the parameter
σ_Δ = Standard deviation of the change
Z_β = Value of standard normal variate for the desired power

Example: Consider an example of metformin drug administered to patients where intervention for 3 months is expected to reduce the HbA1c level by 1 g/dL. What will be the sample size for this study under the assumptions of σ_Δ = 7.5 with 95% confidence level and 80% power?
Here, σ_Δ = 7.5, Δ = 1.0, Z_α = 1.96 and Z_β = 0.84

$$n = [(1.96 + 0.84)\, 2 \times\ 7.5 \times 7.5]/(1.0)2 = 441$$

Thus, a sample of 441 patients is required to be covered in this study.

Situation D: Sample size for comparative studies: Interest may be to compare complications in patients undergoing colorectal surgery with c-reactive protein (CRP) level at the baseline. Here again, the outcome parameter is a proportion which is a complication rate. The calculation of sample size is discussed in the following studies:

Situation D: Comparative studies for proportions: The formula for calculation of sample size in this situation is:

$$n = 2\,PQ\,[\frac{Z_\alpha + Z_\beta}{d}]\,2$$

where P_1 = Parameter for group 1
P_2 = Parameter for group 2
P = $(P_1 + P_2)/2$
Q = 1 – P
d = $P_1 - P_2$

Thus, the information required for the calculation of sample size is as follows:

- Approximate value of *P* for the control group (say group 1)
- Approximate value of *P* for the interventional group (say group 2)
- Confidence level (usually 95%)
- Power of detecting the difference as significant (usually 80%)

Example: Suppose the cure rate on a standard treatment is 60%. A new treatment is claimed to have a cure rate of 80%. What is the minimum number of patients required to verify the claim at 95% confidence level and 80% power?

In this case, P_1 = 0.80, P_2 = 0.60, and thus
$P = (P_1 + P_2)/2 = 0.70$ and $Q = 0.30$.
Further, $d = P_1 - P_2 = 0.20$, Z_α = 1.96, and Z_β = 0.84.

Substituting these in the formula, the sample size works out as 82. Thus, 82 patients will be required to be administered the newer drug and control drug after proper randomization.

Situation E: Comparative studies for averages: In other situations, the parameter of interest could be average. The formula for calculation of sample size in this situation is:

$$n = (\sigma_1^2 + \sigma_2^2)\,[\frac{Z_\alpha + Z_\beta}{d}]\,2$$

where σ_1 and σ_2 are standard deviations and *d* is the difference in the mean values for two groups.

Example: A trial is proposed to be conducted with two arms, say new treatment protocol and existing standard of care, with the claim that the duration of hospital stay will be reduced by 2 days with the new treatment protocol as compared to the existing standard of care. The standard deviation for these two arms is 3.9 and 2.6 days, respectively. What will be the minimum sample size for testing the claim with 95% confidence level and 80% power?

In this case, σ_1 = 3.9, σ_2 = 2.6 and thus *d* = 2 days.
Further, Z_α = 1.96 and Z_β = 0.84.

Substituting these in the formula, the sample size works out as 43. Thus, 43 patients each will be required to be treated by the new treatment protocol and existing standard of care.

STATISTICAL ANALYSIS

For continuous variables, while undertaking the statistical analysis the assumption of normality is required to be tested. For data satisfying normal distribution, the mean and median should be approximately equal and the standard deviation generally <30% of the mean, else the data will not satisfy the normality assumption. The exact test for testing the normality of data is the Shapiro–Wilk/Kolmogorov–Smirnov test. The desirable pathway for deciding about the method of statistical analysis to be used in a given situation is depicted in **Flowchart 1**. The details of the exact test to be used in different situations are outlined in **Table 8**.

TEST OF SIGNIFICANCE FOR POPULATION MEAN (μ)

Situation A: *One sample test when standard deviation (σ) is known*: In this situation, the null hypothesis is H_0: $\mu = \mu_0$, i.e., the population mean μ is equal to a given value μ_0. The alternative hypothesis could be $\mu \neq \mu_0$ or $\mu < \mu_0$ or $\mu > \mu_0$.

For such situations, the appropriate significance test is "*Z* test" which is defined as:

$$z = \frac{\bar{x} - \mu_0}{\sigma/\sqrt{n}}$$

Here, "*n*" denotes sample size and $\bar{x}$ is the sample mean. The test statistic follows the standard normal distribution.

Example: The normal value of the pulse rate is 72, with standard deviation 10. It is assumed that the pulse rate follows the normal distribution. In a sample of 16 persons doing physical exercise, the mean pulse rate observed was 78. Does this experiment provide evidence that the mean pulse rate among the persons doing exercise is higher than the normal? The null hypothesis H_0 in this situation will be that the mean pulse rate for persons doing physical exercise is not different from the normal pulse rate. The alternative hypothesis would be that the mean pulse rate for persons doing the physical exercise is higher than the normal pulse rate.

In this case, $n = 16$, $\sigma = 10$, $\bar{x} = 78$, and $\mu_0 = 72$. Substituting the values in the formula, the *Z* statistic is computed as:

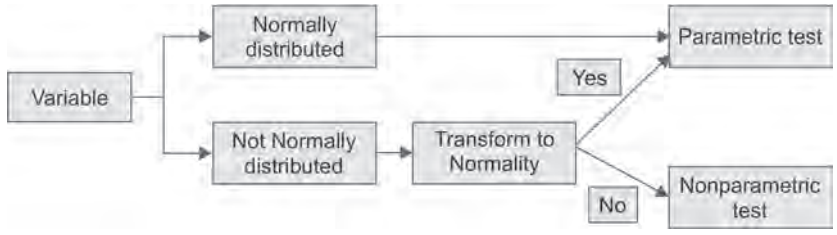
$$Z = (78–72)/(10/\sqrt{16}) = 6/2.5 = 2.4$$

Since this is a one-tailed test, the *P*-value is calculated as:

$$P\,(Z > 2.4) = 1–P\,(Z \leq 2.4) = 1 – 0.9918 = 0.0082$$

As the computed *P*-value is < 0.01, one can confidently reject H_0 given this result. Thus, the average pulse rate for persons doing physical exercise is higher than the normal pulse rate.

Situation B: One sample test when standard deviation is unknown – In most practical situations, the standard deviation for the population will not be known. In such situations, the



FLOWCHART 1: Pathway for statistical analysis.

TABLE 8: Summary of the statistical tests to be used at different situations.

	Type of data		
	Continuous variable		
Situations	***Parametric test***	***Nonparametric test***	***Categorical variable***
One sample	*Z* test (for large samples) One-sample *t*-test (for small samples)	Sign test	*Z* test (for large samples) Fisher exact test (for small samples)
One sample: Pre–post comparison	Paired *t*-test	Wilcoxon Sign Rank test	McNemar or *k* test
Two independent samples	Two independent sample *t*-test	Wilcoxon Rank Sum test	Chi-square test
More than two groups	One-way ANOVA	Kruskal–Wallis test	Chi-square test
Two or more groups repeat observations	Repeated measure ANOVA	Friedman test	Cochran's Q
Association/correlation	Pearson correlation	Spearman correlation	Contingency coefficients
Prediction of outcome from predictor values	Univariate linear/nonlinear regression	–	Univariate logistic regression
Prediction of outcome from several predictor values	Multivariate linear/nonlinear regression	–	Multivariate logistic regression

(ANOVA: analysis of variance)

standard deviation s in the formula is replaced by the estimated standard deviation (s). The distribution of the sample mean $\bar{x}$ is no longer normal. Instead, the sample mean follows a "*t*" distribution.

The test statistic "*t*" is defined as:

$$t = \frac{\bar{x} - \mu_0}{S/\sqrt{n}}$$

The *t* distribution is described by its degrees of freedom. For a sample of size *n*, the *t* distribution will have (*n* – 1) degrees of freedom. As the sample size *n* increases, the *t* distribution approaches the normal distribution. *Example*: Persons working in tea garden are reported to have higher blood pressure (BP). In order to examine this, a sample of nine tea garden workers were selected and their BP was measured. **Table 9** summarizes the results on systolic blood pressure.

The normal systolic BP is known to be 120 mm Hg. In order to test whether tea garden workers have high BP, the null and alternative hypothesis are given by:

H_0: μ = 120.0

H_0: μ > 120.0, it being a one-tailed test

The test statistic "*t*" is computed as:

$$t = (126 - 120.0)/\{7.2/\sqrt{9}\} = 6/2.4 = 2.5$$

Degrees of freedom = 9 – 1 = 8

The table value of "*t*" for 8 degrees of freedom with 5% level of significance (one-tailed) is 2.306. Since the calculated value of "*t*" is more than the table value of "*t*" there is sufficient evidence to reject the null hypothesis. Hence, the average systolic BP of tea garden workers is more than the normal BP.

Situation C: Matched pairs: In many experiments, one is interested in comparing the measurements for the same set of individuals in the "before" and "after" situations. Such studies have *a* matched pair design, where the difference between the two measurements in each pair is the variable of interest. Analysis of data from a matched pairs experiment compares the two measurements by subtracting one from the other and basing the test hypothesis upon the differences. Usually, the null hypothesis H_0 assumes that the mean of these differences is equal to 0, while the alternative hypothesis H_1 would be that the mean of the differences is not equal to zero (the alternative hypothesis may be one or two sided, depending on the experiment). In this situation, using the differences between the paired measurements as a single observation, the standard *t*-test for one sample is followed. The difference for each pair of values is denoted by "*d*". Once this is obtained, the situation reduces to one sample "*t*" test given by:

$$t = \bar{d}/\{sd/\sqrt{n}\}$$

where $\bar{d}$ is the sample mean and s_d the sample standard deviation of the differences.

TABLE 9: Sample test when standard deviation is unknown.

Variable	*Value*
Sample size (*n*)	9
Sample mean ($\bar{x}$)	126 mm Hg
Sample standard deviation (s)	7.2 mm Hg

Example: For eight patients undergoing treatment for liver disease in a hospital, the albumin levels were measured before and after the treatment. The results are given in **Table 10**.

Test whether there is a change in albumin levels with the treatment.

Here,

Null hypothesis H_0 = There is no change in the albumin level

Alternate hypothesis H_1 = There is change in the albumin level

For the above example, "*n*" = 8, $\bar{d}$ = 0.075, and s_d = 0.17

Substituting these in the formula, the "*t*" value is computed as:

$t = 0.075/\{0.17/\sqrt{8}\} = 1.25$ and degrees of freedom = 8 – 1 = 7

The critical value of *t* for 7 degrees of freedom and 5% level of significance (two-tailed) is 2.365.

Since the calculated value of "*t*" is less than the critical value of "*t*," the null hypothesis of no change cannot be rejected. Thus, there is no change in the albumin levels of liver patients with the treatment.

Situation D: Two-sample test: In situations dealing with comparison of the mean of two populations, i.e., averages of one group with that of another group to test whether they are equal or not, a two-sample student's *t*-test is used. In this, independent samples are drawn from two populations. Based on the sample values, the formula for the two-sample "*t*" test is given by:

$$t = \frac{\bar{x}_1 - \bar{x}_2}{s\sqrt{\{(1/n_1) + (1/n_2)\}}}$$

where n_1 and n_2 = Sample sizes

$\bar{x}_1$ and $\bar{x}_2$ = Sample means

s = Pooled sample standard deviation

Subscripts 1 and 2 referred to groups 1 and 2, respectively.

Here, the degrees of freedom will be $n_1 + n_2 - 2$

Example: Two independent samples of 15 males and 15 females were examined for 24-hour creatinine excretion in urine samples. Apply a suitable test of significance to examine if a difference exists in results by gender. The results are given in **Table 11**.

The null hypothesis for this example is that there is no difference in average 24-creatinine excretion between males and females. Since it is not known a priory that a male would have higher creatinine excretion or a female, the alternate hypothesis is two-tailed. In this case, the computations are as given in **Table 12**.

TABLE 10: Albumin level (g/dL).

Patients	*Before treatment*	*After treatment*	*Difference*
1	5.2	4.9	0.3
2	3.9	3.8	0.1
3	4.1	3.9	0.2
4	4.8	4.8	0.0
5	4.6	4.7	–0.1
6	4.9	5.1	–0.2
7	4.2	4.1	0.1
8	3.7	3.5	0.2

TABLE 11: 24-hour creatinine excretion (mg/dL).

Patients	*Male*	*Female*
1	16.8	23.4
2	20	22.2
3	17.3	22.1
4	17.2	16.9
5	15.8	14.4
6	20.5	23.4
7	24.9	25
8	18.7	25.7
9	17.8	28.3
10	22.2	22
11	25.1	21.1
12	18.6	18.2
13	17.1	19.7
14	21.3	20.8
15	23.5	17.5

TABLE 12: Alternate hypothesis.

	Male	*Female*
Sample size	15	15
Sample mean	19.79	21.38
Sample SD	3.03	3.65
Pooled SD	3.39	

(SD: standard deviation)

Substituting these in the formula, the value of "*t*" is 1.30 with 28 degrees of freedom. The critical value of *t* for 28 degrees of freedom at 5% level of significance (two-tailed) is 2.048. Since the calculated value of *t* is less than the critical value of *t*, the null hypothesis of equality cannot be rejected. Thus, the samples do not provide sufficient evidence that the average level of creatinine excretion in men is any different than in women.

TEST FOR PROPORTIONS

Similar to the test for averages, the *Z* test (based on the Gaussian distribution) is also employed in testing for proportions.

Situation A: One-sample test: In case of a one-sample test, the test statistic "Z" is given by:

$$Z = \frac{p - P}{\sqrt{P(1-P)/n}}$$

Here, p = Sample proportion
P = Proportion under null hypothesis
n = Sample size

Example: In a hospital, out of 400 consecutive patients of diabetes, the males were 216. Does the data suggest that the prevalence of diabetes among males or females is equally likely? In this situation, the null hypothesis is that the proportion of either gender is 50%, as against the alternative hypothesis that it is not 50%. In this example, n = 400, p = 216/400 = 0.54, and P = 0.50.

Substituting these values in the formula the calculated value of *Z* is 1.6 which is less than the critical value of 1.96 at 5% level of significance. Hence, the null hypothesis that the gender of the diabetic patients is equally likely cannot be rejected.

Situation B: Two-sample test for proportions: Many times, proportions (cure rate, prevalence of a condition, etc.) for two groups are required to be compared and in such situations a two-sample Z test is used, which is given by

$$Z = \frac{p_1 - p_2}{\sqrt{\{p_1(1-p_1)/n_1\} + \{p_2(1-p_2)/n_2\}}}$$

Here, p_1, p_2 = Proportions for samples 1 and 2
n_1, n_2 = Sizes for samples 1 and 2

Example: In samples of 60 men and 40 women of age 50–55 years, the proportion of cataract cases was 62% and 75%, respectively. It is of interest to know whether the prevalence of cataract is higher among women as compared to men. Here, n_1 = 60, n_2 = 40, p_1 = 0.62, and p_2 = 0.75.

Substituting these in the formula, the computed value of *Z* is 1.4. The critical value of *Z*, one-tailed with 5% level of significance, is 1.64. Since the calculated value of *Z* is less than the critical value, the null hypothesis cannot be rejected.

TABLE 13: Test of significance.

Situation	*Statistical test of significance*
Association of attributes	Chi-Square test
Comparing the averages for more than two groups	F-test, analysis of variance (ANOVA)
Follow-up observations over time: Comparison of proportions between groups	Repeat measure analysis

OTHER COMMONLY USED TESTS

Some of the other commonly used statistical tests of significance are chi-square test, *F*-test, etc. **Table 13** summarizes the situations where these tests are employed. The data used in the test of significance are collected through surveys or experiments (**Table 13**). The next section describes the details on sampling techniques for gathering of data.

STATISTICAL SOFTWARE

Various software (Microsoft Excel) are used in undertaking statistical analysis of data on health (**Table 14**). Other software such as SPSS, SAS STATA, and R are used.

HOW TO READ A SCIENTIFIC PAPER

Reading and understanding research papers is a skill that every single doctor and scientist has had to learn during graduate school and to be able to distinguish between good and bad interpretations of research. Scientific paper reading is a completely different process from reading an article. Not only we have to read the sections in a different order than they're written, but necessary to take notes, reading paper

TABLE 14: Software used in undertaking statistical analysis of data on health.	
Microsoft Excel	
Background	This is part of the Microsoft Office suite of programs. Excel version 1.0 was first released in 1985, with the latest version Excel 2016
Application features	• Extremely easy to use and interchanges nicely with other Microsoft products • Excel spreadsheets can be read by many other statistical packages • Add-on module which is part of Excel for undertaking basic statistical analyses • Can produce very nice graphs
Limitations	• Excel is designed for financial calculations, although it is possible to use it for many other things • Cannot undertake more sophisticated statistical analyses without the purchase of expensive commercial add-ons
Source	Most computers come with Microsoft software already installed. For blue-plated (UniSA) computers, contact the IT helpdesk to install the latest Microsoft Office software. For your own computer, you can always purchase Microsoft Office from a retail store

multiple times, go through the other papers too in order to understand some other details. Reading a first paper may take very long-time, but process will go much faster as reader gain experience.

Benefits of reading the scientific paper: Journal papers are latest and reflection of latest development in the field. In today's word journals are the most approachable means of obtaining the information. To learn how a certain research is conducted, and explain the data every physician must learn to do research, because one day most of the clinician could be writing papers too. Student can develop critical thinking about quality of research papers. It is important to learn scientific paper quickly and insightfully.

Reading a scientific article is a complex task. The incorrect way to read the scientific paper is to read it like a textbook (reading from title to literature cited, digesting every word without any insight or criticism). The best way to start the reading is the "skimming the article" to identify its structure and features. Look for the author's main points as you proceed further. Generate questions before, during, and after reading. Draw conclusion based on your own experiences and knowledge, take notes as you read to improve understanding and recall.

Scientific papers are broadly categorized in to two types; Review articles: Which is a summary and conclusion of many studies and give an overview of the scientific field. Primary research articles: Contain the original data and conclusions of the researchers who himself involved in the experiments. Review and Primary research paper can be distinguished by the following ways:

- Many reviews will be labeled as "review" on the first page of the article.
- Reviews don't have a "methods" section.
- In a review article, graphs, tables, or figures containing actual data will contain citations in the figure legend to the primary research papers that originally reported the findings.

The Typical "Anatomy" of a Paper

Most articles are divided into the various sections: Before start reading the scientific paper, we should know the components of a scientific paper these are enumerated as:

- Title and authors
- Abstract/Summary
- Introduction
- Materials and Methods
- Results
- Discussion
- Acknowledgements
- References
- Figures/Tables
- *Title and authors*: Title is very descriptive (often states the main finding) and is not about being creative. Order of authors is important.
- *Abstract/Summary*: Gives the brief description of subject, purpose for the study, major findings of the study, relationship between these findings and the field.
- *Introduction*: Presents the background information for a fellow scientist (possibly in another field) to understand why the findings of this paper are significant. Introduction mainly consists of accepted state of knowledge in the field, focuses on a particular aspect of the field, data related to particular field. It is important for the clinician to approach the introduction systematically: Grab a blank piece of paper: Take notes, Draw mini figures, Define vocabulary Answer these questions: What is the accepted state of knowledge? What are the available data prompted the work on this paper? What is the hypothesis being tested? What are the basic conclusions? Making notes gives us benefits to take a break (hours to days), then resume the reading of paper and you won't have to re-read the part you have completed.
- *Material and Methods*: Should be detailed enough for another scientist to replicate the work (volumes, times, company material was purchased from etc.). In reality, often compressed and you may need to look up another paper that is referenced for more detail. Should you read the materials and methods? Skim the paper before the result, then switch back to article to clarify the experiment methods. Whether sample number is taken appropriate?
- *Results*: While the introduction poses the questions being asked, the results describe the outcome of the experiments that were done to answer the questions. Figures and tables are used for interpretation of the results. How to read the results: Read the text straight through, examine the figure. Figure should be able to explain: (1) The basic procedure, (2) The question it sought to answer, (3) The results, (4) The conclusion; and (5) Criticisms.
- *Discussion*: Data is analyzed to show what the authors believe but readers not necessarily have to agree with their interpretations. How to read Discussion; Take notes and answer these questions: What conclusions do the authors draw? Be sure to separate fact from their opinion/

interpretation? Describe for yourself why these data significant whether it contribute to knowledge or helpful in correction of the errors.
- *Acknowledgements*: Thank people who contributed materials, clinical nonclinical or technical people. (May not be authors).
- *References*: Papers cited in the text; what parts of the paper cite other papers?

How Should We Read a Scientific Paper?

It is not necessarily that we should read scientific paper in same order. A four-step method should be adopted based on: *Ann McNeal, School of Natural Science, Hampshire College, Amherst MA—*
- *Step 1*: Skim the entire paper: Look at the major headings (whether they follow the "anatomy" just described) How many figures are there, what kinds of figures are they (tables, graphs, microscopic images) What is the conclusion of the paper? (It may not give you any clue to you at the moment, but note for a moment.)
- *Step 2*: Vocabulary: Go through the paper as a whole simply underlining words and phrases you do not understand. At this moment we are not reading the paper for comprehension of the whole paper, but try to understand the words and then comprehend it.
- *Step 3*: Read for comprehension, section by section; Introduction-what is the accepted state of knowledge in the field (take notes and even draw your own figures). What is the previous data prompted to do this work? What question are they answering? (Is there a clear hypothesis?) What are their conclusions? Materials, Methods and Results: Go through the methods first or read them as you read the results. Figure should be able to explain: (1) The basic procedure, (2) The question it sought to answer, (3) The results; and (4) the conclusion. After reading one should be able to explain all of these to another colleague. Discussion; try to understand what conclusions do the authors draw? Categorize and differentiate fact from their opinion/interpretation? Try to understand significance of the data, whether it enhancing your knowledge or helpful in correcting the errors.
- *Step 4*: Reflection and criticism: Write down your thoughts whether you agree with the authors' rationale for conducting this research, and if they perform the experiments properly? Do you agree with the authors' conclusions from these data? Have they neglected any factors that could have accounted for their research? What further questions do you have? What might you suggest they do next?

Tips for Successful Reading

- Spend a lot of time on each paper now look up every detail that you are unsure of. (Time you invest now will pay off in the long run). The best ways to learn and to retain the information is discovering the answers for yourself.
- Imagine yourself teaching the paper or figures to colleagues—teaching something to others is also another great way to learn.
- Start making a database of procedures that you take the time to look up and teach to yourself (e.g., western, immunoblots, RT-PCR, Neutralizing antibodies assay, apoptosis assays, etc.).
- The more you understand the research methodology, the more critical you can be of data analysis and interpretation.
- Read papers when you are tuned and interested in reading.
- If you are already in the field you plan to stay in, consider starting a database on papers that relate to your lab/project/responsibilities. You will be able to impress your seniors/colleagues with your quick analysis and summary of a monumental paper.

SUMMARY

Researchers need to understand the features of different study designs, with their advantages and limitations so that the most appropriate design can be chosen for a particular research question. Evidence-based medicine offers a useful tool to determine the type of research design used in a particular study.

Transforming Emergency Department with Digital Technology

12 CHAPTER

Rajesh Kumar Gupta

INTRODUCTION

Emergency department (ED) in any hospital is usually where patients present with no prior appointment, seeking immediate attention for an acute condition. In such a scenario, urgent care can be provided only if a patient's medical record is available real time, accessible easily on the move, with information shown in a way that is suited for emergency room (ER) clinicians, nurses, and technicians.

Digital technology plays an extremely important role in defining such care pathways. It has revolutionized the way doctors and nurses retrieve and view a medical record, initiate diagnostic and procedure orders, get real-time alerts and notifications, and adjust treatment plans on various devices at the point of care or on the move.

For a better understanding of the ER digital transformation, let us break the urgent care delivery process in the following steps:

1. Ambulance management
2. Check-in at ER
3. Triage
4. Initiating a care protocol
5. Clinical documentation
6. Discharge home or transfer to inpatient department (IPD)

Each step is described further in detail with the possible digital transformation solutions one can take to improve the urgent care delivery process.

AMBULANCE MANAGEMENT

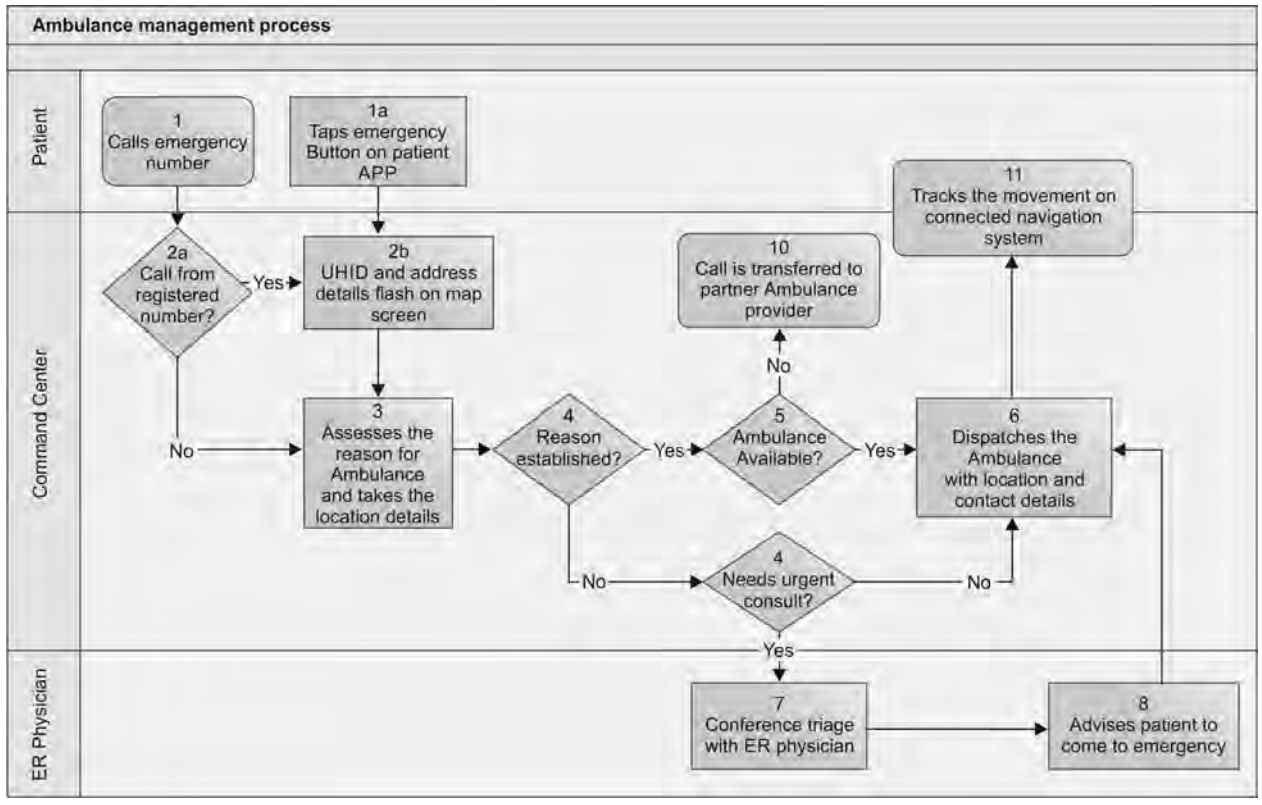
The ambulance management process can vary a little from hospital to hospital; however, the core remains the same. (**Flowchart 1**). As a best practice, before proposing a process automation, we must document the process flow. Each step in the process should be measurable for further analysis in terms of effectiveness and efficiency, especially when data can be represented in a dashboard format, as described in the admin dashboard section later.

Request for Ambulance

Digital technology enables initiation of the care delivery process even before a patient physically arrives at ED. Today, patients can request for an ambulance at the touch of a button, using digital platforms such as a patient app or patient portal. This automatically initiates a call to the emergency number of the hospital, with the exact geolocation fetched from the calling device, and patient demographic details getting populated automatically for an already registered patient. A set of configurable questions to derive at the criticality of a patient's condition can be defined as displayed in the screen in **Figure 1**. A single-screen command center view automatically retrieves key medical information of the patient and helps in quick decision-making according to the patient's current acute condition and past medical history. Appropriate category of the ambulance is dispatched by a single click and tracked via Global Positioning System (GPS).

Patient Care in Ambulance

The process flow depicted in **Flowchart 2** describes the patient care process in the ambulance. While care initiation in an ambulance is always expected to be prompt, retrieving a patient's past medical record from the paramedic app enables the health workers to take an informed decision quickly. If no previous record exists, the app provides the functionality to register the patient and generate a unique hospital identification (ID) within a single click and push the patient details automatically to ER reception where the team can be ready proactively, to receive the patient, generate a barcoded wristband for patient ID with unique hospital identification (UHID), maintaining immediate care continuum. Referral to other specialty experts can be initiated from the ambulance itself, thereby saving critical time in getting help once the patient arrives in ER. Integration between patient monitoring systems and electronic medical record (EMR) via mobile devices allows real-time monitoring by both clinicians in the ambulance and senior doctors at the ER department through real-time data transmission (**Fig. 2**). Equipping ER command center with video conferencing equipment and high-speed internet enables the opportunity for teleconsultation with specialists at the hospital. Ability to view and analyze medical records helps not only in concluding a diagnosis, initiating appropriate treatment, but also in completing the triage in the ambulance itself. On arrival, the patient can then be taken to the appropriate area



(ER: emergency room; UHID: unique hospital identification)

FLOWCHART 1: Ambulance management process.

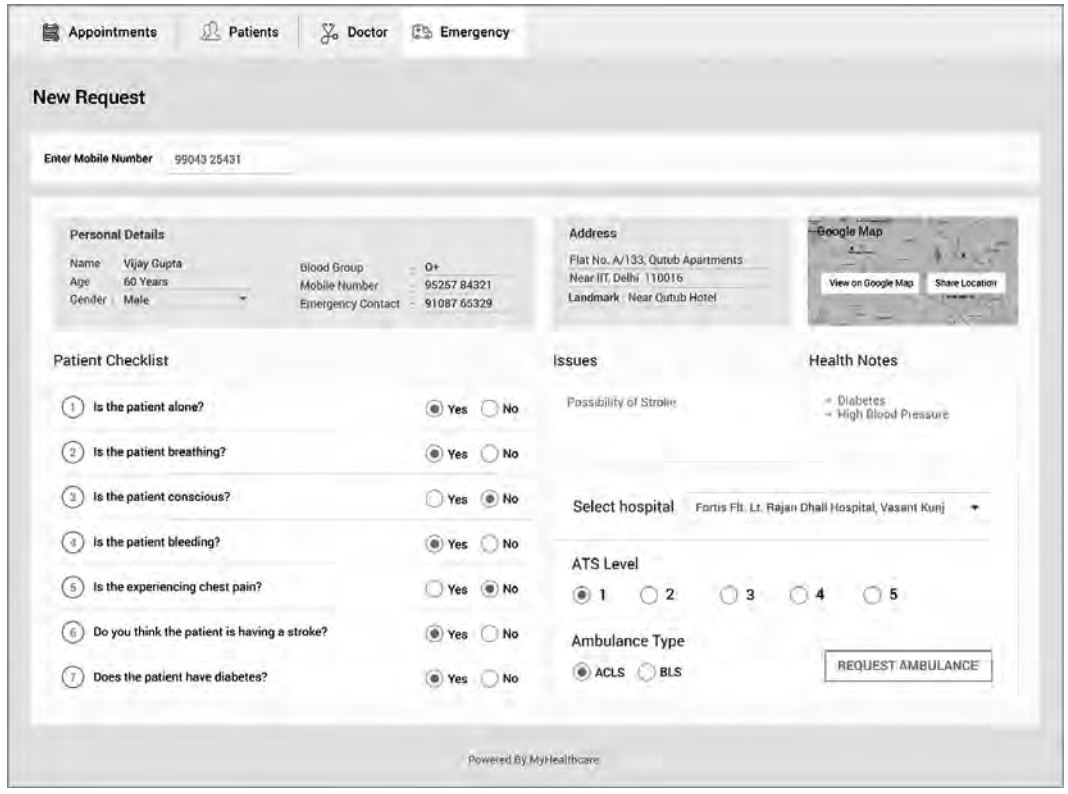


FIG. 1: Ambulance request.

(ER: emergency room)

FLOWCHART 2: Patient care in ambulance.

in ER, intensive care unit (ICU), or operation theater (OT) immediately.

CHECK-IN AT EMERGENCY ROOM

Check-in of the patient coming by ambulance can easily be a one-click activity with process automation (described earlier) which transfers entire billing data to the hospital information system (HIS) for further processing while the ambulance is made available to cater to the next patient immediately. If a patient is arriving in his/her own transport, the attendant can be allowed to check-in online via a mobile device. This reduces the documentation burden on already stressed triage and reception staff and expedites the check-in process for patients.

TRIAGE

The biggest challenge in digital transformation in an emergency setting is the inability of EMR systems to provide a single view for ER clinicians to find all the information required in real time. It is practically impossible for them to navigate through multiple menus and screens of EMR software to retrieve the details required or to perform an action as close to near real time as possible, considering how critical time is in an ER setting. The ER clinical dashboard is a one-screen view that attempts to overcome this challenge and help ER clinicians to manage a patient as described further, as shown in **Figure 3**.

Emergency room dashboard provides a holistic view and at the same time allows clinicians to act quickly with the following functions in real time:

- Color-coded bed and triage category management with easy bed shifting within ER and real-time LOS
- Critical alerts and notifications
- *Triage*: Entering the vitals, triage documentation and initiating a treatment protocol
- Nursing and physician assessments, specialists' referrals—with color-coded status as due, overdue, and completed
- Order tracking of laboratory, radiology, other diagnostics, and medication administration with adverse drug reactions
- Short cuts to place a new order
- Status update on transfer request to IPD or discharge
- Quick response (QR) code-based quick actions

The triage process should be configurable to adopt a set of guidelines (Australasian, Canadian, etc.), followed by ED. Alternatively, the system should allow defining custom guidelines for ED. The ability to view test results with a quick turnaround time enables speedy treatment for patients, referral with the right specialist, and faster clinical decisions, thereby improving patient outcomes and increasing patient satisfaction.

CLINICAL DOCUMENTATION

The EMR module can integrate a wide variety of clinical records and documents into a patient's medical record. The system allows a quick generation of patient history, systemic review, and physical examination information by allowing configuration of the clinical notes as per a structured format. The clinical note can be designed in such a way that it requires minimum typing effort and more touch-based documentation such as selections from a dropdown, radio buttons and checkboxes, to save time. Voice to text feature can also be provided in case detailed notes need to be recorded by clinicians. The discharge summary format can autopopulate already captured relevant information from the patient record, making it easier and faster with the elimination of transcription errors. Provision to

FIG. 2: Teleconsult in ambulance.

Courtesy: My Healthcare Connected Care Ecosystem.

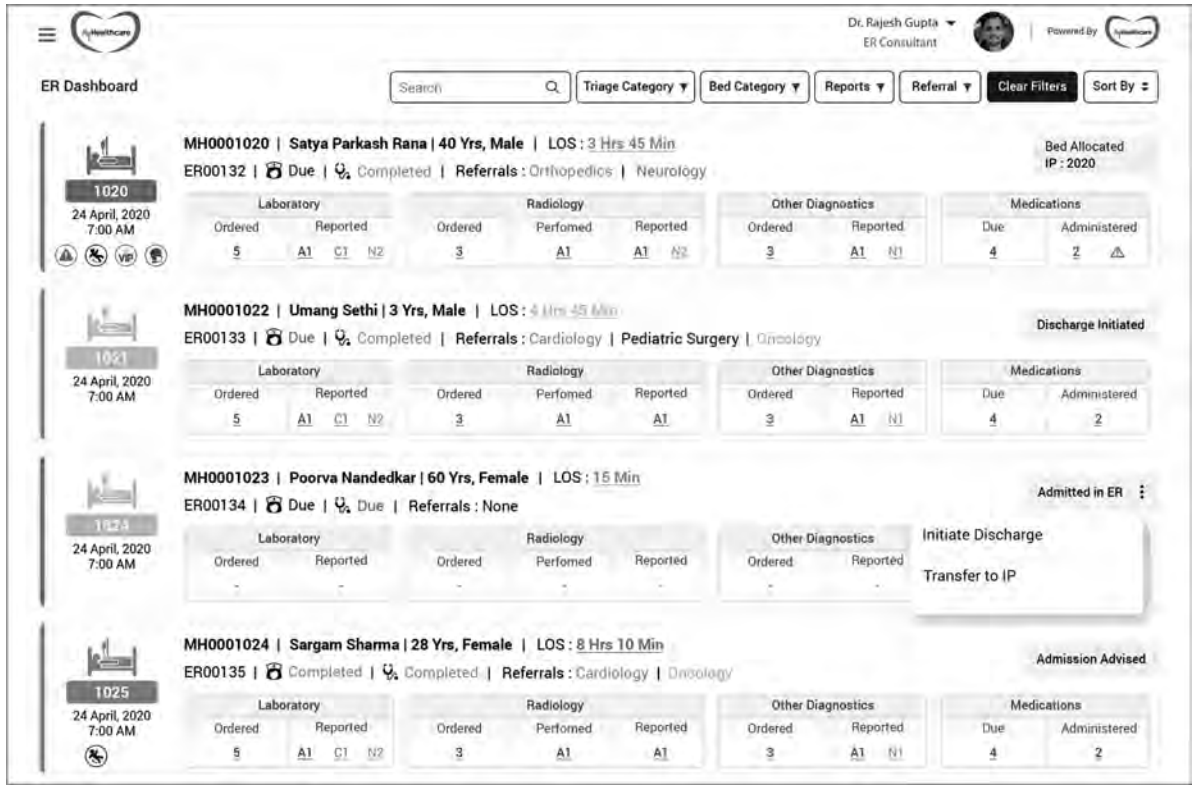

FIG. 3: Emergency room clinical dashboard.

Courtesy: My Healthcare Connected Care Ecosystem.

manage the images in addition to creating the various clinical notes for the patient care makes the document more evidence-based. Documentation features may include:

- Recording clinical notes in prespecified templates with data prepopulated as much as possible
- Dynamic validation rules—age, gender, encounter type, specialty, etc.
- Two-step documentation—draft notes entry by one person and review/finalization by another as per predefined setup and rules
- Audit trail maintained for the amendments and addendums made for traceability and accountability
- Sharing the notes amongst clinicians for review/second opinion

INITIATING A CARE PROTOCOL

Despite the success of process standardization in multiple other industries, its adoption in health care has always been challenging. Having said so, hospital managers, clinicians, and nurses are beginning to realize the potential of coordinated interdisciplinary care to improve the quality of care and reduce revenue leakage at the same time. While individual care is essential, standardizing evidence-based best practices is a significant part of delivering effective, safe, and affordable care. There are numerous benefits to standardized care:

- Improved patient safety by reducing errors
- Improved quality of care
- Reduced redundancy of work
- Better compliance to documentation
- Reduced process waste
- Improved productivity and efficiency
- Reduced costs
- Consistent outcomes
- Higher patient satisfaction

Standardized clinical protocols offer specific instructions on best practices to treat a given condition with the use of evidence-based medicine. They help in making care delivery more consistent and efficient and bridge the gap between what clinicians practice and what evidence-based medicine recommends (**Fig. 4**).

An example of an automated care protocol is shown in **Figure 4**. This allows to make certain steps and actions mandatory (pre-ticked when the protocol is initiated) while providing the flexibility to change it real time depending on the patient's conditions, availability of past reports, drug allergy profile, etc. The right use of devices (computer, tablet, or mobile) enhances the adoption of clinical protocols to a great extent by providing a single view of clinical protocols from initiation to completion. Technology adds value by highlighting and measuring any deviation from the clinical protocols with clinical justification.

FIG. 4: Clinical protocol.

Courtesy: My Healthcare Connected Care Ecosystem.

DISCHARGE HOME OR TRANSFER TO INPATIENT DEPARTMENT

It is extremely important to discharge the patients from the ER or transfer them to IPD if their clinical condition is not favorable to discharge. This is to ensure that the department has the adequate number of beds ready to receive new patients should there be an influx of patients from a nearby accident or disaster. Discharge initiation or transfer request to IPD from the ER clinical dashboard itself makes it easier for ER clinicians to track the process described in **Flowchart 3**.

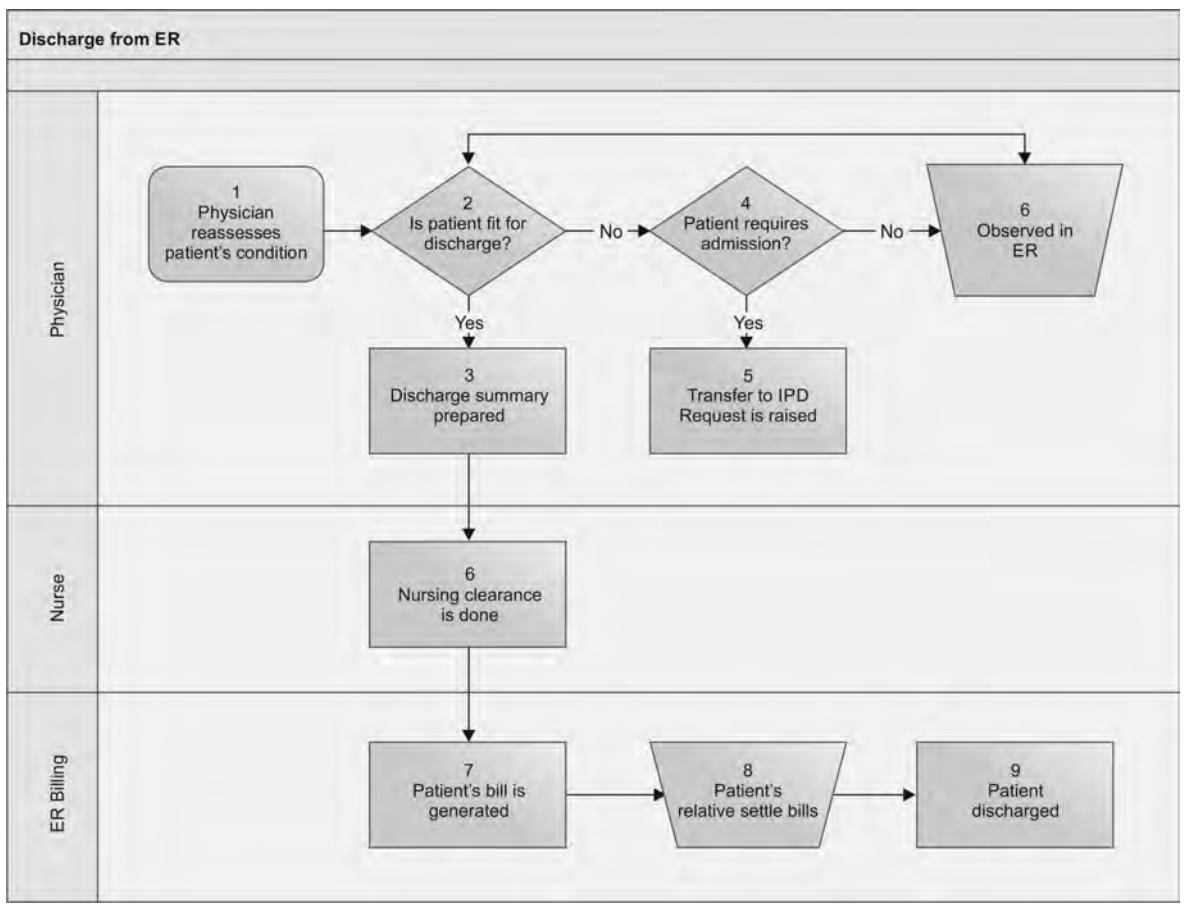
The discharge status is updated on the ER clinician dashboard when the request is acknowledged, the bed is allocated, and so on, thus avoiding time wastage in multiple follow ups. This also results in increased overall patient satisfaction. Automated discharge and transfer to the IPD process also allow measuring the turnaround time of each step. Details of such key performance indicators (KPIs) are described further in the ER admin dashboard section.

EMERGENCY ROOM ADMIN DASHBOARD

Dashboards provide a consolidated view for ER operation managers to access, interact, and analyze real-time and meaningful information to be able to make smarter, data-driven decisions (**Fig. 5**). A good dashboard for the ED enables the head of the department or his/her designated administrator to monitor and measure performance and metrics on the go. They can visualize and analyze data and focus on KPIs across ER processes that have been laid out in consultation with the medical administration and quality departments of a hospital on a single-screen dashboard, helping with valuable insights to drive quick and accurate decision-making.

For instance, it can be anywhere from few minutes to many hours from when a patient arrives in ER and a physician or nursing assessment is done or when a patient's emergency medical treatment is complete and he/she leaves the ED to either go home (discharged patients) or to a hospital bed (transferred to IPD). Knowing the total length of stay in ER is important for understanding the patients' overall experience. The longer a patient stays in the ED, the longer a new patient must wait to see an emergency doctor. The patients' total length of stay is dependent on several factors. For instance, while patients are being treated in the ED, they may also be waiting for things such as laboratory results, referrals by other specialists, results from an imaging, or observing how they respond to treatment. If ER patients remain in the ED waiting for an IPD/intensive care unit (ICU) bed in the hospital to become vacant, it increases their length of stay. An ER admin dashboard with drill-down view till a single transaction level really helps the administrator to find a root cause for delay and its impact on care delivery and thus to initiate an immediate corrective action. An effectively implemented ER admin dashboard can provide the following benefits:

- Total visibility into ER department
- Compliance to processes and defined turnaround time (TAT)
- Improved outcome



(ER: emergency room; IPD: inpatient department)

FLOWCHART 3: Discharge process.

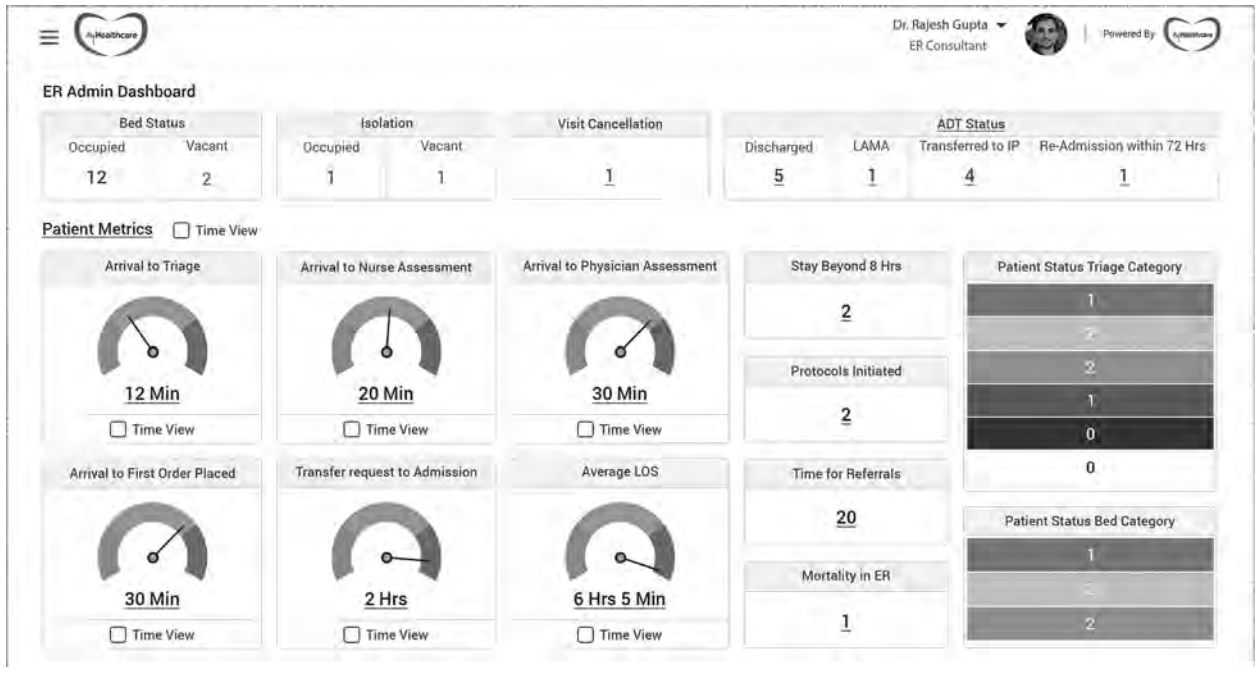


FIG. 5: Emergency room admin dashboard.
Courtesy: My Healthcare Connected Care Ecosystem.

- Increased productivity
- Reduce costs

Dashboards allow us to measure performance objectively with data as proof. For example, we could see metrics such as average time taken to complete a specialty referral, the average time taken to acknowledge a referral request, etc. This metric can be compared between different specialties in a leadership dashboard, which would eventually lead to an overall improvement in the performance and results. However, for any dashboard to provide accurate information and any process automation to work effectively, it is necessary to have a robust and stable process. Only a stable process can give rise to meaningful data which can then be processed and converted into information to taking smart decisions. Recent advancements in technology in the form of QR codes in mobile devices and interoperability with medical devices have made technology hand in hand with ER making it much easier to implement digital technology in making a process more robust and stable.

TECHNOLOGY HAND IN HAND WITH EMERGENCY ROOM

Quick Response Code Technology

Barcode technology has been in use in health care for decades, especially in sample tracking and laboratory process automation. The success of barcode technology in a laboratory process prompted wider use in health care across various departments. A barcoded wristband to identify the right patient has enabled faster completion of clinical transactions. The QR scanner (available in a smartphone camera module) reads the patient's UHID and his/her bed details from the patient's wristband and ties it to any new order, documentation, and point-of-care test. It also helps nurses to administer medication by following five rights: (1) Right patient, (2) Right drug, (3) Right time, (4) Right dose, and (5) Right personnel. Scanning technology can also prevent blood transfusion mishaps, such as giving the wrong blood to the wrong patient. After scanning the patient's wristband and blood bag, the computer system alerts the nurse if the wrong blood unit is being transfused or if it is for the wrong patient. With the use of barcode technology in ER, it ends up optimizing many of the existing processes, which ultimately changes the way hospitals practice emergency medicine, and reducing the manual errors drastically.

Mobility Devices

The ED by its nature of work requires a lot of actions to be done on the move; hence, handheld devices have started playing a big role in enabling the clinicians to perform their tasks on mobile devices (**Figs. 6** and **7**). With high-speed data connectivity being available easily across the globe at a much lesser cost, and with Wi-Fi being an integral part of hospital infrastructure planning, the use of the mobile device has reached a greater acceptability. Camera modules of mobile devices help in capturing images and sharing them in real time across the care team by saving it in EMR as part of clinical documentation. It also acts as a barcode scanner, thereby eliminating the need of a bulky computer on wheels which is much more costly to procure and maintain. Additionally, with people getting so used to using a variety of apps on their smart devices, the training effort required to increase EMR adoption has gone down to a great extent. Patients are also increasingly demanding for platforms where they can contribute and engage in their own health management. Therefore, tablets and smartphones are increasingly brought into daily use by clinicians and patients alike as they are finding it much easier to receive results, alerts, decision support, and charting on these devices. As part of the overall infrastructure planning, hospitals are now looking to implement touch screen tablets

FIG. 7: Vitals view.

Courtesy: My Healthcare Connected Care Ecosystem.

with every bed similar to having a paper chart mounted next to the bed but much more secure with the capability of generating additional information, which can be used for data analytics.

Interoperability

The adoption of digital health technology is largely dependent on systems' integration to leverage data and insights from various diagnostics, monitoring, and treatment devices used in silos currently. Data lying in individual systems do not provide a holistic view. For instance, a laboratory result in conjunction with medication administration provides more meaningful insights into what is the impact on laboratory values when a medicine is administered. Since episode-based EMR is the primary interface most clinicians are adopting today, the path to improved data-driven outcomes is likely to be through the EMR only. However, unless EMR is tightly integrated with next-gen internet of medical things (IoMT) devices and other clinical applications using integration standards [such as health level 7 (HL7), fast health interoperability resource (FHIR), etc.] and coding standards (such as ICD-10, SNOMED CT, NANDA, and LOINC), meaningful clinical data analytics and predictive analytics will not be possible. As a transaction-based system, the EMR is fundamentally not designed to facilitate real-time, point-of-care clinical decision support especially when large data is lying in silos. Hence, it is extremely important to choose software solutions which comply with the latest integration standards and all efforts should be made to interface these systems as *one* clinical system for the hospital.

SUMMARY

It is an exciting time to be in a digital healthcare transformation space. Digital innovation and its implementation into the ER department process design has improved both the patient experience and care delivery with better outcomes. The future lies in relentless innovation to facilitate continuous adoption of digital technology for improved care delivery, increased patient engagement in care, and increased process efficiency in ER.

Advanced and Future Technology in the Emergency Department

13 CHAPTER

Devendra Richhariya

INTRODUCTION

Technology has revolutionized the way medical professionals work, communicate, and process information. Nowhere is this more apparent than in the emergency department (ED). Digital communication tools allow nurses and clinicians to uncover and track data in real time and adjust the course of treatment. As healthcare architects, we strive to incorporate creative and cost-effective technologies into ED spaces to help improve patient outcomes and the delivery of care. The emergence of medical technology and new equipment helps healthcare in maintaining the quality and moving forward, and medical technology advancements will not slow down anytime soon.

The ED is particularly focused as this is the face of any healthcare system, about 40–60% of the inpatient and observation patients being admitted through the ED. Emergency medicine is the field of practice based on knowledge and skills which is used to prevent diagnose and manage the acute and urgent aspect of the illness. The goals of the emergency care are to improve the patient care, lessen the patient care stress on staff, limit the financial cost to the hospital, and allow more available time for teaching.

Today, our emergency care system has multiple roles, not only to attend and manage urgent and lifesaving emergencies but also to maintain quality and safety standards, disaster preparedness, and public safety net care and provide care even with increasing patient volume with limited resources. The newer technology has an acceptable wide range of role and impact on the ED within the larger hospital and healthcare system and can address a wide range of issues which include:

- Patient flow and overcrowding by information technology
- Workforce issues across multiple disciplines
- Tracking patient safety and the quality and efficiency of emergency care services
- Emergency care-related clinical research
- Use of newer technology for setting up emergency care in rural settings

The a list of innovations that are transforming the way emergency care is provided is given in the following text.

ONLINE CHECK-IN

Recent advances in telemedicine also enable the patient to virtually check-in with healthcare staff in the ED before arrival. Several EDs allow for patients to check-in online via a mobile device, Entering personal information such as insurance and point of contact data. Registration can occur at home, in the car, in the waiting room, or bedside in a treatment room. This elevates the paperwork burden on already stressed triage and reception staff and expedites the check-in process for patients. Implementation of algorithms and artificial intelligence will help the triaging patients to get medical care at the right time and right location.

PATIENT FLOW SOFTWARE

Gone are the days of nurses walking up and down hallways documenting empty beds. Today, patient flow software manages where patients are (and are not) within the hospital. It can identify available beds by specialty, thereby streamlining the registration and decreasing wait times. These systems have been said to improve communication across departments and expedite both admissions and discharge procedures.

REAL-TIME LOCATING SYSTEM

Similar to patient flow software, real-time locating systems digitize information regarding where a patient is, or is not, during his/her course of treatment. This technology can also be adapted to track all movements in the hospital by applying location transmission tags to patients, beds, staff, and equipment alike. With this information, practitioners are able to more accurately track movements to efficiently manage time and care. Additionally, hospital administrators may utilize movement data to analyze workflow, standardize care, identify best practices, and eliminate waste.

MINIATURIZATION OF IMAGING AND DIAGNOSTIC EQUIPMENT

Point-of-care ultrasound machines allow emergency doctors to make diagnosis easier by identifying injuries and

illnesses such as bleeding in the abdomen, gallstones, kidney obstructions, or acute heart failure. While medical imaging is required to perform comprehensive scans, point-of-care ultrasound (POCUS) allows emergency physicians to answer binary questions that may influence the course of care and dramatically improve outcomes. Physicians are able to travel with a dedicated imaging machine, eliminating the waste of learning how to operate a different machine or having machines sit idle. Miniaturization is also starting to extend into the fields of endoscopy and laryngoscopy, where a handheld device is replacing a bedside cart.

Noninvasive bedside laboratory testing is also changing the delivery of care model. The i-STAT blood testing system delivers laboratory-quality test results through a handheld device and then wirelessly transmits results to a patient's electronic medical record (EMR). This bedside technology eliminates the waste of transporting samples to and from a laboratory and frees up highly coveted ED real estate.

Research has shown that immediate access to imaging is vital to the diagnosis and outcome of stroke and head trauma patients. However, because CT scanners have traditionally been large and expensive, they are not always immediately accessible to the ED. New miniaturized CT scanners are portable and wireless, able to be brought directly to a patient's bedside. These portable CT scanners are revolutionizing the standard of care by eliminating the dangers associated with both the transportation and wait times traditionally required to move a critical patient to a medical imaging suite.

Handheld Devices: Portable Ultrasound, ECG, and Other Point-of-care Devices

As with the rest of society, over the past several years EDs have become more computerized. Tablet, computers, and smartphones are increasingly common in daily use by practitioners and patients alike. Physicians can now review EMR data (such as glucometer readings or stethoscope sounds) from anywhere on their smartphones. Given the prevalence of handheld devices, it is inevitable that more decision support, charting, and patient record management will be performed on these devices. Moving forward, all horizontal surfaces in an ED should be adaptable into a touch-down workstation with data connectivity and power (including the incorporation of wireless inductive charging surfaces to eliminate unnecessary wires).

The bigger machines of ultrasound ECG are a thing of the past which require one manpower to move. The portable diagnostic devices, which are almost pocket-size and user friendly, are easier to operate and are helpful in treating the patient quickly and thus diagnostics are carried out on the spot.

A few years ago, only a radiologist had the privilege to carry out the ultrasound and only in the radiology department which was sometimes not feasible since it was difficult to move critically ill trauma patients to the radiology department. Now more and more emergency physicians are getting trained and using POCUS for the immediate answer (yes/no) about intra-abdominal bleeding (**Fig. 1**). Handheld devices allow any doctor to use them easily while working on a code or a critically ill patient (**Fig. 2**).

Long back ago ECG can be interpreted on the smartphone with one lead but many situations can be missed easily, and interpreting 12-lead ECG is required for detailed assessment. Now the available device allows the end-users to get 12-lead ECG wirelessly on their smartphones/tablets, which is as accurate as a similar standard bedside exam (**Fig. 3**).

FIG. 1: Handheld ultrasound.

FIG. 2: Handheld echocardiography.

FIG. 3: Wireless 12-lead electrocardiograph.

With handheld devices, long waiting hours for laboratory results are also gone. Handheld, lightweight point-of-care testing (POCT) devices and accurate blood analyzers equipment allow doctors to evaluate the patient's blood sample on the spot and wirelessly transmit the results or the data to colleagues, thus saving invaluable time during emergency situations and enabling the emergency physician in timely decision-making.

TELEMEDICINE

Equipping ED treatment rooms with cameras, monitors, and high-speed internet invites new opportunities for remote consultation with specialists around the world. This technology empowers small rural hospitals to partner with sophisticated centers of excellence, no matter how far from the facility, to provide patients with a higher standard of care. Some EDs incorporate smart TVs in the exam rooms connected to the facility picture archiving and communication system so that imaging data can be pulled up in a patient room as an aid for discussions. In the future, touchscreen tablets outside every exam room door will function as both a room sign and a tool for medical staff to bring up patient data prior to entering the room, similar to having a paper chart mounted next to the door but more secure and capable of generating additional information.

Additionally, Wi-Fi-connected equipment, both in and outside of the hospital, allows for patient data to be securely collected and transmitted to physicians for evaluation and tracking (**Fig. 4**). For example, systems currently exist in which a patient may upload glucometer readings or stethoscope sounds directly to their EMR for physicians to review.

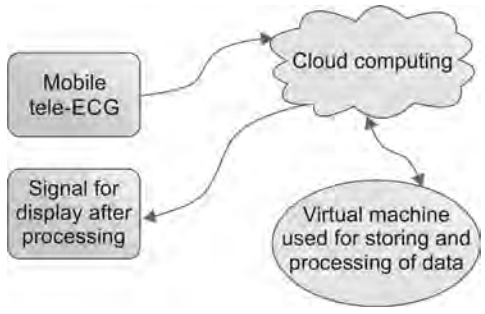
BARCODE SCANNER

Barcode scanner is another relatively new advancement in technology implementation in the ED (**Fig. 5**). More and more healthcare organizations are integrating barcode technology into their facilities; many of their processes ultimately change the emergency medicine practice. On arrival to ED, a patient receives a wristband with a unique code and the scanner captures the code from the patient's wristband and matches it to any test, lab result, or procedure. The bar code technology is helpful in the speedy delivery of accurate results. The bar code technology reduces the labeling errors and manual errors which take a lot of time to rectify. It has been reported that barcode technology increases the patient satisfaction and positive health outcomes, and there is a huge potential for expanded use of the technology. The bar code technology, also known as radio-frequency identification (RFID), allows improving turnaround time on laboratory test results which are helpful in initiating the definitive treatment early and early referral to the right physician which ultimately increases the patient satisfaction.

Each time patients provide blood or urine samples, the nurse scans the patient's wristband and then scans the specimen; it updates the patient's EMR and his/her specimen identification code is connected to his/her ID number, which increases efficiencies and decreases the incidence of error.

Barcode technology creates a tracking process that helps decrease medical errors because a nurse scans a patient's wrist band each time a process is done. Scanning technology can also prevent prescription mishaps, such as giving the wrong medications. After scanning the patient and his/her medication, the computer system alerts the nurse if the wrong medication is being administered or if it is for the wrong patient.

The barcode technology reads the barcode through the skins and also helps the surgical team to track surgical tools and sponges during surgery with accuracy rates between 98 and 100%.



Mobile tele-ECG

Signal for display after processing
Virtual machine used for storing and processing of data

FIG. 4: Secure data transfer to the physician for analysis.

FIG. 5: Barcode technology.

COMPUTERS ON WHEELS

To enhance healthcare delivery, the use of electronic health records has become necessary for healthcare facilities to create a point-of-care environment where a patient's EMRs and all interfaces are available to healthcare providers together. Healthcare industries have large investments in computing technology to ensure that an electronic health record (EHR)-equipped computing device is present virtually at all doctor–patient interactions. Facilities are equipped with wall-mounted computers in their infrastructure to save space and computers on wheels (COWs) save cost also. Nurses carry a computer with them as they conduct patient interactions during a shift, thus enabling them and also the physician to access EHR for each patient (**Fig. 6**). Another benefit of COW is that the care provider can use the same computer throughout his/her shift, so COWs are cost effective as well as ensure that EHRs are always accessible at the point of care.

Helpful in Streamline Workflow

This is a common practice in healthcare facilities throughout the country that nurses and medical officers conduct clinical round with patient interaction, then come back to stationary computers at the nursing/physician station, and record all vital details of interaction and physician orders. COWs allow nurses and physicians at the point of care to record all vital information at the same time which streamlines the process. COWs are also helpful in reducing the multiple steps of the process. Radiological images of a patient can also be accessed from the hospital's internal network while interacting with the patient during morning or evening round, and an appropriate clinical decision can be taken instantly. Storage space can also be created in the same trolleys enabling nurses to bring supplies and medications with them to the patient's bedside and minimizing trips to the supply and medication rooms on each shift.

FIG. 6: Computers on wheels (COWs).

Helpful in Reducing Error and Improve Patient Safety

As discussed earlier, nurses and physicians record patient care data and record progress notes and patient interaction at the point of care which are helpful in reducing record-keeping errors and improving patient safety. By using COWs, nurses and physicians need not go back to workstation for data entry and they are less likely to forget an entry, leave out an important detail, or even be interrupted by an emergency that takes away their focus from the vital task of recording a patient interaction or the administration of medication. COWs are helpful in medication dispensing also as some manufacturers have customized storage drawers that contain medication, along with a barcode scanner. The wristband of the patient and medication is scanned to verify that the prescribed medicine is given to the correct patient and automatically generates an online record of the interaction. Complete medicine delivery systems are attached to the COWs, and the movement of medications from a secure loading station to the patient's bedside can be tracked through a barcode. With medicine delivery systems, dispensation errors can be drastically reduced because drawers are secured and only unlocked by scanning the barcode on the patient's wrist.

Promote Patient Engagement

Facilitating patient engagement throughout the healthcare delivery process is an important aspect for improving patient satisfaction and leading to improved healthcare outcomes. As we know, paper records were kept out of the reach of the patient at the nursing station and seldom shared with the patient. But with the help of COWs, reports and imaging can be shared and discussed with the patient as well as his/her illness during physician–patient interaction. In this way, patients and family feel engaged in healthcare processes and are also more likely to return to the facility where they had a good experience. Data can also be updated and shared with the patient and patient queries can be answered.

Outperform Other Technologies of Healthcare

Other technologies, such as wall-mounted computers and tablet smartphones, have similar functions to COWs but because of their versatility, practicality, and low cost, COWs are used in healthcare facilities. COWs deliver many of the same benefits as wall-mounted computers or tablet computers in the healthcare environment, so why is it that healthcare facilities everywhere prefer mobile computer carts? There are several reasons, but it ultimately comes down to cost, versatility, and practicality. Although tablets are light weight and many touchscreen tablets are incapable of facilitating rapid recordings of patient data in comparison to a traditional keyboard, poor battery life makes them inefficient for a healthcare environment. Tablets have a smaller size of screen and most of the emergency medical system strongly advise 24″ screens; EMR software is also not compatible with tablets. Wall-mounted computers are effective, but they have different ergonomic configurations from COWs. In contrast, COWs are both mobile and ergonomic. They can be connected with a powerful monitor/computer combination and can be configured with battery systems that provide enough power for an entire shift or longer. They are easy to transport between patients and provide more benefits to patient care workflows; hence, hospitals should invest in COWs rather than purchasing wall-mounted computers for every room in the hospital.

MEDICAL DRONES

Recently, the e-commerce giant Amazon made headlines when it promised drone-assisted package delivery; now, the healthcare industry is exploring ways to use drones in healthcare medical emergencies and healthcare supply deliveries (**Fig. 7**). The year 2020 started with a pandemic along with earthquakes, cyclones, and flood that destroyed road infrastructure and hence it was difficult to deliver the medical aids to rural areas. Drones are equipped with a global positioning system (GPS) and mapping system which allow the healthcare person to figure out the location where the people have taken shelter after a natural disaster; they are also able to assess the requirement of medicine, water, food, blankets, etc. Drones also help in reaching these affected people either by ground or by air. Drones can perform a variety of tasks as a disaster relief emergency responder to deliver drugs, vaccines, and medical aids very quickly.

In the future, you may call a drone through your device/smartphone in an emergency situation which can fly in with

FIG. 7: Medical drone.

life-saving medical equipment such as automated external defibrillators (AEDs), blood products, and prescriptions. Drones not only can transport medical equipment but also can provide instruction for cardiopulmonary resuscitation (CPR) to the performer.

DRIVERLESS AMBULANCE

With the development of driverless cars and the potential for turning cars into points of care, some governments are considering driverless ambulances as technology. These ambulances can work as "medical taxis." They can pick up low-risk patients and transfer them to the nearest hospital or clinic for treatment. The need for paramedic staff to respond to every call would be reduced and only be limited to critically ill patients. Initially, it would be uncomfortable to travel to the hospital in a driver-less ambulance but probably we have to get used to this concept. Vitals can be recorded passively and stored in the cloud and a driverless ambulance robot can notify to the hospital if there is an urgent situation that needs to be handled.

APPS SIMPLIFYING COMMUNICATION ADMINISTRATION AND IN-FLIGHT EMERGENCIES

Various apps simplify the communication in emergency care. During the medical transfer of a patient, apps not only help by calculating the estimated time of arrival based on the GPS, but users are also able to send pictures of the ECG, injury, medicine list of the patient, real-time data, and the parameters of the patient to the emergency physician in advance. An ED can be alerted by the paramedics before arrival with the patient. Similarly, the stroke team and ST-segment elevation myocardial infarction (STEMI) team can also be alerted that involves a neurologist, intervention neurologist, and intervention cardiologist. Advance information allows ED nurses and doctors to prepare much better and faster for the critically ill patient. Apps developed for resuscitation help in documenting the critical events during CPR and also measure time countdown according to protocol and help in optimizing the chest compression. Apps are also helpful in debriefing the case so that the team can learn from the collected data as well. A team of aviation experts can develop an app to help physicians, which includes the most common in-flight medical emergency situations that could be encountered during a flight. Apps also define the role of flight and cabin crew during in-flight emergencies as well as the medicolegal implications for volunteers who assist.

VIDEO GAMES FOR PRACTICING REAL SITUATIONS

Video game technology also applies to healthcare. The app allows the emergency physician to simulate the performance of airway procedures. Realistic endotracheal intubation scenarios can be created so that the emergency physicians can better prepare for difficult airway management. The app scores on the basis of the physician's skills displayed and also monitors the virtual patient's vital signs while the procedure takes place.

FUTURE OF EMERGENCY MEDICINE

As pressures mount for EDs to do more with less, many healthcare systems have turned to lean principles borne out of the manufacturing industry to cut waste and improve efficiency. Lean planning tools rely heavily on data analytics—both collection and management software. By tracking analytical data [such as movement times collected with real-time location system (RTLS)], administrators are able to identify optimal registration procedures, treatment process times, and staffing schedules. From a patient care perspective, lean principles seek to standardize work processes to ensure that outcomes are reproducible and predictable, improving patient outcome and departmental satisfaction scores.

Digital technologies support patients to receive quick and efficient care at the same time; they also support healthcare facilities to handle situations more safely and more confidently. Using self-driving ambulances, equipped with various sensors and wearable gadgets, healthcare workers and paramedics get a patient's vital data in advance and get more time to prepare for urgent situations.

In the coming years, emergency services will be more sophisticated, streamlined, data-based, efficient, and faster than ever before, while taking both the needs of the patient and the limitations of caregivers into consideration. So, hopefully, within a couple of years, no one will have to wait for proper care. Technological innovation, and its incorporation into ED design, has improved both the patient experience and care outcomes.

As advanced medical technologies are incorporated in the ED, high-tech products are designed to accelerate blood clotting and are available as a kit. Products with blood clotting technology slow blood loss after a person begins to hemorrhage. The kit comes with a tourniquet and gauze dressings layered with anticoagulants that control blood loss of penetrating trauma such as stabbings, gunshots, or vehicular rollover accidents. First responders commonly use the kits to treat when pressure is applied to the bleeding wound.

On one side, medical technology creates manufacturing jobs, improves patient health outcomes, and boosts the economy; on the other side, experts are apprehensive of rising healthcare costs. In spite of that, as new medical technology makes its way into EDs, it changes the way hospitals run their EDs. ED physicians, nurses, and first responders must continue to learn new skills to keep pace with all the high-tech changes.

SUMMARY

The ED is revolutionized by the inclusion of various advanced technologies such as online check-in, handheld devices, monitoring system, and telemedicine. Digital communication tools allow nurses and clinicians to uncover and track data in real time and adjust the course of treatment. Today, our emergency care system has multiple roles, not only to attend and manage urgent and lifesaving emergencies but also to maintain quality and safety standards, disaster preparedness, and public safety net care and to provide care even with increasing patient volume with limited resources. Implementation of advanced technologies in the ED is helpful in conducting the multiple roles of ED more efficiently. The newer technology has an acceptable wide range of roles and impact the ED within the larger hospital and healthcare system and can address wide range of issues.

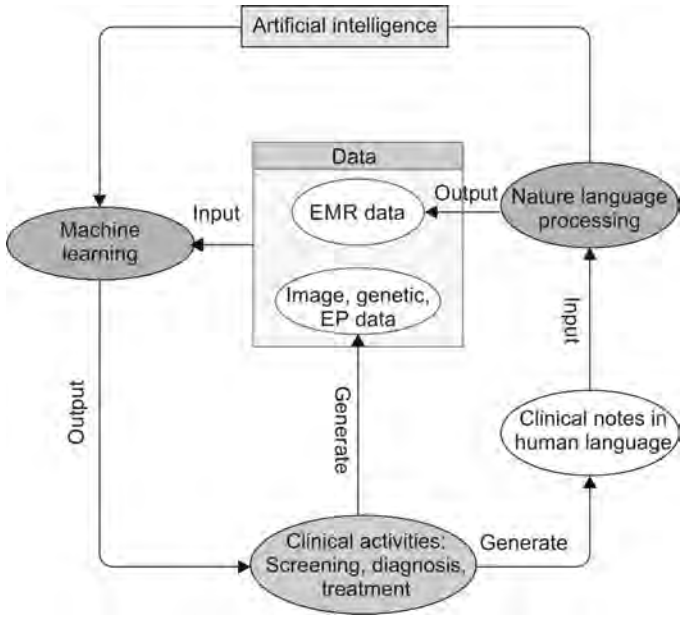
14
CHAPTER

Artificial Intelligence in Healthcare

Sandhya Shankar Pandey, Devendra Richhariya

INTRODUCTION

Over the last many years, some major changes have been occurring in healthcare. Technology has been involved in more precise, efficient, and impactful interventions in radiology and risk assessment, of chronic diseases and cancer, at exactly the right moment in a patient's care. Patients demand more from their providers, as payment structures evolve and the volume of available data continues to increase at a staggering rate. Artificial intelligence (AI) improves patient care. AI offers a number of advantages to diagnostics, care processes, treatment variability, and patient outcomes over traditional analytics and clinical decision-making techniques (**Flowchart 1**). More precise and accurate learning algorithms can be available as they interact with training data, allowing healthcare workers to gain unprecedented insights. Leading researchers and clinical faculty members foresee a major impact from AI in the various areas of the healthcare industry within the next decade and revolutionize the delivery and science of healthcare.



(EMR: electronic medical record; EP: electrophysiological)

FLOWCHART 1: Artificial intelligence in clinical data generation, machine learning, data analysis, and clinical decision-making.

MAPPING MIND AND MACHINE THROUGH BRAIN–COMPUTER INTERFACES

It is not a new idea to use computers for communication, but direct interface between technology and the human mind without the need for keyboards are being used nowadays and is a cutting-edge area of research and significant applications. Brain–computer interfaces (BCIs) backed by AI could restore patients' abilities to speak in neurological diseases and trauma to the nervous system and interact meaningfully with people and their environments. By using a BCI and AI, the neural activities of the affected hand can be decoded and allow that person to communicate the same way as normal people using a ubiquitous communication technology such as a tablet, computer, or phone. BCIs could drastically improve the quality of life for patients with amyotrophic lateral sclerosis (ALS), strokes, or locked-in syndrome as well as for those who experience spinal cord injuries.

ARTIFICIAL INTELLIGENCE IN DEVELOPING THE NEXT GENERATION OF RADIOLOGY TOOLS

Magnetic resonance imaging (MRI) machines, computed tomography (CT) scanners, and X-rays are noninvasive radiological techniques, helpful in diagnosing complex diseases. Physical tissue samples through biopsies are also required in many diagnostic processes for conclusion, which carry risks for infection. Experts predict that AI will enable the next generation of radiology tools that will replace the need for tissue samples with accurate and detailed results. AI allows clinicians to develop a better understanding about the aggressiveness of cancers and target treatments more appropriately. AI is helpful in knowing the phenotypes and genetic properties of tumors by creating image-based algorithms by enabling "virtual biopsies" and advancing the innovative field of radiomics.

ARTIFICIAL INTELLIGENCE IN EXPANDING HEALTHCARE IN DEVELOPING REGIONS

Developing nations around the world usually face shortages of trained healthcare providers, including ultrasound technicians and radiologists, which can significantly limit access to life-saving care. AI is now taking over some of the diagnostic duties that are typically allocated to humans, which could thus help mitigate the impacts of this severe deficit of qualified clinical staff. For example, chest X-rays with signs of tuberculosis can be screened by AI imaging tools, often achieving a level of accuracy comparable to humans. Technology could be deployed through an app available to providers in low-resource areas, reducing the need for a trained diagnostic radiologist on site. However, developers of the algorithm should be careful to account for the fact that different ethnic groups may have unique physiologies and environmental factors that will influence the presentation of the disease. It is very important to make sure that the data represents a diversity of disease presentations and populations and the algorithm should not be developed on the basis of a single population.

ARTIFICIAL INTELLIGENCE IN REDUCING THE BURDENS OF ELECTRONIC HEALTH RECORD

Digitalization of the healthcare industry by implementing electronic health record (EHR) has brought various changes including myriad problems associated with cognitive overload, endless documentation, and user burnout. Clinical documentation, order entry, and sorting consume most of the user's energy and time so EHR developers are now using AI to create more intuitive interfaces and automate some of the routine processes that consume less user time. Natural language processing (NLP), voice recognition, and dictation are helping to improve the clinical documentation process but have some limitations. AI may also help to prioritize tasks that truly require the clinician's attention, routine requests from the inbox, such as medication refills, and process result notifications.

ARTIFICIAL INTELLIGENCE AND ANTIBIOTIC RESISTANCE

Populations around the world are under the threat of antibiotic resistance due to overuse of these critical drugs, thus making changes in superbugs that no longer respond to treatments. Multidrug-resistant organisms can cause disaster in the hospital setting and community and claim thousands of lives every year. AI tools can help to identify infection patterns and highlight patients at risk before they begin to show symptoms and provide accurate and faster alerts for healthcare providers. Hospitals that are using EHR and creating mountain of data should use AI to the fullest potential, to create a smarter, faster clinical trial design to live up to the expectation for infection control and antibiotic resistance.

ARTIFICIAL INTELLIGENCE IN ANALYSIS OF PATHOLOGY IMAGES

Pathologists are one of the most significant sources of diagnostic data for healthcare providers across the spectrum of care delivery, and decisions are based on a pathology result. Right diagnosis depends on a more accurate pathology result and that is where digital pathology and AI has the opportunity to deliver. Digital pathology and AI can provide extremely large digital images which allow the providers to identify nuances that may escape the human eye. AI is now able to assess behavior of malignancy, rapid or slow progression, and patients can be treated based on an algorithm rather than clinical staging or the histopathologic grade. AI can also improve productivity by identifying features of interest in slides and directing us to the right thing to look at so that we can assess what is important and what is not. AI increases the efficiency of the pathologist and increases the value of the time he/she spends on each case.

ARTIFICIAL INTELLIGENCE IN MEDICAL DEVICES AND MACHINES

Smart devices are taking over the consumer environment, offering real-time video from the inside of the cars that can detect when the driver gets distracted. Smart devices are critical for monitoring patients in the intensive care unit (ICU) and in the healthcare environment, and inserting intelligent algorithms into these devices will ensure that patients receive care in a timely manner. Using AI devices can identify deterioration or give an alert for the development of complications which can significantly improve outcomes and may reduce costs related to hospital-acquired complications. AI can alert an ICU doctor to intervene early.

ADVANCING THE USE OF IMMUNOTHERAPY FOR CANCER TREATMENT

Immunotherapy is one of the most important modalities for cancer treatment. Patients may be able to beat stubborn tumors by using the body's own immune system, and oncologists still do not have a precise and reliable method for identifying which patients will benefit from this option; only a small number of patients respond to current immunotherapy options. AI with algorithms and data can analyze highly complex datasets and may be able to suggest new options for targeting therapies to an individual's unique genetic makeup.

ELECTRONIC HEALTH RECORD AS A RELIABLE RISK PREDICTOR

It is a challenge for providers and developers to extract and analyze EHR data in an accurate, timely, and reliable manner. It is very difficult to understand exactly how to engage EHR in meaningful risk stratification, predictive analytics, and clinical decision support as it is all dependent on data quality and integrity issues. A mishmash of data formats, structured

and unstructured inputs, and incomplete records will make the analysis complicated. Many successful risk scoring and stratification tools have been developed through EHR analysis by researchers by connecting deep learning techniques. But these algorithms should truly improve clinical care and should be devoid of any hidden biases in the data.

ARTIFICIAL INTELLIGENCE IN MONITORING HEALTH THROUGH WEARABLES AND PERSONAL DEVICES

Almost all consumers now have access to smartphones with sensors that can collect valuable data about their health with step trackers that can track a heartbeat around the clock. AI plays a significant role in extracting, collecting, and analyzing this data through apps and other home monitoring devices and offer a unique perspective into individual and population health.

MAKING SMARTPHONE SELFIES INTO POWERFUL DIAGNOSTIC TOOLS

The quality of smartphone cameras is getting better day by day and can produce images that are viable for dermatology and ophthalmology analyses by AI algorithms. Various tools have been developed by researchers that identify developmental diseases by analyzing the images of a child's face. Smartphone images will be an important supplement to clinical quality imaging, especially in underserved populations or developing nations. Most of the population are equipped with pocket-sized, powerful devices that have a lot of different built-in sensors; a craniofacial abnormality can be detected by evaluating a child's jawline, eye, and nose placement. In areas with a shortage of specialists, smartphone images of eyes, skin lesions, wounds, infections, and medications can be collected and transmitted to specialists which will be helpful in reducing the time-to-diagnosis for certain complaints.

BEDSIDE CLINICAL DECISION-MAKING WITH ARTIFICIAL INTELLIGENCE

Artificial intelligence by powering predictive analytics and clinical decision support tools can provide earlier warnings for conditions such as seizures or sepsis, which often require intensive analysis of highly complex datasets. AI with various algorithms in it allows healthcare to develop the processes that will enable proactive, predictive interventions. Clinical support decisions by learning machine can also be helpful in deciding whether to continue care for critically ill patients, such as a patient with coma after cardiac arrest by analysis of electroencephalogram (EEG). AI algorithms are helpful in risk scoring and early alert, clinical decision support. AI provides a new era of clinical quality and exciting breakthroughs in patient care.

ADMINISTRATIVE APPLICATIONS OF ARTIFICIAL INTELLIGENCE

There are a number of administrative applications of AI that provide substantial efficiencies in healthcare. As an administrative application, AI can be used in claims processing, clinical documentation, revenue cycle management, and medical records management. The use of AI in hospital administration settings is somewhat less appealing as compared to patient care.

SUMMARY

Artificial intelligence has already arrived in healthcare. Traditional healthcare providers are now opting for technologies equipped with algorithm with AI. AI promises great benefits to patients but it equally presents risks to patient safety, health equity, and data security. The active role of the doctors and those from across the wider healthcare is to reasonably ensure that the benefits are maximized and the risks are minimized.

15
CHAPTER

Use of Simulation-based Education in Emergency Medicine

Asit Misra, Brad Gable

INTRODUCTION

Simulation is defined as "a technique that creates a situation or environment to allow persons to experience a representation of a real event for the purpose of practice, learning, evaluation, testing or to gain an understanding of systems or human actions" as per the healthcare simulation dictionary. Simulation-based education (SBE) became popular in emergency medicine (EM) in the last 20–25 years. SBE is one of the key components of the EM training curriculum in many countries, including the United States, Canada, the United Kingdom, and Australia. "The validity or value of simulation education and training has never been proven in any other industry." One of the forefathers of SBE, Dr David Gaba, once stated, "No industry in which human lives depend on the skilled performance of responsible operators has waited for the unequivocal proof of the benefit of simulation before embracing it."

Simulation-based education plays a vital role in developing competencies in the EM trainees by providing them opportunities to become proficient in high-frequency, high-risk situations and procedures as well as low-frequency, high-risk circumstances. This type of education also provides the trainees with a conducive and safe learning environment to practice and learn from their mistakes. SBE in recent years has proved to enhance not only the technical skills of the trainees but also the nontechnical skills of the trainees such as interprofessional teamwork, crisis resource management, communication, systems-based practice, and professionalism.

HISTORY OF SIMULATION

One could argue that simulation is as old as a primitive man. The trial-and-error method of learning is nothing more than a series of simulated events. However, modern medical simulation harkens to the middle ages when animal models were used for education. Examples of anatomic models and trainers span nearly all continents and cultures. In 1700s France, Angélique Marguerite Le Boursier du Coudray utilized a cloth birthing simulator to train midwives and surgeons. Modern medical simulation can trace its roots to anesthesia education in the 1970s. The first computerized full-body human simulator known as "Sim One" was developed by Drs Denson and Abrahamson in 1967. A year later, in 1968, Dr Michael Gordon unveiled the cardiopulmonary patient simulator "Harvey." Since that time, SBE has expanded into nearly all specialties and across the spectrum of allied health professions.

EDUCATIONAL THEORY

Simulation-based education in medicine is supported by various pedagogical and andragogical approaches as well as by learning theories ranging from the adult learning theory, constructivism, experiential learning model of Kolb, Dewey's experiential learning theory, deliberate practice, and mastery learning. A combination of these approaches and learning theories helps develop a learner's knowledge and skills needed to successfully perform and practice medicine.

Adult Learning Theory

Adult learners are self-directed and self-motivated. They want to know why they need to learn something, and they tend to relate the learning to their life experiences. The principles of adult learning, as described by Knowles are as follows:

- Adults like to be an active participant in the learning process.
- They have both intrinsic and extrinsic motivation to learn.
- They want to know the relevancy of the teaching with their job.
- They are self-directed and goal-oriented.
- They prefer a safe and respectful learning environment.
- They expect feedback on their performance in order to improve themselves.
- Adults prefer personal and informal learning environments.

Constructivism

Using the constructivist approach in SBE helps the learners to keep up with the changing nature of the information. It also prepares them to handle any uncertain or undefined challenges that they can face in real-life scenarios. As per Conner, constructivism is suitable for teaching something that is new (technology), sophisticated, and where time is

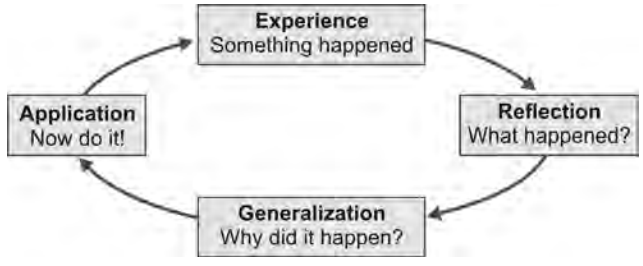
of the essence. The constructivist approach also helps the learners work around their understanding of the subject and to discover new ways to deal with the situation in reality, e.g., crisis resource management.

Kolb's Experiential Learning Model

This provides a basic structure for any SBE session by providing learning strategies applicable to adult learners. In this model, the learner(s) receives a specific experience in a simulation session followed by their reflection on this experience. This reflection helps the learners to develop some concepts and make suitable changes to improve. Later on, the learner(s) apply these new concepts or generalizations and test them in new or similar simulation scenarios or real-life situations. This continues in a cyclical process (**Flowchart 1**).

Dewey's Experiential Learning Theory

Previous research has shown that experiential learning promotes various important competency domains required for a healthcare provider to succeed, such as decision-making, critical thinking, problem-solving, teamwork, and system-based practice. One can define experiential learning as education gained by experiencing, interacting, and reacting to certain situations (scenarios). Dewey's experiential learning theory supports the theoretical claim that simulation-based medical education (SBME) can provide a platform for adult learners to build their knowledge base by experiencing new information and relating it to their own experiences. The learners can also apply their knowledge in different new situations or scenarios to experience different outcomes. SBE is helpful for learners to achieve higher levels of cognitive learning outcomes as per revised Bloom's taxonomy (analyze, define, create, evaluate) (**Fig. 1**).



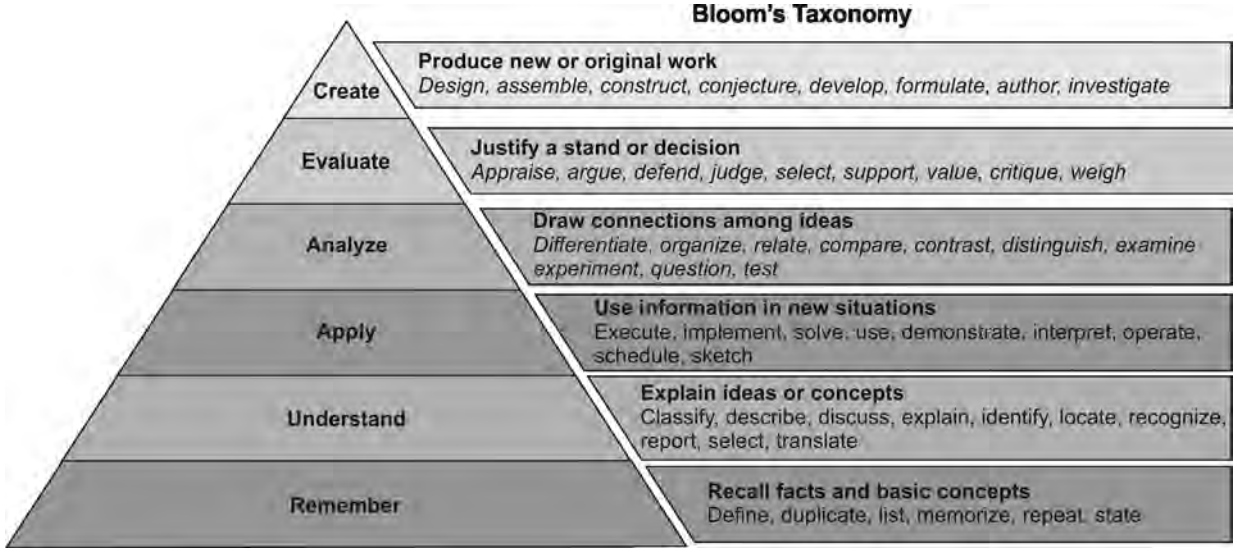
FLOWCHART 1: Simple illustration of Kolb's experiential learning cycle.

Deliberate Practice

Deliberate practice is a term commonly used in SBE and is based on the principles of behaviorist learning theory. Ericsson and his team first used this term to describe the achievement of skills by the learners in different professions, including healthcare. They explained how repetitive practice with feedback on performance could improve a learner's skills to achieve set goals in various conditions. Deliberate practice is crucial in healthcare professionals' education, especially for those who are expected to perform in a highly stressful or demanding situation.

Mastery Learning

The origin of mastery learning can be linked to Carroll's model of school learning. McGaghie and colleagues contributed to developing the simulation-based model of mastery learning. The model is founded on three popular educational theories: (1) Constructivist, (2) Behavioral, and (3) Social learning. In simple words, mastery learning focuses on the achievement of a learner's competency to meet the set educational outcome (result) rather than how much time is needed to reach the same. For example, during a simulation-based educational session, learners, after practicing a skill while receiving feedback from content experts, are expected to perform the same skill to demonstrate their competency. Learners can practice alone and under supervision until they can demonstrate their mastery and competency in that skill. To that end, using mastery learning theory, some learners may achieve competency before traditional time-based milestones, while others may take longer.



Bloom's Taxonomy
Create
Produce new or original work
Design, assemble, construct, conjecture, develop, formulate, author, investigate
Evaluate
Justify a stand or decision
Appraise, argue, defend, judge, select, support, value, critique, weigh
Analyze
Draw connections among ideas
Differentiate, organize, relate, compare, contrast, distinguish, examine
experiment, question, test
Apply
Use information in new situations
Execute, implement, solve, use, demonstrate, interpret, operate,
schedule, sketch
Understand
Explain ideas or concepts
Classify, describe, discuss, explain, identify, locate, recognize,
report, select, translate
Remember
Recall facts and basic concepts
Define, duplicate, list, memorize, repeat, state

FIG. 1: Bloom's revised taxonomy and descriptions of each category applicable to simulation-based medical education.

SIMULATION TYPES AND METHODS

Educators must choose the appropriate type of simulation and modalities of simulation according to their learners' training needs and the desired educational outcomes. Simulation sessions can be conducted in situ (at the place of work), in a simulation center (or a designated simulation space), or in a mobile environment (simulation vehicle).

The simulation was previously described in five categories according to a scheme proposed by Dr David Gaba. These designations are: (1) Verbal, (2) Standardized patients, (3) Part-task trainers, (4) Computer (virtual) patients, and (5) Electronic patients. With the exponential growth of technology in recent years, these categories would likely need to be expanded and further categorized. Below is an adapted list of Dr Gaba's categories:

- *Verbal*: Oral boards, tabletop simulations, communication skills
- *Standardized patients*: Objective structured clinical examination, communication skills
- *Part-task trainer*: Procedure skill training
- *High fidelity mannequins*: Full-body mannequins, mock code training
- *Tissue models (animal and cadaveric)*: Procedure training
- *Screen-based*:
  - *Augmented and virtual reality*: Phone-based, head-mounted
  - *Applications*: Downloaded to a phone
  - *Serious games*: Avatar simulations
  - *Telesimulation*: Learners/instructors participate remotely from the simulation

In addition to the acquisition of knowledge, simulation in healthcare can be used for other purposes such as process testing, identification of latent safety threats, verification of systems-based practices, equipment validation, and research and development.

Educators must consider providing appropriate realism to meet the learning objectives and suspend the learners' disbelief. Realism is defined as an ability to represent a situation that is observed during real-life conditions. Another term that is used along with realism in simulation is fidelity. Fidelity is defined as the degree of realism; the higher the fidelity, the higher the realism. However, a high-fidelity simulation session may not result in higher learning outcomes. There should be a relationship between simulation fidelity and its perceived value of the education session (**Fig. 2**). Although realism is important, it does not necessarily mean increased cost. Low-cost simulators and low-fidelity simulations can also improve the learner's knowledge, confidence, and skills. This is especially true when learning high-value procedures and concepts.

PLANNING A SIMULATION CASE

Simulation case development begins with the identification of a knowledge gap or a discrete learning objective. The number of objectives should be limited to allow learners to fully explore the objective and determine how the knowledge they gain will be applied to their practice. After the objectives are defined, the simulation faculty will then determine the following before writing the case:

- Location where the simulation will take place
- Type of simulation to be used

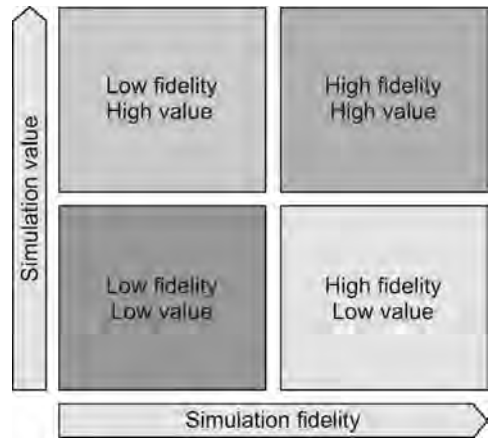

FIG. 2: Relationship between simulation fidelity and value.

- Number of learners
- Number of subject matter experts and debriefing faculty required

Once these are defined, the simulation faculty can begin writing the case. The case should be written in such a way that learners from various levels of expertise will have varied outcomes based on their interventions. Using the Dreyfus model of expertise, most residents will fall into the advanced beginner, competent, and proficient stages.

When writing a case, faculty members are asked to balance the signal-to-noise ratio. The signal-to-noise ratio is the balance of giving the learners the information needed to successfully manage the case while managing distracting or irrelevant information. Novice learners require a high signal-to-noise ratio as their educational focus should be on knowledge and skill acquisition. For example, a post-graduate year (PGY) 1 resident managing a patient in cardiac arrest should be given information such as the patient's oxygenation and should have staff provide clear closed-loop communication. As learners become more advanced, the amount of "noise" present in simulations can increase. Senior residents managing a patient in cardiac arrest may have to deal with "noise" such as updating the patient's family members, communicating with staff who are not using closed-loop communication, and calling consultants.

The single most crucial aspect of SBE is debriefing. This is a skill that, like all others, must be learned, coached, and continually practiced. In order for a debriefing to be successful, a prebrief is an essential element. It is within the prebrief where psychological safety and debriefing rules are established. In addition, debriefers may share their debriefing stance or "basic assumption." A number of debriefing models and approaches have been described. However, one of the most commonly referenced is debriefing with good judgment. Allowing learners the opportunity to reflect on their performance in a safe learning environment is paramount. Through this process, learners can reinforce the knowledge skills and attitudes that should be fostered while beginning to change those that require correction. Not only must this be facilitated by a trained debriefer, but adequate time must also be allotted for the debriefing. A ratio of 2–4:1 can be used when determining the amount of time necessary for debriefing relative to the time the simulation case requires. Therefore, a 10-minute simulation would require a 20–40-minute debriefing.

USE OF SIMULATION IN EMERGENCY MEDICINE

Evidence of simulation use to deliver training to EM trainees, physicians, and other staff working in the EM department can be found from early publications on its usage. Chapman et al. described how they used simulation to teach emergency thoracotomy to medical students, resident trainees, and physicians working in the emergency department and compared their performance by using assessments on written, computer, and animal models. However, there are other evidences of the early use of simulation in teaching EM department administration. The increase in adaptation and use of simulation in EM is seen from the year 2000 onward based on the number of publications reporting it. A publication on the rapid growth in the use of SBE in EM reported an increase of 62% between 2003 and 2008 in the United States.

Some uses of SBE in EM are as follows:

- Procedural skills training
- Mock codes and code blue response for decision-making and critical thinking, and resuscitation skills
- Human factors and crisis resource management (CRM) training to improve problem-solving skills
- Nontechnical skills training to address professionalism, interprofessional collaboration, team dynamics, communication, and ethics
- Overcrowding and patient flow management and multitasking
- Testing of process and system to identify errors
- Providing a safe environment for learners to apply clinical knowledge and practice skills for low- to high-risk scenarios and skills
- Assessment of trainees for the achievement of competency for skills and knowledge

Simulation-based education in EM helps to improve the attitude, confidence, and comfort of the trainees. It advances knowledge and skills, changes in behavior, and application of the skills in the workplace. The simulation also helps to reduce medical errors and complications and to improve clinical and patient outcomes. Some studies have been able to demonstrate the impact of SBE on clinical outcomes (**Table 1**).

TABLE 1: Studies demonstrating the impact of simulation on clinical outcomes.

Study	*Conclusion*
Barsuk et al. (2009)	Reported that simulation-based training for insertion of a central venous catheter (CVC) resulted in a significant reduction of procedure-related complications (number of needle passes, fewer arterial punctures, fewer catheter adjustments, and higher success rates) for actual CVC insertion in the medical intensive care unit when compared to the traditionally trained group
Biese et al. (2011)	Reported that simulation-based training resulted in a significantly decreased rate of inappropriate urinary catheter placement
Sauter et al. (2016)	Demonstrated how simulation-based training of emergency medicine clinicians and trainees for providing procedural sedation for reducing a subluxated shoulder joint resulted in significantly faster time to the procedure
Theilen et al. (2017)	A simulation-based training of a pediatric emergency medicine team resulted in a significant reduction of PICU admissions and PICU bed days with a significantly reduced hospital mortality rate

(PICU: pediatric intensive care unit)

HOW TO INTEGRATE SIMULATION EDUCATION INTO AN EMERGENCY MEDICINE CURRICULUM

Initiating simulation into an already existing curriculum will not be a "none to all" proposition, but this approach has been described previously. More likely, adding SBE will involve gradually adopting simulation into the curriculum and, at a minimum, will involve all of the following: (1) Willingness of the program to trial SBE, (2) Faculty champion, and (3) Buy-in and feedback from the learners to meet their educational needs. The absence of any of these three features will likely result in the simulation program not being successful. The first step in a gradual integration of SBE is likely to be either a desire of the program to adopt this method of education or a passionate faculty member to serve as the simulation champion.

When determining the type of SBE to use when beginning the integration process, it is best likely to look at features unique to the program that might make this process easier. If there are identified knowledge gaps or "holes" in the curriculum that simulation could easily fill, these would be of the highest value to the learners and the program. These are likely to be low-frequency, high-risk procedures, cases, or situations. The simulation champion should also identify local resources that might allow for cheap and easy models of education. A few specific examples of local resources include:

- Butchers who discard animal parts that can be used for procedure training (tracheas for cricothyroidotomy, skin for suturing)
- Academic institutions with access to unique technology (computer systems for developing applications or serious games, augmented or virtual reality systems)
- Industries that can donate supplies or equipment (gels or polymers for making models, plastics for constructing task trainers)
- Other programs that may share simulation resources [obstetrics and gynecology (OB/Gyn) program to share a birthing simulator, surgery program to share a thoracostomy trainer]
- Expired materials from within the hospital and health system

There is a litany of publications describing low-cost models that have blueprints and descriptions available for free online. In addition, many simulation companies offer grants and discounts to many new simulation programs.

A wholly integrated simulation curriculum may present in several different ways. It may involve low-stakes formative education and/or the use of high-stakes summative evaluations to promote learners to the next level of training. Below, we describe just one sample curriculum that involves simulation

in two ways. First, new interns are on-boarded through a simulation "Bootcamp." Second, SBE is integrated into the rest of the existing curriculum and comprises half of all didactic time.

Bootcamp models for resident education have been previously described. A sample 1-month curriculum is presented in **Table 2**. This describes a once-weekly training for a total of four sessions, with each session consisting of 4 hours of education.

Simulation education can be woven into the existing curricular framework. Here, we outline a year-long simulation curriculum that was integrated into the existing systems-based didactic model (**Table 3**). Each month, the first and third weeks were dedicated to traditional didactics. The second week was assigned to procedure-based education. The fourth week was designated as the large-scale simulation case education. From year to year, the procedure education would remain constant while the simulation cases would change.

TABLE 2: Postgraduate year 1 orientation bootcamp. Each session comprises 4 hours of simulation education. Session 4 comprises four simulated cases with professional debriefing.

Session	*Skills*
1.	Airway management, needle decompression, tube thoracostomy
2.	Central line placement, defibrillator/pacer, arterial line placement
3.	Slit lamp, genitourinary exam, intraosseous access, ultrasound
4.	Simulation cases: i. ST-elevation myocardial infarction with ventricular tachycardia arrest ii. Septic shock from pneumonia with respiratory failure iii. Ruptured abdominal aortic aneurysm iv. Severely injured trauma patient (requiring intubation, chest tubes, central line placement)

TABLE 3: Sample systems-based simulation curriculum divided into procedure training and simulation cases.

Months	*Topics*	*Procedures*	*Simulations*
July	Otolaryngology/ Dermatology	HEENT nerve blocks, cricothyroidotomy, oropharyngeal foreign body removal, lip laceration repair, ear laceration repair, dental reimplantation, laceration repair	Pediatric airway foreign body, expanding neck hematoma, facial trauma requiring cricothyroidotomy
August	Cardiology	Defibrillation, cardioversion, transcutaneous pacing, temporary venous pacemaker, pericardiocentesis, cardiac ultrasound	Patent ductus arteriosus, heart block requiring pacing, pericardial effusion with obstructive shock
September	Gastrointestinal	Focused Assessment with Sonography in Trauma, nasogastric tube placement, orogastric tube placement, gastroesophageal varices balloon tamponade, anoscopy, paracentesis	Pediatric intussusception, variceal hemorrhage with hypovolemic shock, ischemic bowel
October	Endocrine/Obstetrics-gynecology	Vaginal delivery, shoulder dystocia, uterine tamponade	Pediatric DKA, shoulder dystocia, eclampsia
November	Renal/Genitourinary	Renal ultrasound, pelvic exam, pelvic ultrasound, Bartholin cyst drainage, urinary catheter placement, priapism management	Pediatric sepsis from urinary source, Fournier's gangrene, cocaine overdose with chest pain and priapism
December	Hematology/ Oncology	Massive transfusion, vascular access, catheter troubleshooting	Pediatric hemophilia with head injury, tumor lysis syndrome, disseminated intravascular coagulopathy
January	Toxicology/ Environmental	Warm/Rewarming techniques, cooling techniques, prehospital equipment review	Pediatric tricyclic overdose, carbon monoxide poisoning, and concomitant hypothermia, organophosphate exposure
February	Vascular/ Musculoskeletal	Vascular ultrasound, venous cutdown, musculoskeletal ultrasound, splinting, casting, musculoskeletal apparatuses, hematoma blocks, joint aspirations/injections	Pediatric trauma with compartment syndrome, tracheoinnominate fistula, trauma with multiple fractures requiring emergent splinting/reduction
March	Neurology/ Ophthalmology	Nerve ultrasonography, regional anesthesia, lumbar puncture, ventriculoperitoneal shunt management, slit-lamp exam, tonometry, lateral canthotomy	Pediatric acute flaccid myelitis, hyponatremia with status epilepticus, Guillain–Barre syndrome with respiratory failure
April	Infectious disease/ disaster medicine	Abscess and cellulitis ultrasound, tabletop disaster drills	Neonatal herpes simplex virus infection, tetanus with respiratory failure, *Trichinella spiralis* with altered mental status
May	Pulmonary	Lung ultrasound, needle decompression, tube thoracostomy, thoracotomy, intubation, difficult airway	Pediatric bronchiolitis, tension pneumothorax, massive hemoptysis
June	Psychology/geriatrics	Delivering bad news, evaluating the agitated patient	Pediatric suicidal patient, altered mental status with basilar artery stroke, geriatric delirium

(DKA: diabetic ketoacidosis; HEENT: head, eyes, ears, nose, and throat)

SUMMARY

While SBE has existed as long as EM itself, recent advances in technology have made it more accessible. However, successful simulation education must still be rooted in sound educational theory and curricular design. SBE spans a wide spectrum of modalities with varying cost, fidelity, and realism. However, SBE has been demonstrated to be well received by faculty and learners and improves medical knowledge, skills, and attitudes. In addition, learners apply the knowledge they gain through simulation in clinical situations. This leads to improvements in systems-based practice, quality and safety, teamwork, communication, and crisis resource management. SBE when properly applied, has demonstrated improved patient-centered outcomes.

16 CHAPTER

Overcrowding Management in Emergency Department

MI Nizami, Ashima Sharma

INTRODUCTION

Emergency department (ED) crowding is one of the leading problems in healthcare across the globe. Evidence shows a tremendous increase in the utilization of emergency services in the recent past. However, the capacity of the emergency healthcare system has not been well developed to respond to such high demands. This condition leads to crowding of the EDs, which in turn impose public health challenges related to the quality of healthcare and outcomes. In addition, the ED might be the only source of healthcare services to people, especially in rural areas. Delivery of timely care is compromised in crowded emergencies. Delay in initiating antibiotics, analgesia, or thrombolysis are all well established in crowded EDs. Crowding might also lead to the violations of the norms and service provision standards, which in turn result in patients leaving the facility without getting appropriate care.

A crowded ED creates problems for the prehospital services as the ambulance crew is unable to unload their patient. This reduces their resilience and capacity to respond to calls. Patients harmed by crowding in an ED continue to suffer even after getting admitted. There is evidence to suggest that patients admitted through crowded EDs have longer hospital stays. Patients are also more likely to be admitted when the ED is crowded because the department's ability to safely discharge patients is compromised. Crowding also harms the hospital personnel which manifests as absenteeism, staff sickness, and burnout. This results in junior staff delivering an increasingly busy and inefficient service. Resident and student education is also compromised and further recruitments into the department are hampered. **Box 1** summarizes the ill effects of overcrowding in ED.

BOX 1: Potential harms of ED overcrowding.

Effects on patients:

- Delayed assessment
- Delay in the initiation of treatment
- Increased walkouts due to perceived ED length of stay (LOS)
- Patients and attendant's frustration and fear
- Low patient satisfaction
- Poor pain relief and morbidity
- Frequent readmissions
- Prolonged hospitalization
- High cost of treatment
- Medication errors and adverse events
- High mortality

Healthcare delivery system process:

- Diversion of ambulance
- High workload
- ED personnel frustration
- Delayed service provision and decision-making
- Shorter time to investigate patients' condition
- Discharging patients with high-risk clinical features
- Prolonged time to transfer outpatients
- High patient readmission rate
- Decreased admission of patients due to crowding
- Overutilization of diagnostic imaging and laboratory tests
- Poor infection prevention and control measures
- Low compliance with standards of care
- Compromised quality of care
- ED fights and medicolegal cases

(ED: emergency department)

DEFINITION OF OVERCROWDING

Crowding is a situation when an identified need for emergency healthcare services exceeds the available resources to provide emergency care to patients within an appropriate time frame. There is not much consensus on the definition of overcrowding despite a large literature describing the consequences of crowding. Defining crowding is important, as it allows measurement, planning subsequent research, and policy evaluation. Access block refers to the delay caused for patients in gaining access to in-patient beds after being admitted. It is almost always associated with overcrowding. There are a number of crowding scales described in the literature, but many are limited by being country specific or lack a gold standard in development or are incompletely validated (**Table 1**).

TABLE 1: Scores for assessing ED overcrowding.

Scale	*Calculation*	*Score*	*Remarks*
ED occupancy rate*	$\frac{\text{Total patients}}{BT}$	ED occupancy rate above 1.0 indicates that there are more ED patients than treatment bays	• Total patients = Number of patients in the ED including those in the waiting room, boarding, hallway, and chairs • B_T = Total number of licensed treatment bays including fast track or observation units, excluding hallway locations
Emergency department crowding score (EDCS)†	• Number of attending emergency physicians • Number of staffed ED beds • Number of critical care patients • Number of total ED patients • Number of staffed hospital beds • Hospital occupancy rate	EDCS score >65 was found to be predictive of both ambulance diversion and the number of patients who leave without being seen by a physician	Generates an output score between 0 and 100
Emergency department work index (EDWIN)‡	$\frac{\sum n_i t_i}{N_a (B_T - B_A)}$	<0–1.5: Active but manageable 1.5–2.0: VERY BUSY but not overcrowded >2.0: EXTREMELY BUSY severely overcrowded	n_i = Number of patients in ED in triage category i t_i = Triage category (ordinal scale 1–5, 5 being most acute) N_a = Number of attending physicians on duty at a given time B_T = Total number of beds, or treatment bays B_A = Number of admitted patients (boarders) in the ED
Real-time emergency analysis of demand indicator (READI)§ scores	$DV = (BR + PR) \times AR$	• DV >7 indicates overcrowding, and further assessment is recommended • BR >1 indicates overcrowding • PR >1.5 indicates an understaffed ED • AR close to 4 indicates a severe burden of illness	$BR = \frac{\text{(total ED patients + predicted arrivals − predicted departures)}}{\text{ED spaces}}$ $PR = \frac{\text{Arrivals per hour}}{\sum\text{PPH for each physician}}$ $AR = \frac{\sum\text{(triage category) (patients at each category)}}{\text{Number of patients}}$

Continued

Continued

Scale	*Calculation*	*Score*	*Remarks*
National emergency department overcrowding study (NEDOCS)‖	$-20 + 85.8 \times \frac{\text{Total patients}}{\text{ED beds}} + 600 \times \frac{\text{Admits}}{\text{Hospital beds}}$ + 13.4 (ventilators) + 0.93 (longest admit) + 5.64 (last bed time)	• 0–50: Normal • 51–100: Busy • 101–140: Overcrowded • 141–180: Severe • >180: Disaster	• Total patients = Total patients in the ED, including those in the waiting room, fast track, or observation areas • ED beds = Total ED beds, including those in hallways • Admits = Total number of boarders/admitted patients in the ED at the time the score is calculated • Hospital beds = Total number of hospital beds • Ventilators = Number of patients in the ED on ventilators • Longest admit = The longest patient boarding time (in hours) at which the score is calculated • Last bed time = The time (in hours) from arrival to bed for the last patient assigned to a bed
ED work score¶	$3.23 \times \frac{P_{wait}}{B_T} + 0.097 \times \frac{\sum n_i t_i}{N_n} + 10.92 \times \frac{B_A}{B_T}$	Using the threshold work score = 4.77, predict the decision for ambulance diversion with 86% sensitivity and 80% specificity	P_{wait} = Number of patients in the waiting room B_T = Total number of beds or treatment bays available in the ED n_i = Number of patients present in the ED in triage category i t_i = Triage category (ordinal scale 1–5, 5 being most acute) N_n = Number of nurses on duty B_A = Number of admitted patients (boarders) in the ED

* Suggested to be the simplest and overall best indicator of crowding.

† Exact calculations for the EDCS are unclear. However, three variables were identified that independently predicted physician and nurse ratings of EDC: (1) the number of boarders, (2) the total number of ED patients, and (3) the number of critical care ED patients.

‡ The triage system used was an inverted emergency severity index (ESI).

§ Demand value (DV) provides an overall measure of demand based on current calculations of the three ratios.

i. Bed ratio (BR) assesses the demand per treatment space.

ii. Provider ratio (PR) calculates how many patients can be seen by the physician providers based on the average number of patients seen per hour (PPH) by each physician.

iii. Acuity ratio (AR) measures the relative burden of illness by averaging the triage categories of all patients in the ED.

‖ Generates an output score between 0 and 200; however, higher scores are possible.

¶ Sometimes referred to as the Boston ED work score. The triage system used was an inverted ESI.

(ED: emergency department; PPH: patients seen per hour)

CAUSES OF OVERCROWDING

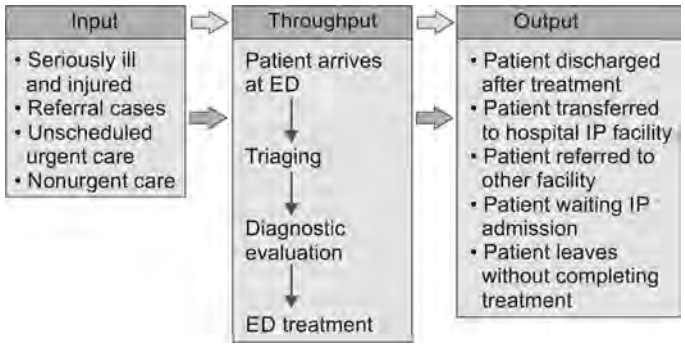
Crowding is caused by multiple factors. These can be best understood in terms of input, throughput, and output. Asplin's conceptual model illustrates the stages that can lead to ED crowding (**Flowchart 1**). Input factors include not only the volume but also the acuity and type of patients. The volume of patients attending EDs has increased dramatically over the last 20 years. The reasons for this are not well understood. With increased longevity, elderly people are requiring disproportionate care.[7] Patients with mental illness and chronically ill patients require extensive ED care. A small increase in any of these groups can have an add-on effect. Input problems do not cause crowding if the rest of the admission and discharge process works well.

Throughput factors refer to activities within the ED that can hinder patient flow. EDs are extremely complex systems and almost any activity can lead to crowding. Poorly designed EDs do not support patient flow and contribute to crowding. A linearly designed department with adequate corridor spacing is probably most efficient. Merely increasing cubicle spaces do not reduce crowding, if processes within the department and in the main hospital are not improved. Delay in diagnostic imaging and laboratory services also contributes to crowding. Inadequate number of medical and nursing staff is a major contributing factor in many underdeveloped healthcare setups. Increasingly stringent emergency protocols and extended care have further increased the workload of EDs. Analysis of the separate components of time a patient spends in the ED has shown that waiting comprises 51–63% of the total turnaround time. Major components are the time taken for radiological investigations, waiting time for the physician's first consultation, and waiting time for blood work.

Output factors are the main cause of ED crowding. Lack of inpatient beds is the single most important cause of crowding. Shortage of critical care beds leads to high acuity patients remaining in the ED. Worldwide, the trend has been to reduce inpatient bed capacity. There is a strong perception that hospitals prioritize more lucrative elective work over emergency admissions.

INTERVENTIONS

Interventions can again be grouped into input, throughput, and output. The strongest evidence comes from throughput solutions. It is important to identify the main causes of crowding in individual EDs. Failure to take this logical step leads to effort being expended on unnecessary interventions.



(ED: emergency department; IP: inpatient)

FLOWCHART 1: Flow diagram of patients through ED.

Input Strategies

Reducing inputs is attractive to administrators and policymakers; however, the evidence of effect is very weak. A substantial number of patients attending the ED can be adequately managed in an outpatient service. However, efforts on directing these patients away once they have arrived in the ED are rarely worthwhile. The effects of limiting the input of patients have not been shown to significantly affect overcrowding and diversion. Developing alternative sources of care away from EDs, such as walk-in centers, has probably met a previously unmet need. The concept of fast-track service evolved from the fact that most of the crowding in ED may actually involve low acuity patients such as those with minor injuries and illnesses. Therefore, fast-track services for such patients may be an important front-end operational strategy to relieve congestion. Few healthcare systems have incorporated emergency nursing practitioners with proper training for dealing with minor ailments in ED.

Throughput Strategies

There are a variety of throughput interventions to reduce crowding in EDs. Ensuring that patients are seen early by a trained emergency physician is helpful. Ensuring adequate training of the nursing staff and the emergency medical technicians cuts down the waiting time. However, these interventions help in lower acuity patients, but not in the critically ill ones. Triaging patients into broad acuity categories and managing them through separate processes can reduce the overall waiting time. Monitoring key bottlenecks, such as time for laboratory and radiology results to become available, is useful. Point-of-care testing is a rapidly evolving innovation which fastens clinical decision-making. Streamlining transfer policies and developing ambulatory care pathways to avoid admissions are important tools for effective disposition of cases in the ED. Appointing nonmedical supportive staff in the form of floor managers and counselors has proved to be a useful strategy in managing the issues of crowding.

Output Strategies

The biggest contribution to ED crowding and ambulance diversion is the inability to get admitted patients, especially those who are critically ill, out of the ED. No significant success will occur without hospital leadership making this a priority. Although ED admissions in many centers are looked at as less profitable, the financial benefit of ED admissions is significant. The possible causes of access block include:

- Disinclination for clinicians to discharge patients.
- Inefficient flow in the discharge process.
- Genuinely insufficient bed capacity.

Holding units are clinical decision units or observation units within the ED. Studies suggest that such units are able to alleviate access block and ED overcrowding.[13] They also contribute to the reduction in hospitalization and improvements in ambulatory care. Observation units have shown to play a significant role in selected clinical conditions, such as acute exacerbation of heart failure[14] and acute pyelonephritis.[15]

There is some evidence to support the role of *social workers* in helping the early discharge of elderly patients and reducing the readmission rate within 6–12 months without an apparent increase in mortality. Discharge lounges are areas

in the hospital for patients to wait until transport and other administrative discharge arrangements are completed. A study found that after the introduction of such lounges, there can be substantial savings in bed hours. Reverse triaging is a relatively new concept based on selecting patients who can be discharged safely with little risk of serious consequences. It has a high relevance in the event of a vast surge in demand for hospital beds.

SUMMARY

Administrators need to consider ED crowding as an unintended consequence of improper policies or their inefficient implementation. A systematic team effort focusing on the local issues in the background of globally acclaimed strategies can help in overcoming the issues of crowding in EDs.

17
CHAPTER

Difficult Patient and Situations

AN Venkatesh

INTRODUCTION

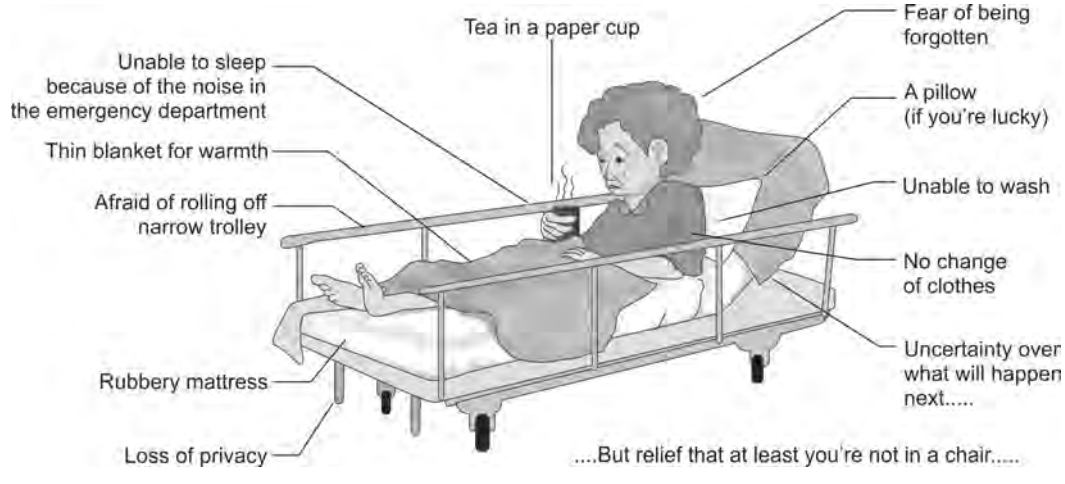
One of the important aspects of the medical profession is interaction with patients and their families. This is one aspect of our care toward our patient which is present irrespective of specialty. But in our medical training, we hardly receive any formal training toward dealing with difficult patients. Though most of the interactions with patients and medical professionals are fruitful and healthy, there are about 15% of them which are described as being difficult by physicians. This number has progressively increased over the years and the current percentage of difficult interactions is much more than 15%. With ever-increasing incidents of complaints about medical professionals and abuse of medical professionals across the globe, it is imperative we look at this aspect of patient care—dealing with difficult patients.

DIFFICULT SITUATIONS

As with many of the difficult situations, patients become difficult patients as a result of culmination of various events during the course of their attendance or consultation. It is most of the times multifactorial (**Fig. 1**). The causative factors maybe as follows:

- Patients—unmet expectations, pain and distress, cry for help, fear of unknown.
- Physicians—work pressure, language difficulties, lack of communication.
- Situation/Circumstances—feeling not care for, concern of resources.

Patients come to healthcare facility seeking help and guidance for their discomfort. It has to be recognized that the patient's condition is an emergency to them. One of the early signs of patients becoming difficult would be anxiety, uncooperative, restlessness, demanding, and verbally abusive. Patients tend to become difficult patients over the course of their journey in the system. It is an important skill to identify early signs and try to resolve their grievance. Along with good diagnostic skills, it is equally important to have good communication skills. Having good and effective communication with patients is one of the most effective steps in managing a patient's expectations and addressing his/her anxiety. This would also help gain the patients' trust and confidence. A breakdown in communication between the physician and patient, if not identified and addressed appropriately, can easily snowball into a disturbing situation. One of the harsh examples of these is the recent increase in violence on healthcare professionals.



Tea in a paper cup
Fear of being forgotten
Unable to sleep because of the noise in the emergency department
A pillow (if you're lucky)
Thin blanket for warmth
Unable to wash
Afraid of rolling off narrow trolley
No change of clothes
Uncertainty over what will happen next.....
Rubbery mattress
Loss of privacy
....But relief that at least you're not in a chair.....

FIG. 1: Difficult situation and circumstances make a difficult patient.

TYPES OF DIFFICULT PATIENT

Although there is no classification of difficult patients, they can be broadly grouped into four types (**Fig. 2**):

1. Resistant patient
2. Manipulative patients
3. Patients who somatize
4. Frequent flyers

Resistant patients: These patients present to be angry or defensive. A change in behavioral pattern of becoming more irritable and responding aggressively can be noticed. With these patients, avoid conflict, modulate your interaction, have a chaperone, and keep in mind your personal triggers. If at any point you feel threatened, try to get away slowly and get help.

Manipulative patients: These patients tend to use rage and threats of legal action in an attempt to get what they desire. It is important to be nonjudgmental during interacting with these patients. If in doubt, seek advice from a senior colleague.

Patients who somatize: These patients often present with a plethora of vague symptoms with frequent exaggerated severity. They tend to be "doctor shoppers." Inexperienced clinicians are at an increased risk in dealing with such patients. They may fall prey to prejudice and tend to overlook a genuine illness. It would be advisable to be safe than sorry.

Frequent flyers: These patients pose a unique challenge in themselves. Empathy is vital with these patients. Identifying these patients and having an agreed plan in discussion with the primary treating team for these patients can ease the interaction with these patients. Keeping the patients informed of these plans and involving them in discussions help better acceptance.

Clinicians in specialties, such as emergency department, have to face patients with increased demands and expectations. It is important that clinicians and other healthcare professionals having increased patient interaction understand and learn to identify early signs of patients becoming disturbed. Some of the early signs could be patients or attendants asking questions frequently and patients getting angry for no apparent reason.

CLINICIANS AS CAUSATIVE FACTORS

Clinicians themselves may be contributing to patients becoming difficult patients. Some of the clinician characters which pose a risk in dealing with difficult patients and situation are as follows (**Fig. 3**):

- Being angry
- Being defensive
- Fatigued
- Stressed and strained

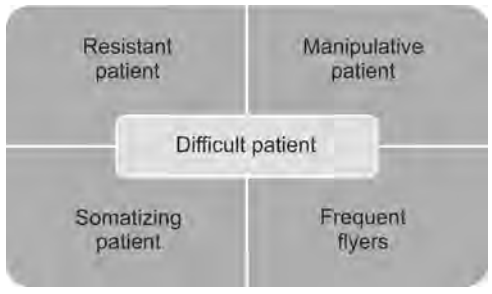


FIG. 2: Types of difficult patients.

When working in a team, it is important that any team members showing any of the above characters are given an opportunity to talk and seek help. It is also a key for the clinician to be aware of his/her own personal state. Dealing with difficult and challenging patients can be very demanding. One should never hesitate to ask for help. As noted by many clinicians, conflicts and stressful interactions are more common during busy periods and during the end of shifts rather than start of their shifts.

The situation in which the patient or family is can also have its influence in compounding the patient's dissatisfaction. It could be things which can be addressed such as overcrowding, making them feel neglected, or situations which can be readily addressed such as needing a glass of water.

There are many examples of difficult families and patients due to situations and circumstances. Clinicians may get a complaint from a concerned family member that the patient has been left unattended in a corner of the emergency department and he/she has been feeling cold and repeated requests for blankets have not got them anywhere. Working in busy shifts, it is easy to relate to such situations. It is easy to just say that we are all busy and we will get to it as soon as we can as we have more pressing patients to attend to athough this may be a factual statement. We can be better-caring clinicians if we get a blanket, apologize, and explain that department is busy. This not only will help us win back our patients' and families' trust and confidence, but also will help to get their cooperation in further care of their patient. We are now becoming aware of the increased number of incidences of patient–clinician discordance. Communication plays a vital role in this situation if your communication is healthy (**Fig. 4**).

HOW TO DEAL WITH DIFFICULT SITUATIONS?

Careful and considerate communication is one of the keys to avoid difficult patients. The importance of communication

FIG. 3: Characters of doctors which contribute to difficult patient.

FIG. 4: Make healthy communication.

cannot be overemphasized in dealing with difficult patients and families.

There is an increased need for guidance on dealing with difficult patients and families but with a varied spectrum of patients and factors involved, it has been a challenge to formulate a formal guideline. We can use certain basic understanding in interpersonal relationships and tailor it to the healthcare setting. When dealing with difficult patients and families, it would be a good idea to be empathic to patients and families. When patients or families are posing a challenge, it could be a culmination of various factors.

Listen to their concerns actively. It would be advisable to listen to concerns with open mind and ears. Let them speak freely; it would let them blow off steam. It would help them to start to settle and help work toward resolution of the difficult situation. Have a clear discussion and try to summarize their concerns. Let them feel in control of the explanation. Remind yourself that the patients may not be upset with you and their response is not personal (**Fig. 5**).

Stay calm. It is much easier said than done. But keeping calm would go a long way in resolving the situation. Be professional and confident but be mindful not to show overconfidence which can come across as being arrogant and can worsen the situation. For example, when talking to a patient or family member who is screaming in the middle of the department, it may be wise to talk in a low measured tone, take them off the shop floor to a quiet room, and offer them to sit. This will give them time to reflect and also ensure smooth running of the department by diverting the distraction.

Ask questions. If required, ask relevant questions to get a better understanding to gather more information rather than being intrusive. Be mindful to be gentle and sensitive. Try not to show any sudden reactions. Take time and answer any questions and do not make any defensive responses. Be gentle and caring. Try not to get too close, try not to touch them too early, and be attentive toward their body language. Apologize for their inconvenience. It will not make you guilty but it may present you to be sensitive. If you have identified any issues or concerns, address them straightaway. Keep the patient and family appraised on the progress. In an attempt to be helpful, be mindful not to make unrealistic promises or promises which you cannot keep up. Involve patients in any solutions, do not forget their families. As these situations at times turn violent, if you feel threatened or unsafe get help of security. Try to lead the conversation and resolve the situation. With the recent incidence of violence on healthcare professionals, it may be safe to get help when you feel unsafe.

Being involved in a stressful situation can be very draining and make you exhausted. Do not forget that you also need time and space to relax. Try and take time, sit out and have a drink, and let the stress of the event pass off before you move on.

ROLE OF EMERGENCY PHYSICIAN TO RESOLVE DIFFICULT SITUATIONS

There could be situation factors contributing to patients becoming difficult. With open access to the emergency department, patients tend to walk into the emergency department even for conditions which are not actual medical emergencies. It becomes important to have a robust triage system to attend to such patients and be able to communicate with patients appropriately, e.g., a person coming into a hospital for a fall from his bike last evening and having sustained grazed abrasion of his knees, wanting to get dressing done before he goes to his work. Although it is a priority for the patient, it has to be explained that he would be seen in a timely order depending on other acuity in the department where patients needing more urgent medical attention would be given priority. It is not uncommon to see patients and family members attending to emergency department seeking advice on a wide spectrum of issues. Some of them are unrelated to the emergency department, e.g., when will a consultant be available? And when they do not get a reply, they tend to get angry. We need to realize that their anger is a form of helplessness as they are not able to find the answer to their question.

It would be better if we could spend few minutes in having a sensible discussion with such patients rather than trying to answer a complaint from an irate patient (**Fig. 6**). In organizations where there is a need identified, it would be productive to have a patient's relations personnel to help in the smooth journey of the patient. As the saying goes "a stitch in time saves nine."

FIG. 5: Listen to the patient.

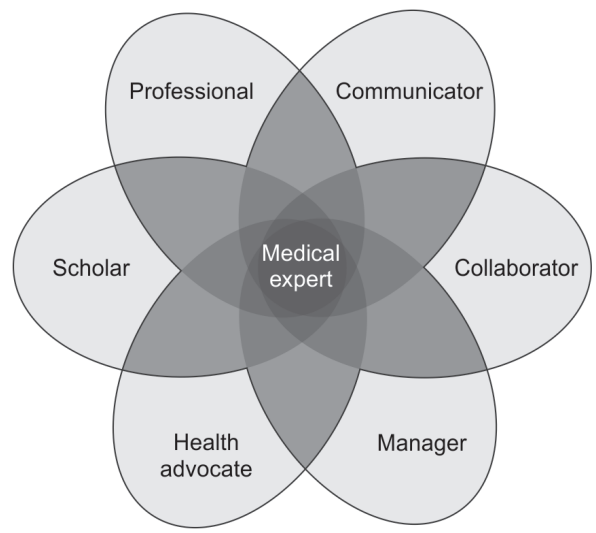

FIG. 6: Qualities required in dealing with a difficult situation.

SUMMARY

Interaction with patients is an integral part of day-to-day clinical practice. Patients presenting to the hospital, especially to the emergency, are already stressed. With a lack of trust in the profession and increased commercialization of healthcare, patients and their families are increasingly getting skeptical about the profession and healthcare delivery system. Patients or family members can become difficult at various stages of their presentation from the time of early registration to the time of their discharge. There is no trigger point can be mentioned for difficult patient and family members but helathcare professionals more so physicians, have to be more aware and vigilant about the early signs of patients or their family members starting to be defensive or difficult. Most of these situations can be resolved if we can recognize the early signs of a patient becoming difficult, such as change in body language, becoming angry and aggressive, and not being cooperative, and act on them. It is very important not to reciprocate or try to fight back. As medical professionals, we need to be patient and listen to their concerns, ask only relevant helpful questions to arrive at a resolution, and act and work to help and seek to resolve the patients' concerns (**Table 1**). It also important to be mindful that the patient's anger may not be directed at the person but it may be the process, the system, or the circumstances. They should not take any anger or comments personally. It may be good to let them talk and "let the steam off" so that they can cool down and a calmer environment is encouraged to have a productive discussion.

TABLE 1: Summary of dealing with a difficult situation.

Listen to patient	• What is the cause of anger • What are the concerns
Stay calm	• Be professional • Confident but not overconfident
Ask questions	• Facilitate understanding • Do not be patronizing

As these situations can at times be highly charged, it is important to assess the situation and get help of security at an early point to ensure the safety of staff and other patients. With incidents of violence on healthcare professionals, there is more awareness about dealing with difficult patients and family members. There is a need for a formal process of dealing with these situations. In the absence of these, we need to have a locally agreed process and have relevant training and education of healthcare staff, more so for frontline staff like the emergency department.

18 CHAPTER

Medicolegal Cases and Writing Medicolegal Reports

Amit Nabar, Devendra Richhariya, Vivekanshu Verma

INTRODUCTION

For any successful investigation of crimes against a person (homicides and sexual offence), medicolegal evidence is the most critical event. It is, therefore, important to develop robust standard protocols and guidelines for medicolegal examination and reporting as well as update them from time to time. Medicolegal cases (MLC) are frequently encountered in everyday medical practice by Medical Officers. The MLCs are on rise; systemic examination and documentation of these cases as per the guideline are an important aspect to avoid legal complications. There are differences in the legal procedures being followed by different states, since law and order is a state subject. Medical Officers should be aware of the guideline/medicolegal procedures of the state in which they are serving. In the emergency department, while attending to a critical patient, the doctor should understand that his/her first priority is to save the life of the patient. He/She should do everything possible to resuscitate the patient and ensure that the patients is out of danger. All legal formalities stand suspended till this is achieved.

MEDICOLEGAL CASES

A medicolegal case can be expressed as any case of injury, disease or infirmity, or death in which law-enforcing agencies have to enquire into the matter and fix the responsibility of a person or a group of persons responsible for causing the said injury, disease or infirmity, or death and penalize as per the existing law of the land. Cases that are to be treated as medicolegal are as follows:

- All cases of injuries and burns, the circumstances of which suggest the commission of an offense by somebody (irrespective of suspicion of foul play)
- All vehicular, factory, or other unnatural accident cases, especially when there is a likelihood of the patient's death or grievous hurt
- Cases of suspected or evident sexual assault
- Cases of suspected or evident criminal abortion
- Cases of unconsciousness where its cause is not natural or not clear
- All cases of suspected or evident poisoning or intoxication
- Cases brought dead with improper history creating suspicion of an offense
- Cases of suspected self-infliction of injuries or attempted suicide
- Any other case not falling under the above categories but has legal implications

MEDICOLEGAL REPORTS

Medicolegal reports (MLR) are documents prepared by a government/private doctor, pertaining to injury, sexual offense, poisoning, or unexplained death. It contains all the facts, observed by the doctor and his/her opinion drawn therefrom. His/her opinion must be based upon the observations made by him/her and not on hearsay evidence. MLC writing comprises the following three parts:

1. *Preamble*: It includes the date, time, and place of examination, name of the patient, his/her residential address, occupation, name of the person/police official accompanying, DDR/FIR No., informed consent of the person being examined, two marks of identification, thumb impression, etc., wherever applicable (**Fig. 1A**).
2. *Findings/observations*: These include a complete description of the injuries/any other findings present; any investigations/referrals, etc., are asked for (**Fig. 1B**).
3. *Opinion*: It includes the nature of the injury, whether simple or grievous, weapon/force used, whether blunt or sharp, or firearms or burns, etc. The duration of the injuries is based on the characteristics of the external injuries.[8]

Preparation of Medicolegal Report

Medicolegal cases are like any other clinical conditions or injuries presenting to emergency department and a doctor's duty is to treat as well as document the details of injuries and communicate to the investigation officer of law-enforcing agencies under Section 39 of the Criminal Procedure Code (CrPC); failure to do so will attract legal penalty and liable to be prosecuted under Section 201 of the Indian Penal Code (IPC). Any doctor who possesses permanent registration with the Medical Council and who has the first contact with the patient should prepare a MLC report; in rape victims, the examination

Serial No.....

Medico Legal Report (Form-II)

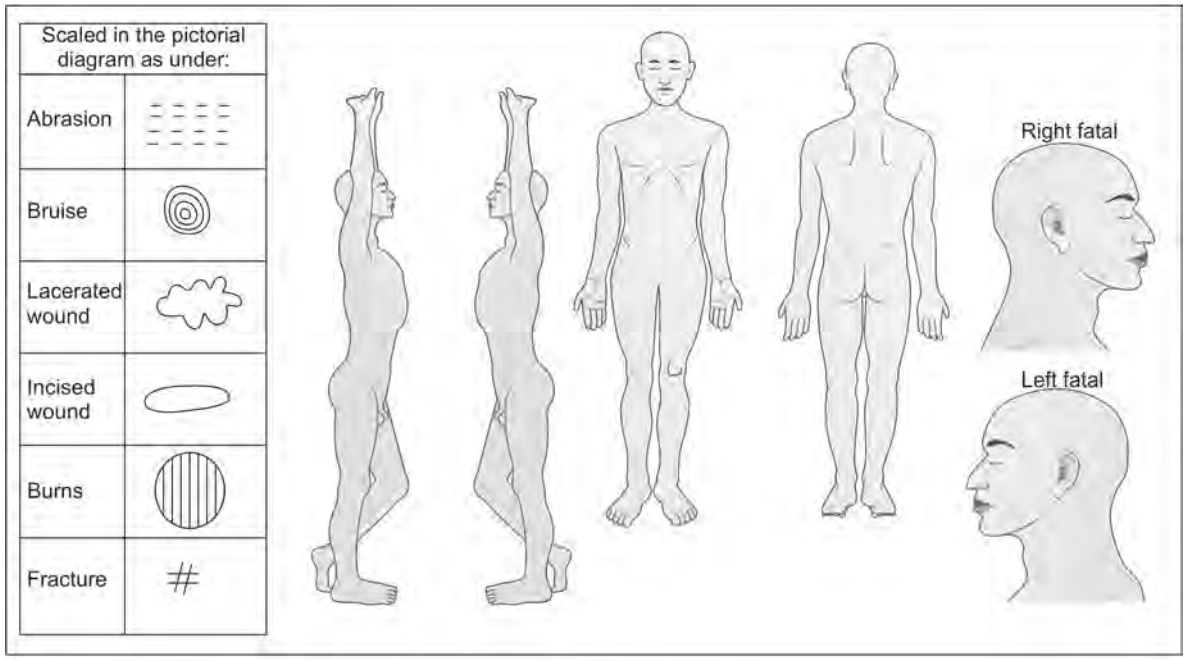
III Particulars of injuries viz type, shape, dimension, location, nature, duration etc., and kind of weapon used:

1. Nature of Injuries_____
(Simple, grievous, Dangerous or pending for observation)
2. Probable duration of injuries _____
3. Kind of weapon used (Sharp, Blunt, Firearm, Fire, Position etc.)_____

SIGNATURE OF THE EXAMINING MEDICAL OFFICER
Name (in capital letters).....
Designation.....

FIG. 1A: Documentation of medicolegal report (general information and description of injuries).



Guidelines

As per section 320 IPC, any injury falling under following clauses in grievous:

1. Emasculation
2. Permanent privation of the sight of either eye
3. Permanent privation of the hearing of either ear
4. Privation of any member or joint
5. Destruction or permanent impairing of the powers of any member or joint
6. Permanent disfiguration of the head or face
7. Fracture of dislocation of a bone or tooth
8. Any hurt (i) which endangers life or (ii) which causes the suffer to be during the space of 20 days
   (a) in severe bodily pain, or
   (b) unable to follow his ordinary pursuits.

At the end in column no. 7 opine whether multiple injuries, individually simple, are collectively dangerous to life.

(CrPC: Criminal Procedure Code; IPC: Indian Penal Code)

FIG. 1B: Documentation of medicolegal report: description of injuries.

and preparation of MLC are done by female doctors. The emergency department is the area where majority of MLR are prepared, but sometimes maybe in wards, after detection of new findings. The consent for medicolegal examination is to be taken in written in all cases except for cases which are in brought by the police, e.g., being arrested on charge of committing an offense; in case of a person below 12 years/unsound mind, the consent of the guardian is to be taken. The institution of proper treatment to the patient and lifesaving is the prime responsibility of the doctor and the hospital in accident or MLC. There should be no delay in providing first-aid. The doctor should complete the injury sheet, which is a part of the assessment of the patient. Situations where a doctor prepare a MLR are as follows:

- Brought by the police for examination and reporting
- Already registered MLC referred from other healthcare system
- After history-taking and thorough examination, if the doctor suspects that the circumstances/findings of the cases are unnatural or mishap and need to inform the police department, e.g., road traffic accident rail, factories accident
- Suspected or evident homicides or suicides
- Suspected or evident poisoning
- Burn injuries due to any cause
- Injury cases where foul play is suspected
- Injury cases where there is a likelihood of death in the near future
- Sexual assault cases
- Suspected or evident criminal abortions
- Unconscious cases where the cause is not clear
- Brought in dead cases where there is a suspicion of foul play
- As per directive of the court

Consent for Medicolegal Report

Always take the consent of the injured person on the MLR form. If the patient is <12 years, take the consent of the guardian/accompanying person and get his signature/thumb impression; consent is not required in case of accused person u/s 53 and 53A of CrPC and even reasonable force can be used for his examination on the request of the police officer, not below the rank of a sub-inspector. If an unconscious/semiconscious patient is brought in an emergency along with family/guardian, the consent shall be taken from them. In case of refusal by the family/guardian, the medical officer shall mention on the MLR that the consent could not be recorded. (Write brief reasons.)

Completion of Medicolegal Record

Documentation is done in duplicate/triplicate in a set Performa as per the hospital policy. Separate Performas may be available for medical examination, examination of drunkenness, etc. All columns are filled up carefully and by the same doctor who had examined the patient. Each MLC is given a fresh MLC number sequentially or parallel series as per the hospital policy. The details are completed then and there only, leaving no provisions to be completed later on. After completion, doctors sign and mention his/her name in full with the designation. The police constable on duty is informed in each case. After registration of a case as MLC, all documents and requisition forms bear the same MLC number including the discharge slip.

Filling of General Details

Registration number, MLC no, name, S/D/W, age, sex, religion, occupation, residential address, details of the person who brought the victim, and mark of identification, the date and time of examination and name of the informed police station are noted and documented.

Filling of Examination Details

Alleged history should be precise and to the point, legible, and clearly written. Description of injuries such as minor injuries and multiple injuries in polytrauma and specialist consultation should be obtained and abbreviation should be avoided. As a part of the documentation of MLR or whenever the investigative officer requests the doctor for certifying the fitness of the patient by making a statement, the examining doctor will certify the same on the original MLC sheet. He/She will mention the date and time clearly with signature and name in full with designation below the certification. Opinion regarding injuries wheather simple grievious or dangerous are to documented based on history, physical examination, laboratory, radiological investigations and specialist opinion. A doctor cannot refuse to examine MLC on the basis of being a private practitioner or by citing a jurisdiction problem. The patient can be discharged after the initial treatment or admitted to the hospital or referred to other hospitals for expert management after being provided first-aid/stabilized and after completion of all necessary documentation.

Filling of Particulars of Injuries

The person should be examined from head to toe in a systematic way from both the front and the back. Always depict the site of the injury and the presence of stains and foreign material on the diagram. All the injuries should be recorded in a way as if you are giving a statement in the court. The following particulars of each and every injury must be recorded:

- *Type of injury* such as abrasion, bruise, wounds (lacerated, incised, punctured, etc.), fracture dislocation, or burns
- *Size*—exact dimensions (in centimeters) of each injury should be noted down in respect of its length, breadth, and depth wherever possible.
- *Shape* that is circular, oval, spindle, triangular, elliptical, crescentic, satellite, etc. Margins/Edges of wounds should be examined (by hands/lenses wherever necessary), regular or irregular having bruise on its vicinity, floor must be examined by just retracting the edges so that tissue can be seen, if any. Foreign matter such as grease, dirt, gravel, straw, coal, paint, glass, weed, metal, palettes, bullets, wads, clothes, and hair should be reported and must be preserved for further analysis.
- *Location and directions of injuries*
- *Age of injuries*—color changes and healing process
- *Duration of injuries*—time elapsed between the infliction of injuries and examination
- *Nature of injuries* such as simple/grievous/dangerous. Doctors shall specify the subsection of the Section 320 IPC as given in the note below for declaring the injury to be grievous. *Section 319 IPC*: *Hurt*: whoever causes bodily pain, disease, or infirmity to any person is said to cause hurt.

Note: As per section 320 of the IPC, only the following kinds of hurt are designated as "grievous injuries:"

- Emasculation
- Permanent privation of the sight of either eye
- Permanent privation of the hearing of either ear
- Privation of any member or joint
- Destruction or permanent impairing of the powers of any member or joint
- Permanent disfiguration of the head or face
- Fracture or dislocation of a bone or tooth
- Any hurt which endangers life or which causes the sufferer to be during the space of 20 days in severe bodily pain or unable to follow his ordinary pursuits
- "*Dangerous to life"* injuries are those which may be fatal if no surgical aid is available, e.g., tension pneumothorax, cardiac tamponade, liver and splenic laceration, deep incised wound in slit throat, stab wound in chest and abdomen, traumatic epidural hematoma and acute subdural hematoma with midline shift.
- *Dangerous weapons*: Dangerous weapon is defined under sections 324 and 326 of the IPC, as any instrument used for shooting, stabbing, or cutting or any instrument which, when used as a weapon of offense, is likely to cause death, or by means of fire or any heated substance, or by means of any poison or any corrosive substance, or by means of any explosive substance, or by means of any substance which is deleterious to the human body to inhale, to swallow, or to receive into the blood, or by means of any animal.

Medical Examination of Victims of Sexual Assaults (Section 164A of CrPC)

Examination should be done only by registered medical practitioner, without delay. Consent should be documented.

Complete history and examination, including genital examination and injuries should be documented. Standard protocols and guidelines should be followed. Preserve samples such as deoxyribonucleic acid (DNA) profiling. Emergency contraception should be given if required. Treatment/prophylaxis should be followed as required and opinion must be sought.

Guidelines for Preservation of Medicolegal Evidence

- Medicolegal evidence should be preserved and subsequently sent or handed over to the investigating authorities for forensic examination and production as evidenced in a court of law. All evidences will be identified,

sealed, and labeled properly. They will be kept in safe custody and handed over to the investigating officer of the case. Once collected, loss/destruction of evidence is a punishable offense. Failure to collect, destruction, or loss of such an exhibit is punishable under Section 201 of the IPC.

- The evidence required to be preserved is related to the nature of a case. In injury cases, the following articles should be preserved in sealed envelopes: (1) Clothing worn by the patient showing evidence of injury such as tears, bullet holes, cuts, and bloodstains. (2) In case of multiple tears, cuts, or holes, etc., each piece of evidence will be encircled and numbered with matching description in the MLC report and case sheet. (3) Bullets recovered from a body should be marked by etching an initial or a mark on the bottom before preservation. (4) All evidence collected should be mentioned in medicolegal documents to establish the chain of custody in a court of law subsequently.
- In cases of suspected poisoning, the following articles will be preserved and ensured that they are forwarded for forensic examination: (1) Gastric lavage/gastric contents/vomitus and soiled clothing and (2) Blood, urine, and any other relevant body fluid depending on the poison ingested.
- In cases of burns and carbon monoxide poisoning, the following articles should be preserved in sealed envelopes: (1) Articles soiled with inflammable substances such as burnt pieces of clothing and scalp hair and (2) Blood (and not serum) for carbon monoxide levels.
- In sexual offenses, the following articles should be preserved in sealed envelopes: (1) Clothing worn by the patient and showing evidence of blood stains or seminal stains, stains of mud, tears/cuts, etc., and (2) Vaginal swab preferably from the posterior fornix/anal swab.

Guidelines for Preservation of Medicolegal Documents

- Original copies of all medicolegal documents will be produced whenever asked for in a court of law.
- All original copies of certificates and reports issued for medicolegal purposes are to be preserved till the finalization of the case in the court of law.
- Medical Superintendent of the hospital will ensure that the documents are kept in the custody of an appropriate officer till the case is finally decided or cleared by the police and judicial authorities. In the case of units other than hospitals, the safe custody will be under unit arrangements.
- Documents pertaining to admitted fatal MLCs are to be processed and preserved as laid down in concerned policy letters.

Time Limit for Registering a Medicolegal Case

There is no time limit for preparing a MLR or registering a case as MLC. A case which otherwise qualifies to be a MLC was not registered earlier is to be registered as MLC by the concerned doctor. A case due to unraveling of new findings, history/clinical examination etc., which later on qualifies to be an MLC is to be registered by the concerned doctor. A MLC is registered as soon as a doctor suspects foul play or feels it necessary to inform the police, at any time after admission. A case is registered as a MLC even if it is brought several days after the incident. If the case brought is a referred case and is already registered as a MLC, fresh report is not required. If a patient hospitalized and later on some facts revealed on the basis of history physical examination and clinical document, medicolegal report (MLR) can be initiated by the concern attending clinician. If death is inevitable, an arrangement to take the dying declaration is made. All the materials such as vomit, gastric lavage sample, and blood urine in poisoning cases; vaginal swab and pubic hair in sexual offenses; and foreign bodies in wounds, etc., are collected. Samples are properly preserved, packed, and sealed and then handed over to the police.

Admission and Discharge of a Medicolegal Case

Whenever a MLC is admitted, the same is documented in admission papers and hospital records. When discharged, the same should be intimated to the police authorities of the hospital. Police is informed if a MLC is taking discharge against medical advice. At the time of discharge, detailed instructions to the patient regarding treatment, follow-up general care, diet, exercise, etc., are given in writing.

Death of a Person Admitted as a Medicolegal Case

The do's and don'ts in case a person admitted as a MLC expires are as follows. Police is informed immediately. The body is sent to the hospital mortuary for preservation, till the legal formalities are completed and the police releases the body to the lawful heirs. A death certificate is not issued, even if the patient was admitted. The dead body is never released to the relatives directly. *In case of a brought-in-dead patient,* police is to be informed. The number of injuries is noted in the MLC record. The article in possession is to be documented and handed over to police/relatives. The dead body is to be sent to the hospital mortuary and handed over to police.

MEDICOLEGAL CLASSIFICATION OF INJURIES

The wounds or injuries are classified as follows:

- *Estimating time since injury*: Time of injury can be estimated by changes in the injury over the period of time (**Table 1**).
- *Mechanical injuries:* Those caused by hard blunt weapons, fall, or friction with a rough surface, etc.: (1) Abrasion, (2) Bruise or contusion, and (3) Laceration.
- Those caused by sharp-cutting and/or sharp edge of sharp-cutting pointed weapons: *Stab wound* which may again be subclassified as: (1) Punctured, (2) Penetrating, or (3) Perforating.
- *Firearms,* e.g., (1) Shotguns, (2) Rifled gunshot weapons, (3) Improvised country-made weapons.
- *Thermal injuries*: (1) Dry heat—burns and (2) Moist heat—scalds and blisters
- *Chemical injuries*: These types of injuries are caused by corrosive acids or alkalis.

TABLE 1: Estimation of time since injury.

Time of abrasion	• Fresh abrasion—red, oozing with serum little blood, and no scab • 12–24 hours—dry exudation, reddish soft scab • 2–3 days—brownish scab • 4–5 days—dark brown and hard scab • 6–7 days—blackish scab dries up, shrinks falling off
Time of bruise	• Fresh bruise—intact skin, reddish color become bluish within an hour • Next 3 days—remain bluish for the next 3 days • 4th day—brownish/bluish black due to hemosiderin • 5–6th day—greenish due to hemotoidin • 7th day—yellowish-bilirubin and gradually fades away
Time of burn	• Fresh burn—erythematous and blister formation • 2nd day—erythematous around a blister or deep injury passes off • 3rd day—pus formation • 4–6th day—slough formation which sheds off by the end of the first week

HOW DOES THE LAW PROTECT THE VICTIM IN MEDICOLEGAL CASES?

The law states that concerns such as legal formalities, monetary considerations, or even the infrastructural restraints of the institution should not prohibit the institution or hospital from providing basic and emergency medical treatment. Here are a few things everyone should know:

- A hospital cannot deny emergency medical care to an accident victim under Article 21.
- It cannot deny treatment on the alleged reason of lack of facilities. The hospital has to provide emergency care and then transfer the patient safely in its ambulance to the nearest facility. This includes government and private hospitals. It also includes private clinics and nursing homes.
- The hospital cannot deny a patient emergent treatment on the basis that he/she is unable to pay the required fees or that there is no close relative to sign for consent (consent is overridden in an emergency).
- In the case of a rape or criminal abortion, the lady cannot be examined by a doctor without a written consent from her.
- In both cases, rape and criminal abortion, the doctor is bound by law to keep the patient's information, including her name, confidential.
- In cases where a woman is being examined, another woman must be present during the examination. In the case of males, another male has to be present at all times.
- In the case of suicide causing death, the doctor is obligated to report the matter to the police for further investigation.
- If the patient is alive and suicide is suspected, the doctor is not obligated to report the matter to the police.
- Please remember that, on visiting a hospital for a MLC, after the patient has received treatment, the doctor or hospital must inform the police about the case. It is advised to take an acknowledgment of receipt for future reference. If the intimation is given orally or via the phone, a docket number is provided which can be used as proof of intimation and is documented in the patient's records.
- Once the patient has stabilized and is fit to give a statement to the police, the patient is then required to authenticate the information that has been provided and the victim/patient will be visited by the police. They will take down the statement of the victim and confirm if a case needs to be filed or not. The doctor is responsible to give accurate information to the police which will assist them in their investigation. After the case is filed, the victim will get a receipt stating the file number and case number. If required, the victim can employ a lawyer to take the case forward.

PRACTICAL TIPS FOR MEDICOLEGAL CASE WRITING

Q. How to describe gunshot and shotgun wound in a medicolegal report?

A. Gunshot is a single bullet injury by a rifled firearm. Shotgun is multiple pellets injury by *desi katta*/improvised revolver. Indian Law enquires in firearm wound description—number of wounds and type of firearm projectile (bullet/multiple pellets), nature of injury (simple/grievous), killing range of firearm by blackening and tattooing, length × breath × depth, location and direction (circular/oval) of entry wound (inverted margins, blackening, tattooing, abrasion collar) or exit wound (everted).

Q. How to describe shotgun wound on the right lower limb in a MLC report?

A. Multiple punctured lacerated wounds of varying sizes 0.2 cm × 0.2 cm × muscle deep present in a diameter of 10 cm on the back of the right thigh 7 cm above the knee, circular in shape, with blackening and tattooing around the wounds, margins are inverted with active bleeding being present. Opinion reserved—X-ray and surgeon's operative notes for depth and grievousness. Opinion is reserved as not all firearm wounds on limbs are dangerous to life. In a distant range of firearm, it is just a laceration, if no fracture or vascular/nerve injury is caused.[6]

Q. How to describe 90% burn caused by kerosene?

A. Indian Law enquires in burn severity—type of burn (dry heat/scald), depth of burn, nature of injury (simple/grievous/dangerous to life), location and percent of burn and its duration. It should be described—superficial to deep burns with blackening and peeling of skin with singeing of hair with red line of demarcation over the following parts of the body. Head as a whole with singeing of scalp hair, face as a whole with singeing of eyebrows and eyelashes, neck and chest as a whole, abdomen in its whole circumference, genitalia in patches and both buttocks in patches with singeing of pubic hair, both upper limbs and both lower limbs, sparing the soles. Total burnt surface area is about 90%. Opinion of injury—dry heat flame burn of fresh duration and dangerous to life.

Q. How to describe chopped wound upper limb by a wooden axe in MLC report?

A. Indian Law enquires in wound description—type of wound to know the weapon (sharp/blunt and heavy/light), nature of injury (simple/grievous), length × breath × depth, location, margins of wound, fresh duration or not. So we can write—chop wound 5 cm × 4 cm × through and through deep, with clean-cut regular margins, and fresh blood oozing out, present over left forearm mid-part with missing of the distal part of left of the upper limb.

Q. How to write MLC findings of an acute poisoning case by suspected aluminum phosphide pesticide?

A. Patient is conscious, oriented with complaints of restlessness, vomiting of grayish color, intense thirst, burning epigastric pain, and dizziness with alleged history of pesticide poisoning? Celphos, amounting three tablets, ingested 1 hour ago at his home, as told by the conscious patient himself.

On examination—Glasgow Coma Score (GCS) = 15/15, moving all for limbs. Pupils are bilaterally equal in size and reactive to light. Blood pressure is 90 mm Hg systolic. Pulse rate is 160/min on a cardiac monitor and carotids are feeble on palpation. Respiration rate is 40/min. Chest—bilateral air entry present. Temperature is 97°F. Face is grayish-blue (cyanosed). Tongue is dry. There is garlicky odor of breath. Abdomen is soft and there is tenderness in epigastrium. Gastric aspiration samples and clothes of patient are sent for forensic science laboratory (FSL) lab analysis.

Q. How to write injuries in MLC report of sexual assault—rape?

A. Patient is conscious, oriented with complaints of severe pain in genitals and bleeding per vagina with alleged history of sexual assault 1 hour ago at her home, as told by the conscious patient herself. Injuries on the body (examined in the presence of female staff): Stains over external genitalia, matted pubic hair, vagina bruised in the posterior wall, labia majora and minora are both contused, edematous and inflamed, hymen torn at 6 o'clock position with fresh bleeding present. A written consent of the patient for examination of genitalia is mandatory in sexual assault cases. Take the consent of parents in case of minors (<18 years). Note marks of identification on the victim's face, such as black mole or any permanent tattoo mark on limbs or old scar mark, for future identification in court evidence. Vaginal swabs of patient should be preserved, sealed, and labeled.

- One glass slide (sealed in an envelope) smeared with the first swab from vagina
- One swab from cervix
- One swab from posterior fornix
- One sealed glass vial containing vaginal swab in normal saline
- One sealed test tube containing air-dried vaginal swab
- One sealed test tube containing air-dried swab of blood for blood grouping and DNA matching
- One sealed test tube containing air-dried swab of saliva for blood grouping and DNA matching[4]

Q. How to send samples to a police forensic laboratory for chemical analysis?

A. Samples are preserved in a sterile transparent container, sealed and labeled. These should be handed over to the police with a forwarding letter enlisting samples and patient's details. Samples include clothes and gastric aspiration samples in suspected poisoning, impregnated bullets, pellets, knife removed from the wound of patient, clothes, and vaginal swabs from a sexually assaulted victim.

Q. During court evidence, the most common question of a defense lawyer to a doctor (who made MLC) in an injury case is: Can this injury be caused by the falling of victim by self on a hard and blunt surface?

First case: Nitish Katara case: Homicidal physical assault by a blunt weapon—comminuted depressed skull fracture of frontal bone by a hammer. The defense lawyer proposed that it was a case of high-speed RTA as the victim was found by the police in the bushes near the roadside. Now the defense lawyer asked the first question: Can skull fracture be caused by falling on a hard and blunt surface?

The doctor replied: No. A wound of this nature could be caused only when a moving person hits a stationary hard surface which results in "countercoup injury" and results in a lesion in an area opposite to the point of impact. But no countercoup lesions were found in Nitish Katara's head. The lawyer lost the case.

Second case: RTA of a 30-year-old pedestrian, hit by a vehicle on the right lower limb while crossing the road, sustaining primary impact injury—Right lower limb deformity with fracture of femur, tibia, and fibula.

Now when the defense lawyer asked the first question: Can this injury be caused by falling on a hard and blunt surface?

The doctor replied: No. If the victim would have fallen from a height, then both his lower limbs would have got injured. There is no abrasion on the left side.

The lawyer asked: If the victim fell on his right side laterally? The doctor replied: Then he would have got injury over the right side upper limbs or trunk too, along with the lower limb. The lawyer lost the case.

Third case: RTA of a 25-year-old male driving a car, taking a turn over a crossing, hit by another car coming in high speed, sustaining whiplash injury of the cervical spine, leading to paraplegia of both lower limbs. Now the defense lawyer asked: Can this injury be caused by falling on a hard and blunt surface?

The doctor replied: No. The victim had no abrasions or bruises on any part of the body. If he would have fallen, then these injuries would be sustained along with deep injury over the neck. The lawyer lost the argument again.

So doctors should go through all the medical documents of the victim, before facing a defense lawyer, whose goal is to prove that the accused has not directly injured the victim and that the victim fell by self, so there is no proven crime and thus no nonfinancial claim for compensation is to be paid by accused. By using common sense during court proceedings, a genuine victim gets justice and compensation is demanded.

DO'S AND DON'TS IN MEDICOLEGAL CASE WRITING TO AVOID LEGAL PUNISHMENT

Doctors often perform a detailed physical examination but make the mistake of not thoroughly documenting the examination. The old medical maxim, "If it is not documented, it was not done," should be remembered. Remember that you may be cross-examined on your report; only write what you

would be prepared to say under oath in court. MLC reports should be prepared in duplicate preferably with a ball pen. Do not alter your report at the request of your patient or a third party; if you receive additional information or you have made a mistake, provide a supplementary report.

Common mistakes in MLC writing are when the wrong side of the body is mentioned, e.g., left limb fracture is noted as right side, relying on memory, and creating confusion and ground for discrediting MLC reports by courts. Disciplinary action is taken in such as a case which includes suspension from job and MCI notice for doctor's negligence. This can be prevented by properly proofreading their reports. The doctor should take all the steps necessary to catch and correct all: Misspelled words, transcription errors, and grammatical mistakes.

- MLC reports are confidential legal documents; any tampering or alteration in entries, such as antedate entries. Fabricating false evidence of crime—Section 191 IPC, punishable for 7 years.
- Issuing or signing false injury certificate—Section 197 IPC, 3 years of jail
- Do not miss the court date on summons as a arrest warrant will be issued. Contempt of court—Section 228 IPC, punishable for 6 months
- Do not state false findings. Giving false evidence under oath—Section 199 IPC, punishable for 3 years
- Always intimate the police about MLC promptly. Not informing police—to screen offender—Section 201 IPC, punishable for 3 years
- MLC report should be kept in safe custody. If lost/stolen or destruction of evidence—Section 204 IPC, punishable for 3 years

Do not rely on memory while writing MLC reports or giving court evidence. Always review and reply.

When writing your MLC report, it is important to remember that how you say it is just as important as what you are saying.

- Doctors, often inadvertently, use hedge words such as "it seems," "I think," "I believe," "it appears," "it could," or "apparently" in their MLC reports. These hedge words lessen the impact of their findings and conclusions.
- "Complete," "thorough," "meticulous," "exhaustive," and other such words should be used to describe the examiner's chart review, research, or examination. These self-serving words will hold the doctor and his/her MLC report at an extremely high standard.
- "Appears," "presumably," "supposedly," "is said," and "evidently"—these terms imply uncertainty.
- "Obviously" and "clearly"—these terms can be used to make the doctor appear patronizing or presumptuous.
- "Malingering"—sometimes police asks for an opinion on "victim of assault patient who are complaining of generalized body pain." In the majority of cases, it is usually better for the doctor to merely document exaggerated pain behaviors, inconsistencies, nonorganic findings, and lack of objective findings rather than making a diagnosis of malingering.
- "Alleged," "credible," and other words directly or indirectly opine on the credibility of the doctor. The doctor is a medical expert, not a credibility expert.
- "Dictated but not read" and "electronic signature"—these practices make the examiner appear to be more interested in cranking out reports and collecting fees than in precision and accuracy.
- Using incorrect, imprecise, or confounding language in the report will raise red flags and result in uncomfortable and unnecessary cross-examination by the lawyer.

SUMMARY

Writing a MLR is an important legal responsibility for doctors in prescribed cases which is helpful for the investigating authority. In MLR, relevant details are noted legibly and confidentially without abbreviation. Giving life-saving treatment is a priority in any MLC. The doctor's duty is to remain nonjudgmental about any case and examine the patient and document the injuries and findings and management. The onus of fixing responsibility of guilt is for the investigating authorities and court.

19
CHAPTER

Medicolegal Issues in the Emergency Department

Adarsh Kumar, Vivekanshu Verma, Devendra Richhariya

INTRODUCTION

Whenever a patient is injured with suspicion of intention of foul play, it becomes a medicolegal case (MLC). When a patient is injured outside the hospital and he/she is brought for treatment, then the doctor has to inform the police and prepare an MLC. When the patient is injured inside the hospital, either due to slipping on a wet floor in the bathroom or due to lack of proper medical care, then it becomes a medicolegal issue for medical negligence. This adverse event should be reported to the legal department by the treating doctor so that proper documentation is implemented for future court litigation.

The issue of medical negligence is one of the most distressing medicolegal topics for the medical practitioners. To face the problem head-on, it is extremely important to thoroughly understand the concept. Medical negligence may be defined as an "act of omission which a reasonably competent medical practitioner, guided by such medical knowledge and practice as is commonly known at the time and at the place where he practices and further guided by such other considerations which ordinarily regulate the conduct of reasonably competent medical practitioners, would do, or doing something which reasonably competent medical practitioners would not do." It is the failure on the part of a doctor to exercise his/her skill and diligence, which are required of a medical professional resulting in harm to the patient. However, deviation from common practice is not necessarily an evidence of negligence. Similarly, a mere accident or error of judgment is also not evidence of negligence. Medical negligence is termed medical malpractice in the American legal system.

To label any act or omission by the doctor as negligence, all the essential ingredients of medical negligence must be present. The essential constituents of negligence include: (1) Duty of care toward the patient (doctor–patient relationship), (2) dereliction or breach in duty of care, (3) damage that results to the patient must be reasonably foreseeable, and (4) direct causation (direct relation between the breach in duty of care and the damage).

WHAT IS DUTY OF CARE TOWARD A PATIENT?

In order to charge a medical practitioner with negligence, the complainant must prove that the practitioner owed a duty of care to the person complaining of negligence. When a patient enters the clinic or hospital, and the doctor starts examining the patient, the duty begins. Even in charitable hospitals where no money is charged, a doctor can be charged with medical negligence. Not charging a professional fee does not protect the doctor from criminal negligence. Where no duty of care existed toward the person complaining of negligence, there would be no liability on the part of the medical practitioner, even where his action or conduct has caused damage to the complainant.

In *Laxman Balakrishna Joshi vs. Trimbak Bapu Godbole & Anr,* the Apex Court has held: A person who holds himself out ready to give medical advice and treatment impliedly undertakes that he/she is possessed of skill and knowledge for the purpose. Such a person when consulted by a patient owes him certain duties, namely (1) Duty to Care in deciding whether to undertake the case, (2) Duty to Care in deciding what treatment to give, and (3) Duty to Care in the administration of that treatment. A breach of any of those duties gives a right of action for negligence to the patient. The practitioner must bring to task a reasonable degree of skill and knowledge and must exercise a reasonable degree of care. Neither the very highest degree nor a very low degree of care and competence judged in the light of the particular circumstances of each case is what the law requires.

The doctor–patient relationship is absent with doctors in radiology, pathology, microbiology, and biochemistry. Because these doctors do not consult or examine patients, they just report the investigations. But in recent times, in intervention radiologic procedures such as ultrasound-guided stenting, radiologists examine and interact with patients and do procedures; hence, the doctor–patient relationship exists.

The doctor–patient relationship is not formed when the doctor sees the acutely ill patient for the first time in

the emergency room. So doctors giving life-saving drugs in emergency are protected by law from allegations of using dangerous drugs without discussing with the patient.

WHAT IS BREACH IN DUTY TO CARE?

It is expected of the doctor that once he/she has obtained the requisite qualification, he/she will acquire skill to treat the patient and exercise good care. It is assumed that he/she will exercise a reasonable degree of skill and care. He/she may not be the best in the community of doctors but it is assumed that he/she is average and his/her expertise should be at least average in his/her peer group. It is also understood that a doctor may not always know the latest in his/her field, but it is expected that he/she is aware of new techniques that are coming to his/her specialty.

Whenever a patient gets injured during patient care, either by wrong drug, wrong route, wrong site, wrong time, or wrong dose, then it leads to medical negligence. When a surgeon operates at the wrong site, by the wrong procedure, on the wrong patient, at the wrong time, or in the wrong surroundings, then it leads to surgical negligence.

In *Dr Ganesh Prasad & Anr. vs. Lal Janamajay Nath Shahdeo*, the National Commission held that "where proper treatment is given, death occurring due to process of disease and its complication, it cannot be held that doctors and hospital are negligent. Though death of the child is unfortunate, it cannot be said that there was negligence on the part of doctor."

WHAT IS DOCTRINE OF RES IPSA LOQUITUR?

Under certain exceptional circumstances where the doctrine of *res ipsa loquitor* applies, the patient is freed from the responsibility of providing the evidence to prove negligence by the defendant. The burden of proof shifts from the complainant to the medical practitioner who has to prove that damage did not occur from his/her conduct of negligence. The maxim res ipsa loquitor is derived from Latin which literally means "the thing speaks for itself." In context to medical negligence, this maxim applies where it is improbable that the damage complained of could have happened without the wrong of the medical practitioner.

In *Dr G. Vivekananda Verma vs. Chinta Bharamaramba & Ors.,* the National Commission held that "the Petitioner Surgeon gave anesthesia himself and has not shown how 'anoxic encephalopathy' occurred and whether immediate action was taken to avoid the complication and whether timely treatment was imparted to the patient to avoid anoxic encephalopathy. From the records of the Swatantra Hospital and NIMS, it is seen that the patient died due to anoxic encephalopathy suffered during Tonsillectomy. We agree with the findings of the state commission that there is deficiency in service and negligence by the Petitioner. It is clear that the doctrine of *res ipsa loquitur* applies in the present case."

In *Baby Geeta & Ors vs. Cosmopolitan Hospitals (P) Ltd. & Ors.,* facts of the case are that a post-term baby was delivered after administering "pitocin" to induce labor. The delivered child suffered high fever, convulsions, and breathing difficulties and within 16 hours of discharge, tests revealed birth asphyxia resulting in lifelong mental retardation, epilepsy, and physical disability of the child. The National Commission observed that proper antenatal monitoring was not done by the respondent hospital and the doctors. Admittedly special care was required but the case was treated as normal delivery. No appropriate care was taken despite the request of the mother that the baby suffering from tremors at times during the night and was not drinking milk actively. From the facts and the medical literature produced, the National Commission held that failure to take into account all warning signals and take immediate steps to prevent birth asphyxia indicates a clear case of deficiency in service and medical negligence. There is enough evidence to show case of *res ipsa loquitur*.

If it can be proved that the damage suffered by the patient was the possible consequence and is consistent with due care provided by the medical practitioner, then the maxim of *res ipsa loquitur* can be refuted. The medical practitioner has to prove that due care was shown toward the patient. In that case, the court will infer that the damage suffered by the patient was the result of misadventure or error of judgment and not due to negligence.

Jaswinder Singh vs. Santokh Nursing Home & Ors. (2012) 4 SCALE 170... was a case where two mops/gauges were left in the abdominal cavity and the patient died due to septicemia. *Gossypiboma* (retained foreign object) is the technical term for a surgical complications resulting from foreign materials, such as a surgical sponge, accidentally left inside a patient's body.

WHY MEDICAL SERVICES WERE INCLUDED UNDER THE CONSUMER PROTECTION ACT, 1986?

In a landmark case of *Indian Medical Association vs. V P Shanta & Ors,* the Hon'ble Supreme Court laid to rest the controversy whether the services rendered by the doctors/hospitals are covered under the Consumer Protection Act (CPA) or not. The Apex Court held that the services rendered by the doctors/hospitals are covered by the CPA unless such services are rendered by them entirely free of charge or to all the patients.

To clarify the concept and coverage of such services under CPA, the Apex Court has clarified the definition of "Service" under Section 2 (O) into three parts, namely:

1. The main part which says that service means service of any description
2. The inclusionary part which says: include the provision of facilities in connection with banking, finance...house construction, entertainment
3. The exclusionary part which says: but does not include rendering of any service free of charge or under contract of personal service

The Supreme Court further observed that "Contract for personal service implies a contract whereby one party undertakes to render services (professional or technical) to or for another in the performance of which he/she is not subject to detailed direction and control but exercises professional or technical skill and uses his/her own knowledge and discretion." Control of personal service implies a relation of master and servant and there is an obligation to obey the orders in the work to be performed as to the manner in which the work is to be performed. Services rendered by the doctors cannot be termed personal service.

A personal service necessarily implies that service is not only provided at the behest of the master but also that service is provided as per the direction of the master. In case of professional service, a professional such as a doctor advises his/her patient on the nature of disease and the treatment

required to be obtained. A professional may not necessarily follow the advice of his/her client while performing his/her functions.

WHAT KIND OF MEDICOLEGAL ISSUES ARE FACED IN DEALING WITH INTERNATIONAL PATIENTS?

Presently, India is seeing a boom in Medical Tourism Industry and gets patients from various countries who seek better medical facilities. When a hospital deals with an international patient, it must ensure that detailed records are kept including the reason for admission, transfer, and plan of care if required. Insurance companies have experts in their panel to cross-verify the line of treatment, and hence it is a good practice to have a team of specialists attend to a patient instead of looking at him/her individually. When any international patient is injured inside the Indian territory, then intimation to local police and MLC reporting are done as we do for all injured.

Then the doctor needs to inform the legal department of the hospital, who will coordinate with the concerned embassy for collection of material evidence of bullet, etc. When any person is injured or poisoned on board in an international flight, then medicolegal formalities need to be done according to the jurisdiction, as mentioned in the contract of flight carrying the person.

MEDICOLEGAL GUIDELINES FOR MANAGING A TERMINALLY ILL PATIENT IN THE EMERGENCY DEPARTMENT

Regulation 6.7 of the Indian Medical Council (Professional Conduct, Etiquette and Ethics) Regulations, 2002 provides:

"Practicing Euthanasia shall constitute unethical conduct. However, on specific occasion, the question of withdrawing supporting devices to sustained cardiopulmonary function even after brain death, shall be decided only by a team of Doctors, and not merely by the treating physician alone. A team of Doctors shall declare withdrawal of support system. Such team shall consist of the doctor in charge of the patient, Chief Medical Officer/Medical Officer in-charge of the Hospital, and a doctor nominated by the in-charge of the Hospital from the Hospital staff or in accordance with the provisions of the Transplantation of Human Organ Act, 1994."

In India, active euthanasia and assisted death continue to be illegal. Active euthanasia entails the use of lethal substances or forces which would cause the death of a person, e.g., a lethal injection given to a person with terminal cancer who is in terrible agony. Active euthanasia is a crime all over the world except where permitted by legislation. If a person consciously and voluntarily refuses to take life-saving medical treatment, the same is not barred by law. The Supreme Court has laid down guidelines with respect to nonvoluntary passive euthanasia (where a person is not in a position to decide for himself/herself, for instance, if he/she is in coma and is incompetent to take a decision in this connection) in the case of Aruna Ramachandra Shanbaug vs. Union of India, (2011) 4 SCC 454, which are as follows:

A decision has to be taken to discontinue life support either by the parents or by the spouse or other close relatives and in the absence of any of them, such a decision can be taken even by a person or a body of persons acting as a next friend. It can also be taken by the doctors attending the patient. However, the decision should be taken bona fide in the best interests of the patient. Even if a decision is taken by the near relatives or doctors or next friend, to withdraw life support, such a decision requires approval from the High Court concerned.

PATIENTS WITH WEAK FINANCIAL BACKGROUND IN A PRIVATE HOSPITAL

The Hon'ble Supreme Court in the landmark judgment of Parmanand Katara vs. UOI, 1989 (4) SCC 286, has held that every doctor, whether in a government hospital or a private hospital, is under a professional obligation to provide immediate medical aid to an injured person to save human life. However, the treatment should be supplemented by the same process of reporting to the authorities, as undertaken vis-à-vis any other patient of the hospital. The cost of treatment is covered under corporate social responsibility (CSR).

MEDICAL NEGLIGENCE

It is important to understand the difference between medical negligence and medical malpractice, as the two terms are at times used interchangeably. Medical negligence is an inadvertent medical misconduct which may occur due to technical insufficiency of the practitioner or due to lack of complete knowledge of a particular case or out of plain ignorance whereas medical malpractice is misconduct done on purpose and generally involves unethical behavior on the part of the medical practitioner. In the hospital and the likes of its setups, delayed medical attention, overdose, wrong medication, wrong surgical interventions, etc., lead to medical negligence. However, in medical streams other than the allopathic system of medicine where patients turn to, more as the last option rather than as a system of choice, which is, of course, a changing trend nowadays, medical negligence has a higher chance of occurrence. The existence of multidisciplinary treatment options has increased the risk to which any person might be exposed. Failure on the part of the doctors to inform/interact with/procure an informed consent form, the patients/attendants are the most common cause of claims of medical negligence. The discrepancy between the documentation, for instance, billing documents, discharge summary, doctor's notes, nurse's chart, etc., also result in claims for medical negligence. One of the common complaints in MLCs is that the patient or his/her family was not explained the risks involved prior to the procedure being undertaken.

Simplified Strategies to Prevent Medical Negligence During Patient Care

At the time of the admission of a patient, it must be ensured that all forms are properly filled and signed by the patient or by a first-degree relative. Uniform fact sheets and consent forms must be used by all the departments in a multidisciplinary hospital. Also, the history of the patients should be accurately recorded. Proper and accurate records are a must in preventing the chances of medical negligence. A doctor from the treating team must explain the risks and benefits of any surgical procedure/treatment that a patient has to undergo in that hospital. Doctor–patient/attendant communication

must take place between a doctor from the treating team and the family and should be recorded by the nurses. Patient–family education is also crucial. Negligence starts when the doctor carelessly prescribes management verbally without written orders, nurses forget in between the chaos of multiple emergency patients, and the individual patient does not get the appropriate treatment. Timely and correct documentation of advice by a doctor is the key to correct treatment.

How to Face a Medicolegal Complaint?

Medicolegal complaints are to be dealt with due caution and care. Facing a medicolegal complaint is something that needs preparation prior to the visit of the patient to the doctor, wherein, however small might be a doctor's setup, there has to be a provision in the system of the clinic or the hospital for appropriately facing the MLC(s) that might come up in the future. The key to fearlessly facing the cases is proper documentation. The legal counsel (in-house/external) should be immediately informed and provided copies of the relevant complaint/notice/summon/warrant. In a multidisciplinary hospital, it is necessary that there is a coordination between the various departments and, when a case arises, not to get into a blame game.

What Constitutes Medical Negligence?

In *Poonam Verma vs. Ashwin Patel,* while deliberating on the absence of basic qualification of a homeopathic doctor to practice the allopathic system of medicine, the Supreme Court held that a person who does not have knowledge of a particular system of medicine but practices in that system is a quack. The person is guilty of negligence per se, and no further proof is needed.

In *Nihal Kaur vs. Director, Postgraduate Institute of Medical Education and Research (*PGIMER*),* a patient died the next day after surgery and the relatives found scissors while collecting the last remains. A compensation of ₹1.20 lakhs was awarded by the State Commission Chandigarh on the ground that negligence was proved in handling the case.

What Does Not Constitute Medical Negligence?

In *Mrs Shantaben Muljibhai Patel & Ors. vs. Breach Candy Hospital and Research Centre & Ors*, the National Commission dismissed the complaint filed by the wife and two sons of the deceased Mr M M Patel who died in Breach Candy Hospital alleging negligence by staff and treatment administered by the surgeon and anesthetist. The deceased had undergone bypass surgery in 1988 and got the mitral valve replaced. Deterioration of 15% ejection fraction (pumping efficiency) was found in 1996. The operation was performed successfully. While undertaking postoperative treatment, there was extubation. As per the medical literature, such chances of extubation are between 8.5% and 13%. Extubation was swift and sudden and immediately noticed by the nurse. The expert doctor was called, but intubation was found difficult and the patient died due to cardiac arrest. The hospital was equipped with the necessary equipment and doctors performed their duties to the best of their ability with due care and caution. The deceased was a high-risk case and such accidental eventuality cannot be controlled. Every surgical operation is attended by risk. If something goes wrong, the conclusion of deficiency in service cannot be drawn. Reasonable care was exercised by the nursing staff. No negligence or deficiency in service was proved. While delivering its judgment, the National Commission has approvingly referred to the observations of Lord Denning in Roe and Woolley vs. The Ministry of Health and An Anesthetist 75: "Every surgical operation is attended by risks. We cannot take the benefits without taking the risks. Every advance in technique is also attended by risks. Doctors, like the rest of us, have to learn by experience; and experience often teaches in a hard way."

MEDICAL MALPRACTICE STRESS SYNDROME

Doctors sued for negligence are dismissed from the private hospital as it brings bad name in media. Doctors lose job and are harassed financially; they lose precious time in attending courts on dates of hearing and lose time in waiting for their turn that could be used in making progress in medicine. Doctors are stressed socially and psychologically. So prevention of negligence is better than facing the allegations in court.

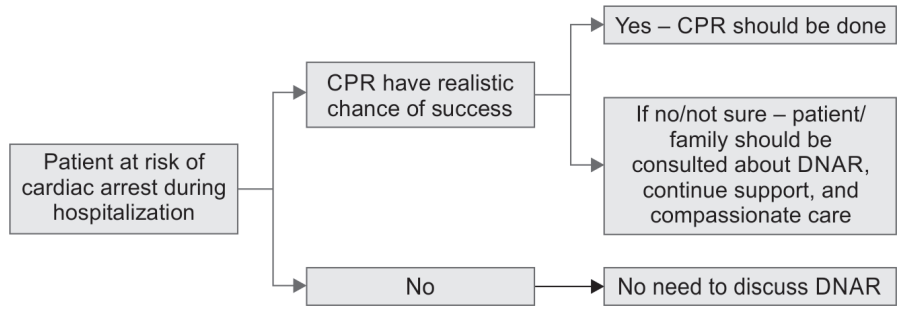
MEDICAL INDEMNITY INSURANCE

Medical indemnity insurance is provided by insurance companies to doctors, nursing homes, or hospitals to pay compensation to patients claiming for medical negligence and malpractice.

DO NOT ATTEMPT RESUSCITATION GUIDELINES

Cardiopulmonary resuscitation (CPR) is an emergency procedure performed in an attempt to revive a patient suffering from cardiac and/or respiratory arrest. In certain situations, providing CPR is likely to increase the suffering of a patient who has a serious and terminal illness. Doctors and hospitals are regularly faced with an ethical dilemma to perform CPR or not. Do not attempt resuscitation (DNAR) is an option that may be exercised by the treating physician in such a situation in the best interest of the patient. DNAR relates to CPR only and its limited value in a certain situation and not to other forms of treatment. The Indian Council of Medical Research (ICMR) guidelines aim to guide the treating physician and patient/surrogate in preserving dignity in death and avoid prolonged suffering to a patient through nonbeneficial CPR while continuing to provide other potentially curative and supportive care. Open communication and decision-making would enhance mutual trust and respect between the treating physician and patient/surrogate (**Flowchart 1**).

- DNAR would apply to a patient with a progressive debilitating, incurable, terminal illness where CPR would be inappropriate, nonbeneficial, and likely to prolong the suffering of the patient in the best judgment of the treating physician. DNAR should be discussed with sensitivity. Compassionate care is important while applying this principle.
- DNAR is distinct from withdrawal or withholding of other life support treatment, and advance directives do not come under the purview of this document



Patient at risk of cardiac arrest during hospitalization
CPR have realistic chance of success
Yes – CPR should be done
If no/not sure – patient/ family should be consulted about DNAR, continue support, and compassionate care
No
No need to discuss DNAR

(CPR: cardiopulmonary resuscitation; DNAR: do not attempt resuscitation)

FLOWCHART 1: Do not attempt resuscitation algorithm.

- There should be an adequate opportunity, time, and space to discuss with the patient and family in private and facilitate a clear understanding of DNAR and its implication. This should be done in anticipation of an impending cardiac arrest during current hospitalization.
- Teamwork and good communication are of crucial importance in decision-making. A combined decision may be taken with the help of another physician, psychologist, social worker, counselor, or hospital administration.
- The DNAR form should be available in the language understood by the patient/surrogate and treating physician. In case the patient/surrogate does not sign the DNAR form, the same should be recorded.
- Hospital administration should make effort to sensitize their healthcare professional on all issues related to DNAR.

EUTHANASIA

The word euthanasia is derived from a Greek word which means "a good death." In the current world, euthanasia has been defined as bringing about a gentle and easy death for someone suffering from an incurable and painful disease or in an irreversible coma (Pearsall and Trumble). Euthanasia may be classified on the basis of informed consent as follows:

- *Voluntary euthanasia*: Euthanasia conducted with the consent of the patient. It is legal in Belgium and Luxembourg.
- *Nonvoluntary euthanasia*: Euthanasia conducted where the consent of the patient is unavailable, e.g., child euthanasia which is illegal worldwide.
- *Involuntary euthanasia*: Euthanasia conducted against the will of the patient.
- *Passive and active euthanasia*: Passive euthanasia involves the act of omission which often involves withdrawing of life support measures, such as artificial feeding and antibiotics which are necessary to continue with life.

Legal Status of Passive Euthanasia in India

On March 7, 2011, the Supreme Court of India legalized passive euthanasia by means of the withdrawal of life support to a patient in a permanent vegetative state. The decision was made as a part of the verdict in a case involving Aruna Shanbaug who has been in a vegetative state for 37 years in King Edward Memorial Hospital. The High Court rejected the active euthanasia by means of lethal medication (injection) which is still illegal in India and most of the countries. In the absence of the law regulating euthanasia in India, the court stated its decision to become the law of the land until the Indian parliament enacts a suitable law.

DISCHARGE AGAINST THE MEDICAL ADVICE FROM THE EMERGENCY DEPARTMENT

Discharge against the medical advice is a common problem, in which a patient chooses to leave the hospital before the treating physician recommends the discharge. Discharge against the medical advice is a problem for many physicians who treat a hospitalized patient and expose the patient to the risk of inadequately treated medical problem and result in the need for readmission. Many physicians struggle with the desire to respect the patient's wishes to leave against the medical advice. In practice, managing this issue presents more complications than simply identifying and prioritization.

Physician–patient communication, informed consent, and underlying psychiatric issues are relevant in practical management. Understanding why a patient chooses to leave the hospital against the medical advice is important so that interventions can be done earliest in a high-risk patient to prevent morbidity and mortality.

Managing Against Medical Advice Discharges

An informed consent is one of the important elements of care in a patient who has decided to leave. An informed consent means that the patient has arrived at the decision in consultation with his/her physician and fully understands the risk, benefit, and alternatives of the decision. An informed consent in discharge planning can be straightforward if the steps are clear. Few questions should be included in the evaluation form of a patient who is leaving against medical advice, e.g., Does the patient understand the admission diagnosis, prognosis, risk, and benefits of leaving the hospital? Is the patient aware of alternative treatment? Can the patient communicate choice? Can the patient articulate reason?

Follow-up

After discussion and discharge with his/her physician and an informed decision to leave against the medical advice has been made, the physician's responsibility is to ensure that the discharge is safe and appropriate as possible, helping the patient to follow-up after discharge.

MEDICOLEGAL IMPLICATIONS OF A PRISONER ABSCONDING FROM THE EMERGENCY DEPARTMENT

Absconding of a patient from the emergency department is of great concern, especially if the patient is under trial or a prisoner. As a result of absconding, the treatment and safety of this patient as well as the safety of society is at risk. Absconding is associated with an increased risk of suicide, self-harm, homicide, and missing from the society. Broadly, absconding has been defined as leaving the hospital without permission. This might be due to differences in the inpatient clinical profile and hospital environment. The common diagnosis in the absconding group is psychiatric and related disorder and substance-use disorder. Whenever a prisoner admits into the emergency department for treatment, he or she is mostly accompanied by the police force. Most of the events occur during daytime, because at that time many more people move around and visit, making it less difficult to make way for the exit. Increase in staffing security in nursing care helps in improving the monitoring and observation of inpatient.

HOW TO DECLARE A PATIENT BROUGHT DEAD?

In every hospital, occasionally a patient is brought to the emergency department who is apparently dead or dead-on-arrival (DOA). Such cases may be natural death or unnatural death. Every doctor should be aware of the procedure to be followed in DOA cases, because such cases have legal, ethical, and social ramifications. Ethically and legally, a doctor should immediately declare a person dead once the diagnosis of death can be clearly established. Legally, the cause of death certificate has to be issued by the doctor in all natural death and after medicolegal autopsy in all unnatural death. The next to kin/relatives get the death certificate by municipality/corporation/panchayat.

Procedure to be Followed in Brought Dead (Dead on Arrival)

First and foremost, all cases of brought dead should be documented clearly in a death register or a brought-dead register; subsequently, adequate history should be collected regarding the event before death, related to disease, drug usage, and injuries, and complete examination of the dead body should be performed. If there is injury, poisoning, signs, or suspicion regarding the nature of death, the case should be registered as an MLC and jurisdictional police must be informed. The body must not be handed over to relatives; the dead body should be shifted to the mortuary (or an empty and safe room if no mortuary is available) and one must wait for the police to arrive and take necessary action.

If there are no injuries or poisoning sign and it looks like a case of natural death and was treated in the same hospital (any doctor of the same hospital), then the cause of death certificate can be issued by the hospital (after persuading all treatment notes, discharge summary, and case sheet), and the dead body can be handed over to relatives for final rites.

If there are no injuries or poisoning signs and it looks like natural death and if the case was not treated by any hospital or doctor, then the case has to be made medicolegal and jurisdictional police must be informed immediately. The body should not be handed over to relatives and they should be informed that this is the only way to get legally a cause of death certificate.

In some hospital, they issue only "brought dead certificate" certifying mere confirmation of death but not the cause of death, is unethical and illegal and misleading. This may lead to false statistics about disease and conditions.

GRIEF COUNSELING

Grief counseling refers to a specific form of therapy which focuses on general counseling with the goal of helping the individual grieve and address personal loss in a healthy manner. Grief counseling is offered by a psychologist, counselor, or social worker. The specific task of grief counseling includes emotional expression about the loss, accepting the loss, adjusting the life after loss, coping with changes within oneself, and the world after the loss. Typical feelings experienced by an individual and addressed in grief counseling include sadness, anxiety, anger, loneliness, guilt, isolation, confusion, or numbness.

The purpose of grief counseling is to help an individual work through the feelings, thoughts, and memories associated with the loss of loved ones. Grief counseling is generally directed toward positive adjustment following loss after the death of loved ones. Grief counseling helps an individual cope with the pain associated with the loss, feel supported through the anxiety surrounding life changes that may follow the loss, and develop strategies for seeking support and self-care.

SUMMARY

There is no doubt that advances in medicine have improved the quality of healthcare being provided to the patients. However, there has also been a rise in unrealistic expectations from the physicians. Many times, patients are not willing to accept anything less than complete recovery. The allegation of medical negligence is a stressful event for every physician, and even if the physician is not found guilty of medical negligence, a lot of suffering has already occurred. It is extremely important for physicians to understand the meaning, scope, and legal interpretation of the term "medical negligence" so as to face the problem head-on.

20 CHAPTER

Examination of Sexual Abuse Victim

Nikhil D Datar, Meghna Shedge

INTRODUCTION

Rape is one of India's most common, injurious, and heinous crimes against women. Statistics state that every 15 minutes, a woman reports rape in India. It causes severe physical, mental, and social trauma to the victim. The effects are devastating, extending to consequences such as unwanted pregnancy, sexually transmitted infections, sleep and eating disorders, and other emotional and physical problems.

Health professionals play a dual role in responding to the survivors of sexual assault. The first is to provide the required medical treatment and psychological support. The second is to assist survivors in their medicolegal proceedings by collecting evidence and ensuring good quality documentation. For accurate examination and evidence collection, it is important that every doctor understands what constitutes the offense of rape.

DEFINITION OF RAPE

According to the provisions of the Indian Penal Code (IPC) further amended in 2013, section 375 defines rape as: A man is said to commit rape if he (a) penetrates his penis, to any extent, into the vagina, mouth, urethra, or anus of a woman or makes her to do so with him or any other person; or (b) inserts to any extent any object or a part of the body, not being the penis, into the vagina, urethra, anus, or any part of the body of such a woman or makes her to do so with him or any other person or; (c) manipulates any part of the body of a woman so as to cause penetration into the vagina, urethra, anus, or any part of the body of such a woman or makes her to do so with him or any other person or; (d) applies his mouth to the vagina, anus, urethra of a woman or makes her do so with him or any other person.

Under the circumstances falling under any of the following seven descriptions:

1. Against her will.
2. Without her consent.
3. With her consent when her consent has been obtained by putting her or any person in whom she is interested in fear of death or hurt
4. With her consent when the man knows that he is not her husband and that her consent is given because she believes that he is another man to whom she is or believes herself to be lawfully married
5. With her consent when at the time of giving such a consent, by reason of unsoundness of mind or intoxication or administration by him personally or through another of any stupefying or unwholesome substance, she is unable to understand the nature and consequences of that to which she gives consent
6. With or without her consent, when she is under 18 years of age
7. When she is unable to communicate consent

PRESENTATION IN AN EMERGENCY DEPARTMENT

A rape survivor may present to an emergency room in different situations:

- *In a critically ill condition (brought by police or any other person)*: The primary response of a healthcare provider should be to provide resuscitation and immediate treatment to the survivor irrespective of the fact whether a police complaint has been made or not. Admission, evidence collection, or filing a police complaint is not mandatory for providing treatment. The survivor is brought to the emergency room (ER) by the police. After a quick triage if found to be physically and mentally stable, examination and evidence collection may be undertaken after the consent of the victim.
- *The survivor comes directly to the ER without informing the police*: After a quick triage to confirm that the survivor is in a stable condition, further examination can be undertaken after the consent of the survivor. The hospital is responsible to notify the police of this serious and cognizable offense. If the survivor does not wish to pursue the police complaint, she may refuse to give consent for evidence collection. The refusal needs to be recorded in writing. It is the survivor's decision whether to file an FIR or not.

EXAMINATION

Who should carry out the examination of the rape survivor? Section 164 (A) of the Criminal Procedure Code states that: Examination of a case of rape shall be conducted without any delay by a registered medical practitioner employed by a government hospital or local authority.

Any registered medical practitioner can conduct the examination and it is not mandatory for a gynecologist to examine such a case. If in case a female doctor is not available for examination, a male doctor should conduct the examination in the presence of a female attendant. In case of a minor/person with disability, his/her parent/guardian/any other person with whom the survivor is comfortable may be present.

The Criminal Law Amendment Act, 2013, in Section 357C Criminal procedure code states that: Both private and public health professionals are obligated to provide treatment, and denial of treatment is punishable under Section 166 B IPC with imprisonment for a term which may extend up to 1 year or with a fine or with both.

Thus, it is clear that every hospital should be equipped to handle such an examination in a quick and effective way to provide uniform and comprehensive healthcare services. In order to achieve this, the following may be considered:

- Every hospital should have a standard operating procedure (SOP) for the management of cases of sexual violence and these must be printed and available to all staff of the hospital.
- The administrative guidelines regarding interdepartmental handling of such cases for examination and evidence collection should be clear to all the staff.
- The administration should simultaneously help the clinical staff to inform the police and complete medicolegal procedures.
- The hospital should have a uniform method of examination and evidence collection. A kit with required pro forma along with the utilities such as nail cutters, syringes, and swabs can be kept ready for immediate use. [The author was instrumental in setting up the Sexual Assault Forensic Evidence (SAFE) kit.]
- Health professionals need to maintain a clear and foolproof chain of custody of medical evidence collected and referring to appropriate agencies for further assistance (e.g., legal support services and shelter services).

QUICK ASSESSMENT

A doctor should ascertain the general condition of the victim and the vital parameters. Injuries and hemorrhage may put the victim's life at risk and if so, treatment must be initiated. The examining doctor should be well aware of the comprehensive care to be provided. As soon as the rape survivor reports to the hospital, initial resuscitation and treatment should be given, followed by consent, detailed history, evidence collection and documentation, and treatment (**Flowchart 1**).

Informed Consent

Consent should be taken for examination, evidence collection, treatment, and police intimation. The doctor shall inform the victim about the nature and purpose of examination and in case of a child, the child's parent/guardian/person in whom the child reposes trust will be informed. This information should include the following:

- Medicolegal examination is to assist the investigation and prosecution of those who committed the sexual offense. This may involve an examination of the mouth, breasts, vagina, anus, and rectum.
- To assist the investigation, forensic evidence may be collected with the consent of the survivor. This may include removing and isolating clothing, scalp hair, foreign substances from the body, saliva, pubic hair, samples taken from the vagina, anus, rectum, mouth, and collecting a blood sample.
- The survivor or in case of a child, the parent/guardian/person, in whom the child reposes trust, has the right to refuse either a medicolegal examination or collection of evidence or both, but that refusal will not result in denial of treatment to the survivor.
- As per the law, the hospital/examining doctor is required to inform the police about the sexual offense. However, if the survivor does not wish to participate in the police investigation, informed refusal will be documented.

The nature of forensic evidence collected will be determined by three main factors: (1) Nature of sexual violence, (2) Time elapsed between the incident of sexual violence and examination, and (3) Whether the survivor has bathed or washed herself.

The Statement

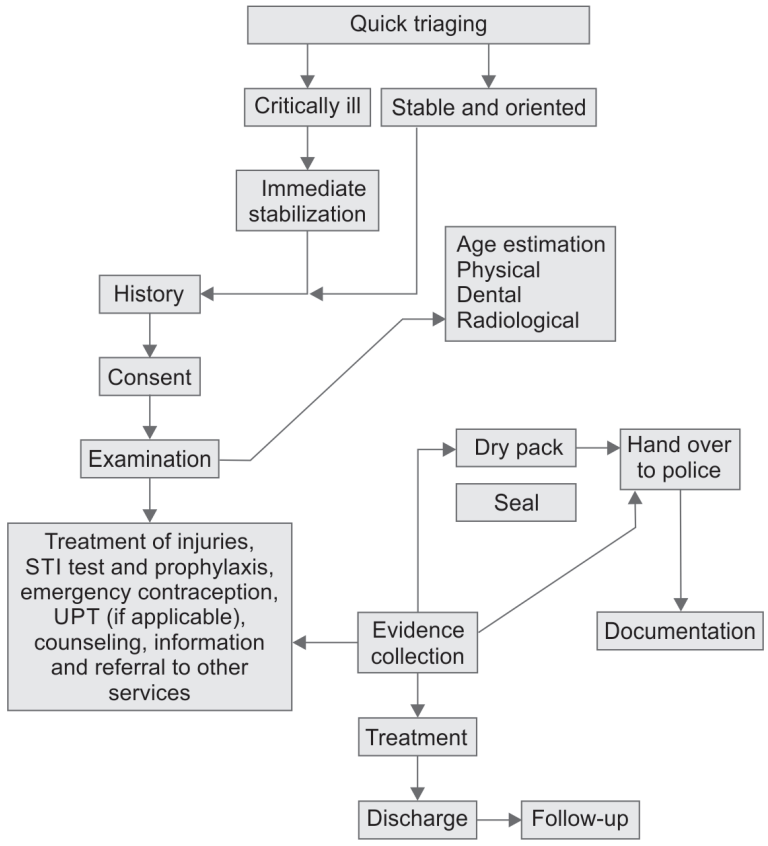
The examiner must be tactful and sympathetic to the victim while taking the statement. The exact narration by the victim is very important and the statement must be written down in her own words as near as possible verbatim. No false modesty should be allowed in writing. The statement may include direct questioning bringing out details about:

- The place and time of incidence
- The number of assailants
- The amount of violence
- Position
- Resistance offered
- Pain, hemorrhage, sensation of penetration, and emission
- Clothes which the victim has worn
- The statement must include whether the victim has changed clothes, urinated, or douched her vagina.

Clothes: The corroborative evidence on clothes speaks for itself. Examining the clothes when the victim has not changed them is very important. The tear in the fabric, marks of mud, stains of blood, and semen should corroborate with the statement of the victim. Clothes should be looked for foreign hair and pieces of clothing different from one worn by the victim (which could belong to the assailant). The clothing should be retained, labeled, and sent for examination.

GENERAL EXAMINATION AND INJURIES

At the time of history taking, examination, and evidence collection, any police personnel should not be present. The whole body must be examined for marks of violence. The victim should be requested to undress herself. Special attention should be given to the nature of the injuries.



(STI: sexually transmitted infection; UPT: urine pregnancy test)

FLOWCHART 1: Summary of managing a sexual abuse victim in the emergency department.

Common injuries are as follows:

- *Head*: Blow on the head or head injury due to fall
- *Neck*: Gripping of throat
- Injuries on cheeks, lips, breast, and chest are common.
- Generalized bruises, lacerations, contusions, bite marks, nail marks
- The marks of rope knots on the wrists and ankles

The examiner should strive to ascertain the following:

- Whether these marks are of injuries or self-inflicted
- Apparent development of the victim's body
- Amount of resistance offered
- Corroboration with the statement of the victim

Examination of the Nails

Scraping from the nail beds constitutes important evidence. Tags of epithelium, hairs, pieces of clothes, and bloodstains are important to collect.

Gait

A note of the victim's gait must be made. If consent is available, the victim's blood should be collected for grouping. This will help in ascertaining whether bloodstains are of the victim or the assailant. A second examination after 48 hours may reveal deep bruises, which may not be evident at the first examination.

Examination of Genitals

A gynecological examination should be conducted in a lithotomy position and in good light. The history of the last menstrual period must be asked for to differentiate menstruation from bleeding due to injuries.

Local Signs of Violence

Pubic hair: Pubic hair may be combed for foreign hairs. Pubic hair matted due to seminal stains, blood, or secretions may be cut and preserved. Stains of blood or semen from the skin must be scraped bluntly and preserved.

Collection of Vaginal Secretions

Instillation of 15 mL of normal saline in posterior fornix can be done and aspiration of contents can be collected and examined. A wet preparation when studied under a microscope may reveal motile or nonmotile spermatozoa. The absence of a spermatozoon does not mean the absence of intercourse. Ziehl–Neelsen staining of another slide may reveal acid-fast, rod-shaped organisms, which are smegma bacilli.

Evidence of Venereal Disease

The examiner should keep in mind signs of various venereal diseases such as syphilis, gonorrhea, and chancroid.

Injuries

Hymen: Especially in a virgin victim, examination of hymen is important. Signs of recent rupture of hymen are ragged edematous edges of the hymen and hemorrhage.

Examination of vagina: Distensibility of vagina should be noted in relation to the number of fingers it admits. The character and extent of injury will vary in proportion to the following:

- Disproportion of male and female organs
- Whether the victim is virgin or not
- The extent of penetration
- Amount of force

Lacerations of the posterior fourchette are very commonly associated with forceful intercourse, especially with a virgin. Finger penetration may lead to lateral vaginal wall tears. Bruising and lacerations in the vagina also must be recorded properly. The absence of injuries may be due to the inability of the survivor to offer resistance to the assailant because of intoxication or threats. Pictorial representation of these injuries can be very helpful for corroborative evidence.

DOCUMENTATION

The collected samples for evidence are properly packed, sealed, and preserved in separate envelopes in the hospital till the time police are able to complete their paperwork for dispatch to a forensic laboratory for tests including DNA. A copy of all documentation (including that pertaining to medicolegal examination and treatment) must be provided to the survivor free of cost.

TREATMENT

Medical treatment should include:

- Measures should be taken to prevent the sexually transmitted diseases
- Emergency contraception
- Prophylaxis for tetanus, hepatitis B, and HIV
- Treatment of wounds
- Counseling and psychological support

Survivors of sexual violence should receive all services completely free of cost. This includes outpatient department (OPD)/inpatient registration, laboratory and radiology investigations, urine pregnancy test (UPT), and medicines. The casualty medical officer must label the case papers for any sexual violence case as "free" so that free treatment is ensured. Each survivor copes up differently and hence psychological support and counseling can help in overcoming trauma and recovery from sexual assault.

EMERGENCY CONTRACEPTION

Emergency contraception can stop pregnancy before it starts. Emergency contraception is a safe way to prevent unintentional pregnancy due to unprotected sex, contraceptives failure, condom rupture, slippage diaphragm, forgotten oral pills, or following sexual assault. Rape resulting in unintended pregnancies causes mental and social burden to the women and society as a whole. Emergency contraception intervenes and prevents a number of unwanted pregnancies by reducing the maternal mortality and morbidity. Emergency contraception is also known as morning-after or postcoital method. It is similar to oral contraceptive but hormone doses are higher. Developing embryo or an established pregnancy is not affected by emergency contraceptives (ECs). EC is effective only if taken on the first few days of unprotected sexual exposure before the sperm fertilizes the ovum.

Emergency Contraceptive Use in India

India was a part of research trial by the World Health Organization (WHO) in 1995–1997 and 1998–2001. Report and recommendations were released in 2001 and EC was approved by the Drug Controller General of India. Nowadays, EC is an important method of contraception for unprotected sex and is most effective if taken within 12 hours of unprotected sex. Awareness is required among women about the timing of dose of the EC. This method is one-time use only so efficacy cannot be calculated by the Pearl Index. In India, maternal mortality is high and mostly due to unsafe abortion. Judicious use of EC plays an important role in reducing mortality and morbidity due to unsafe abortion.

Types of Emergency Contraceptive Pills

Ulipristal: It is more effective than progestin-only or combined pill in preventing unprotected pregnancy. It was approved in 2010 and can be taken up to 120 hours after unprotected intercourse.

Progestin-only: Progestin levonorgestrel 1.5-mg single dose or 750 μg 12 hours apart in two doses can be taken up to 72 hours.

Combined pill: It contains both estrogen and progestin in a higher dose. It delays the ovulation and is the most effective if taken within 3 days of unprotected intercourse.

Emergency Contraceptive Use

History of the last menstrual period, length of cycle, time since the last unprotected intercourse, any history of chronic illness, and physical examination are not generally required; however, Urine Pregnancy Test is recommended if pregnancy is suspected. Follow up after the use of emergency contraceptive if menstruation occurs within 7 days or expected periods; counsel and encourage for regular methods. If no menstruation occurs within 7 days or expected periods, perform a Urine Pregnancy Test; if it comes negative, wait for 1 more week and, if positive, counseling is recommended. There are no serious side effects of EC but only mild, which resolve within 24 hours. Mild side effects are nausea, vomiting, mild headache, mild tenderness in breast, dizziness, fatigue, and delay in menstruation.

SUMMARY

The aim of the examination is to provide holistic health advice and to collect evidence for forensic examination. The legal duty of the doctor is to collect accurate evidence regarding the use of force and the signs of offense. The judiciary has to pronounce the verdict if the crime of rape has occurred or not. All efforts must be made to carry out the examination in a quick, uniform, and systematic manner keeping in mind the

dignity of the woman. Any physician from the government or private sector may conduct the examination. In case a female physician is not available, a male physician can conduct the examination in the presence of a female witness. The Ministry of Health and Family Welfare of the government of India has made uniform guidelines and ready pro forma to assist the physician in dealing with sexual assault survivors and their examination. These can be downloaded from https://main.mohfw.gov.in/reports/guidelines-and-protocols-medico-legal-care-survivors-victims-sexual-violence.

21 CHAPTER

End-of-life and Palliative Care in the Emergency Department

Naeem Toosy

INTRODUCTION

Emergency medicine is the acute specialty dealing with undifferentiated patients. Other than initiating the diagnostic process, identifying patients who may deteriorate, and resuscitating patients, the specialty has a holistic remit that extends to public health. Emergency departments (EDs) provide an access point for patients with chronic illnesses as well as those who are approaching the EOL. Easy access means that these departments are well placed to provide a safety net for patients who fall through the cracks of a healthcare system increasingly fragmented between various specialties and subspecialties.

Though many patients who know they are dying express a preference to remain at home during their final journey, the fact remains that many actually end up visiting an ED in the last few months of their life. Among the reasons for this often is inadequate communication in the lead-up period from the various specialists with their curative focus, the inability of patients or their families to cope with symptoms, inadequate social support, and cultural factors. The ED assumes an important role at this juncture of their lives as decisions about the trajectory of hospital care and initiation of life-sustaining interventions (e.g., mechanical ventilation and dialysis) are influenced by what happens in the ED.

The World Health Organization (WHO) defines palliative care as "*an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual.*" Investigations such as the SUPPORT trial (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment—JAMA 1995) have shown that currently, the ill or dying patients receive care that often, unfortunately, does not meet their expectations. This may be due to the fact that in the ED environment, it can be a challenge to address the EOL needs of a patient and his/her families.

However, by engaging the patient and his/her families in conversations about their goals of care, the trajectory of their illness, option in palliative care, and its associated hospice services, the emergency physician can significantly improve the quality and experience of patients approaching the end of his/her life. Such activity is in keeping with recommendations of international organizations such as the American College of Emergency Medicine (ACEM). The American College of Emergency Physicians (ACEP) on its website suggests a screening tool. Such tools can be used by anyone in the healthcare team, i.e., physician, nurse, and social worker, to screen and flag patients who may benefit from palliative care.

An ACEM expert consensus group placed core topics in palliative care that the emergency physician should be cognizant of into the following three groups:

1. Recognition of the EOL needs of the patient
2. Essential primary palliative care skills
3. A logistic understanding of palliative care delivery in the ED

TRAJECTORY OF DYING AND END-OF-LIFE DECISION-MAKING

Despite the challenges of predicting life expectancy accurately, it is still useful to recognize when a patient has entered the final stages. This is especially important when we realize that a significant proportion of healthcare spending is incurred in the final few months of a patient's life, without necessarily giving patients or their families satisfaction or contentment with the healthcare system.

Four dying trajectories have been described: *Terminal illness, organ failure, frailty,* and *sudden death.* Familiarity with these trajectories can assist the physician to contextualize these illness presentations and improve the recognition of the end of life. An example of terminal disease is metastatic cancer. Patients with metastatic cancer whose prognosis is poor nevertheless tend to maintain relatively good function until the very end. Once these individuals are significantly weakened by the illness, then their final trajectory is reasonably predictable.

Congestive heart failure and chronic obstructive airway disease are common EOL organ-failure diagnoses. Though patients who suffer from such conditions have a decline in their overall health over time, there are often sharp spikes of

deterioration but also unexpected recoveries. It is, therefore, challenging in the short term to prognosticate on their final decline. In addition, there may be other considerations such as the eligibility of such patients for organ support technology, e.g., ventricular assist device or extracorporeal membrane oxygenation (ECMO), which can be a bridge to transplantation or recovery. In these cases, unless the goals of therapy have been clearly defined before acute deterioration, it may be beyond the emergency physician to initiate palliative care. The emergency physician may be in a position to initiate such a discussion with the patient or family.

Frailty is characterized by the patients who reside in long-term care facilities or who are dependent on family care which might be due to advancing dementia or other severe incurable neurologic conditions. Often, a patient may be profoundly disabled for months to years prior to his/her ultimate demise, which often occurs from complications of the underlying illness rather than the disease itself. These complications are often the reason for their attendance to an acute care facility. Though a single hospitalization may not portend the final trajectory, a number of hospitalizations over the recent past can be a red flag that gives an opportunity to explore the patient's goals of care.

Although not common, sudden cardiopulmonary arrest is another trajectory as patients, who experience sudden or dramatic deterioration in the community, most often are brought to the ED. The resuscitative attempt and the intensive care admission for those who achieve a return of spontaneous circulation (ROSC) are often resource-intensive but without the outcome one would desire. This is especially true in those patients who are already critically ill (e.g., end-stage cancer) or who have an exceedingly low chance of either survival or return to a functionally independent status. Massive myocardial infarction, especially in the setting of previous myocardial damage, intracranial emergencies, and traumatic brain injuries, are other examples of conditions from which the prospect of meaningful survival may be limited and decisions on withdrawal of life-sustaining treatment may be necessary. This is why in patients with underlying health issues, a proactive approach to discussing these issues should be adopted so that there is time for them to consider their decisions and come to terms with them.

At the heart of EOL, care is understanding the patients' and families' preferences. The fact that some of the interventions are time-critical make it much more of a challenge to explore these preferences in the ED. As a majority of patients lose decision-making ability near the EOL, then this is the only critical time for emergency physician to decide.

- If there is an advance directive, and
- If not, to ensure that the patient's appropriate surrogate decision-maker is identified

Clearly, knowledge of the laws of the jurisdiction one is working in is useful as these directives can take the form of living wills, out of hospital DNR [do not resuscitate orders, physician orders for life-sustaining treatment (POLST)], etc., in different places.

When no written directives exist, then previously expressed wishes from an appointed decision-maker or surrogate (on occasion, a legally appointed healthcare proxy) may be sought. In many developing countries, there may not be formally established mechanisms to register these decisions or there may be cultural, religious, or legal challenges.

PALLIATIVE CARE AND BIOETHICS

The basis of decision-making in these situations is guided by bioethics. Specific bioethical issues relevant to EOL care include the principles of:

- Autonomy and self-determination
- Futility
- Justice
- Declaration of death and organ donation

Autonomy refers to an individual's right to make the decision about his/her own healthcare. However, in order to exercise this right, an individual should be competent and has the capacity. Capacity can be determined by medical and/or psychiatry professionals; however, competence can only be determined by a court. It is important to realize that even a surrogate decision-maker should only make decisions that they believe represent the patient's own wishes.

Decisions on the futility of therapy require trust between the family of the patient and clear and open communication with the medical team. Occasionally, due to either lack of trust of the patient or his/her family's religious or cultural beliefs, there is an impasse between medical professionals and the patient or his/her family. In these situations, a family may wish to seek another opinion or transfer the patient to another accepting healthcare facility. In rare cases, courts have been called on to mediate or make decisions. These processes are generally beyond the scope of the EDs and it will be necessary to involve palliative care professionals and/or the institution's ethical committee.

The principle of justice revolves around the stewardship of resources, especially intensive care unit (ICU) beds. Improper utilization of ICU beds can take up precious resources that could have been utilized for patients who are likely to benefit from advanced interventions such as extracorporeal life support, dialysis, and transplants. However, resource allocation is something that needs to be decided at a macro level and is often beyond the scope of the individual clinician. Trust, transparent communication, and cooperation are needed between regional institutions in order to utilize these resources efficiently.

Organ donation and declaration of death require clear pathways and legislation. Investment in these is worthwhile as it means organs can be recycled to help individuals with end-organ failure. In an ED, it is not uncommon to pronounce circulatory death in a patient not responding to resuscitative measures; however, the diagnosis of brain death is more involved and requires several physicians performing tests generally beyond the scope of an ED.

COMMUNICATION AT THE END OF LIFE

On a practical level, communication is one of the cornerstones of EOL care. These skills are needed by emergency physicians involved in these challenging but important conversations with patients and their families. The goal of effective communication is to enable "*shared decision-making,*" defined by the Institute of Medicine as "*care that is respectful of and responsive to individual patient preferences, needs and values, and ensuring that patient values guide all clinical decisions.*"

The concept of "*decision frames*" is a key one because the way information is presented to patients can have a significant impact on the decisions they make. In 1981, Tversky and

Kahneman suggested the prospect theory. According to this theory, when choices are presented in terms of the possibility of further gain, then people are less likely to take risks; however, when the choice increases the possibility of losing something, people are willing to take more risks. This is often because if the available decision is framed wrongly, then a patient with even a vanishingly small prospect of benefit may end up being intubated and ventilated.

In communication, the general principle is to use an "*Ask-tell-ask" approach*, allowing patients to express their emotions and feelings as well as their reservations and fears. There are several guides for the way to structure a goals-of-care discussion. The ACEP suggests one on its palliative care web page. Other examples include the guide proposed by Buckman and Kason or the six-step approach that uses the *SPIKES acronym* (**Box 1**).

A structured approach to responding to the participant's emotions is summarized by the *NURSE* acronym which reminds us to *Name* the emotion that the participant seems to be experiencing while showing *Understanding* of the emotion and *Respecting* it. It is also important to *Support* the participant and *Explore* an aspect of his/her emotion in order to establish an empathetic connection.

Although these skills can be taught and improved, the physician also needs to be genuinely empathetic and caring for this not to be a hollow exercise. It is important to be aware of communication behaviors that impact the encounter negatively. These include avoiding difficult topics, lecturing the patient with facts while failing to deal adequately with the emotional content of the conversation, colluding with the participants in avoiding difficult topics, and offering reassurance prior to allowing the patient to express his/her emotion fully.

BOX 1: SPIKES guide to a goals-of-care discussion.

Setup (S): Key preparation step to ensure that interruption-free and private conversation can take place

Perception (P): It is important to start by exploring the patient and family's perceptions

Invitation (I): The participants should be invited to share how much information they want to disclose

Knowledge (K): The information should be presented in a clear way in common language allowing time for comprehension and questioning

Empathy (E): It is important to let participants express their emotions and to empathize with them

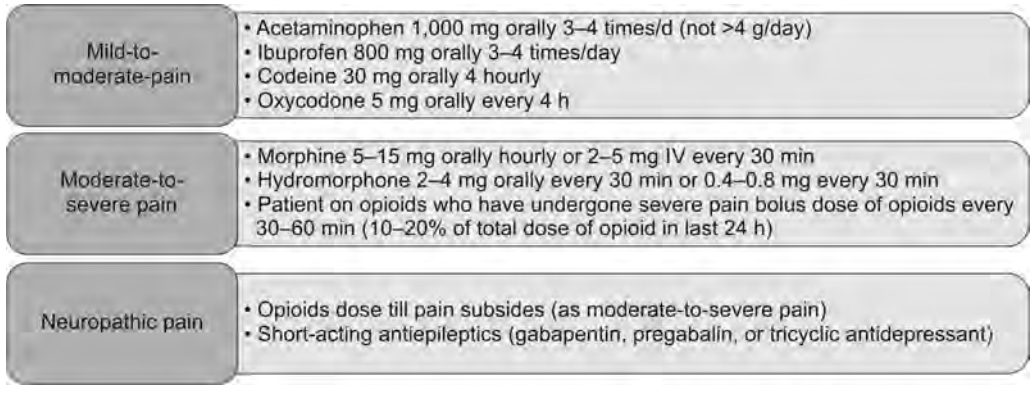
Summarizing (S): Summarizing the conversation to ensure that there is agreement on what has been discussed

END-OF-LIFE SYMPTOMS MANAGEMENT

On a practical level, a patient with an EOL trajectory often comes to the ED to seek relief symptoms that have overwhelmed him/her, his/her family, or his/her caregivers. The emergency physician needs to confirm the patient's diagnosis and prognosis, ascertain what arrangements are already in place, and initiate an open empathetic dialogue. It is important, therefore, for an emergency physician to have an understanding of common and distressing EOL symptoms and some of the ways in which these may be relieved.

It is important to realize that good palliative care dictates an active strategy that aims to relieve the patient from distress, e.g., pain (**Flowchart 1**). Common distressing symptoms at the EOL include *dyspnea, increased respiratory secretions, managing pain, fatigue, anxiety, delirium,* and *common gastrointestinal (GI) symptoms such as nausea, vomiting, constipation, or diarrhea* (**Table 1**). Although it is important to consider treatable disease processes that may be the cause of these symptoms, it may well be that no significant pathological process is found after a thorough assessment.

As an example, although a patient complaining of dyspnea may have treatable pathology such as pulmonary embolism, often the cause of the patient's symptoms may be subjective. In the absence of hypoxemia, the use of oxygen therapy is controversial, though it may be needed for patient appeasement. If needed though, high-flow nasal cannula or noninvasive ventilation should be considered prior to invasive mechanical ventilation. Simple measures, such as a fan, may also make a significant difference. Liberal use of opioids or benzodiazepines for air-hunger and anxiety, antipsychotics for agitation, antimuscarinics such as glycopyrrolate to control respiratory secretions, and medication to control gastrointestinal symptoms can be helpful. In an emergency situation, a distress protocol using a cocktail of drugs as suggested by Godbout may be considered to obtain rapid relief, giving time to consider the other factors.



Mild-to-moderate-pain
• Acetaminophen 1,000 mg orally 3–4 times/d (not >4 g/day)
• Ibuprofen 800 mg orally 3–4 times/day
• Codeine 30 mg orally 4 hourly
• Oxycodone 5 mg orally every 4 h
Moderate-to-severe pain
• Morphine 5–15 mg orally hourly or 2–5 mg IV every 30 min
• Hydromorphone 2–4 mg orally every 30 min or 0.4–0.8 mg every 30 min
• Patient on opioids who have undergone severe pain bolus dose of opioids every 30–60 min (10–20% of total dose of opioid in last 24 h)
Neuropathic pain
• Opioids dose till pain subsides (as moderate-to-severe pain)
• Short-acting antiepileptics (gabapentin, pregabalin, or tricyclic antidepressant)

(IV: intravenous)

FLOWCHART 1: Acute pain management during end-of-life care.

TABLE 1: Symptomatic treatment during end-of-life care.	
Nausea and vomiting	• Gastroparesis induced—metoclopramide (10–20 mg orally or IV every 6 h) • Medication, uremia induced—metoclopramide, haloperidol (0.5–2 mg IV 8 hourly), ondansetron (8 mg orally every 8 h) • Raised ICP-induced vomiting—dexamethasone (4–8 mg orally/intravenously once daily usually combined with other antiemetics) • Bowel obstruction induced—octreotide (100–200 µg subcutaneously 3 times per day), dexamethasone (4–8 mg orally/intravenously once daily)
Anorexia	Dexamethasone (2–4 mg orally/intravenously once daily)
Constipation	• Senna glycoside 1–2 tablets as a single dose per day • Bisacodyl 10 mg rectally once daily • Polyethylene glycol (PEG)
Dyspnea	Oxygen BiPAP morphine (2–4 mg IV every hour), nonpharmacological approach, e.g., breathing training, opening window for ventilation, elevation of head, end-of-the bed
Cough	• Codeine 30 mg orally every 6 h • Morphine 2–4 mg IV every hour as needed
Excessive oral secretion	Glycopyrrolate 0.2 mg IV every 4 h (maximum 4 doses)
Oral care	Pilocarpine 5–10 mg tablet orally 3 times daily, antimicrobial mouthwash, oral hydration mouth swab, lip balm humidifier
Fever	• Acetaminophen 650–1,000 mg orally/IV every 6 h, maximum 4 g/day • Naproxen 250–500 mg orally twice daily
Anxiety insomnia	Lorazepam 0.5–2 mg orally/IV every 6 h, psychological intervention will be more helpful, risk of fall may increase with sedation
Delirium	Haloperidol 0.5–1 mg orally/IV every hour. Agitated refractory cases, additional antipsychotics agents, and benzodiazepines and careful monitoring

(BiPAP: bilevel positive airway pressure; ICP: intracranial pressure; IV: intravenous)

SUMMARY

Although palliative and EOL care traditionally is considered to be the remit of oncologists, specialists in palliative care, and intensive care doctors, increasingly some of the responsibility for the assessment and care of these patients is falling on emergency physicians. As improvements in public health, nutrition, and healthcare increase the proportion of the population that is elderly or has chronic health conditions, it is essential that all medical professionals have an understanding of the balance between the quantity and the quality of life.

As the ED is often at the interface of healthcare specialties and society, it is imperative that EOL and palliative care principles, communication, treatment options, disposition choices, and medicolegal aspects are incorporated into an emergency physician's training curriculum.

22
CHAPTER

Death Declaration

Rammohan Radhakrishnan, Sahanya Ramesh Shetty

INTRODUCTION

Certain aspects in the emergency department (ED) prove to be an uncomfortable and challenging part in resuscitation efforts; one such aspect is that of delivering the news of the deceased patient to his/her relatives. It is evident that sudden death in emergency rooms is a common phenomenon; however, most physicians find it to be a daunting task due to being undertrained in this aspect. Even after the regularity in experiencing sudden death in ED, physicians generally draw skills from their own past experiences and each has his/her own manner of delivering the bad news. Situations are trickier when it involves the death of a child. Hence, delivering bad news along with appropriate care after the death is a systematic and meticulous pattern one must follow in order to ensure peace and harmony amongst the relatives.

POSSIBLE CIRCUMSTANCES OF DEATH

Whatever the prognosis of the patient, death in a hospital takes place in two scenarios. (1) One is where the death of a patient may be expected. In this case, the relatives are aware of the long-standing condition of the patient and the chronic ailments he/she is suffering from. Somehow, this becomes a more justifiable cause of death in the eyes of the relatives. It is much commonly seen and much easier to be accepted by the family members. (2) The second is sudden death of the patient in the emergency room. This does not really give much time for the family members to anticipate such an outcome. Hence, it is too sudden and unexpected for them to deal with it lightly. These are scenarios where the relatives can get a little violent or frisky, if the situation is not being handled with much compassion and care. The attack of healthcare personnel involved is very likely to occur in such situations. The emergency consultant involved should be the one delivering the news with care, keeping in mind the state of mind of the family members.

EFFECT OF DEATH ON SURVIVORS

Situations may arise where the traumatic series of events may take a toll on the members of the family involved in the accident or attached very closely with the deceased. In such cases, immediate efforts must be put to make sure of their well-being physically and psychologically.

- Suicidal intentions must be taken seriously as the loss of a near and dear one can produce a sense of survivors' guilt. These can be more common in situations where the patient died of suicide. Turning down these conversations may not be therapeutic for the survivor and further add on to the process of grieving. Counseling regarding guilt and responsibility of the death of deceased must be started early.
- Spouses of patients, especially ones from many years of marriage, have an undying attachment with each other. They have a higher risk of dying after a short while.
- The most common symptoms presenting would be hallucinating the presence of deceased (auditory, visual), denial, prolonged hysteria, and/or anger. Such patients require psychiatric consultation.
- Asking for sedative medications for sleep or to reduce anxiety is also prevalent. Usually, they do not need to be treated with sedatives; rather they require verbal and behavioral therapy to help change their process of thought.
- Threats to other members of the family, such as criminal gang threats, are of a serious concern for the safety and security of the other family members. The police should be notified at the earliest.
- Usually, when one of the parents dies, the other parent is overburdened with the responsibility of taking care of the children. In such cases, the surviving parent does not get the time or opportunity to grieve for his/her spouse. This pattern must be observed by other family members, and time and space should be provided for the spouse to accept the loss of the deceased.
- In any of the above scenarios, where one might think of a need for help, possible methods would be: Psychiatric consultation, if required need for hospitalization, calling on relatives for care and support, or making sure that at least a helper is present at all times.

EFFECT ON EMERGENCY DEPARTMENT PHYSICIANS

Emergency physicians are on the go constantly at handling multiple patients with acute ongoing crises simultaneously.

Hence after declaring a death, physicians consider it mostly their own professional failure. With recent advances in medicine, death can be prevented in most scenarios; hence, physicians consider it as a defeat failure on their part at a patient's death. Physicians also may fail to answer some questions posed by the family members. The blame of death can also be put on the physician, which may add on to the fear of death or unresolved fears of death that may make the physician even more uncomfortable. Healthcare providers are often taught how to save lives during courses such as advanced trauma life support (ATLS), advanced cardiovascular life support (ACLS), and pediatric advanced life support (PALS). However, they are not prepared for the consequences in the event of the death of a patient and how to handle and deal with it. However, these matters can be resolved by adequate education of breaking the bad news to the family, which prevents in leaving a negative impact on them after the loss of the deceased.

COMMUNICATION STRATEGIES

Prior to Death

Update on Deterioration of a Patient's Condition

It is advisable to constantly update the family members at regular intervals about the condition of the patient. It should include information regarding the initial condition of the patient when the patient presented in the ED, medical intervention required, if resuscitation is underway, and prognosis of the patient. It is difficult task to constantly update the family about the patient condition. In the event of procedures, such as endotracheal intubation, defibrillation, and other invasive procedures, someone from the ED team can be sent to update the family. In very few cases, the patient's family is allowed to view the resuscitation efforts going on from a distance. This practice is not widely accepted and encouraged. It is quite debatable about the presence of family members at the time of resuscitation. Carefully explain to the family about the deterioration in condition and the possible causes of it and patiently listen to their questions and answer them. Try to develop a sense of trust between the family members and yourself. In order to enable an *efficient and considerable technique to communicate to the family*, a patterned mnemonic *ABCDE*, after Rabow and McPhee's, is established.

- *A—Advance preparation*:
  - Acquaint yourself with adequate clinical information about the patient. In the event of it, carry a few medical documents with basic clinical findings of the patient, i.e., laboratory results, medications administered. This will help in providing a clearer picture of the prognosis and treatment given, to the family.
  - Allocate a spate room where disruptions in conversation can be prevented. If possible, instruct staff not to interrupt, unless it is an emergency.
  - Prior preparation in mind about how to deliver the news to the family may help in maintaining a calm and composed conversation. It is always advisable that the attending consultant should deliver the news to the family. The ones with less experience may observe and learn from the experience.
  - Mentally prepare yourself about all possible outcomes from the family members.
- *B—Build a therapeutic environment/relationship*:
  - Prior to meeting all family members, ensure who wants to and who does not want to be a part of such conversations.
  - Before starting the conversation, introduce yourself to all present and ask for family members to introduce themselves too.
  - Be clear and discreet in delivering the news. You may also foreshadow it by saying, "I am sorry to say, but I have bad news."
  - Acknowledge cultural differences and personal considerations. Avoid touching the relatives if they prefer not to. Avoid using phrases of humor or irrelevant discussions not pertaining to the patient.
  - Try to develop a space for comfort during this conversation. This enables the relatives to ask any questions or doubts they have about the treatment provided. This helps in building a more trustful relationship between the doctor and the patient's family.
  - Avail for your time in the future as well. Family members may go through a tedious process of grief. Accept to be available to provide information in the near future if necessary.
- *C—Communicate well*:
  - Prior to informing the patient's condition, ask the relatives about what they know. Try to be a good listener to what they already know. This can help you anticipate the reaction from them after getting the news.
  - Care and compassion should be considered while talking to them. Avoid the use of medical terms that they may not be able to understand. Prefer words such as cancer and death.
  - Compose yourself in a calm state of mind. Allow them some space and silence to react to the news. Avoid showing your own expression of sadness or emotion at such stages.
  - Collect their queries and questions regarding their understanding of the cause of death. Help them in clearing their doubts if they have any. Repeat and clear out the statement for better understanding.
  - The initial shock of the news may not help in retaining the information provided by you. Establish a way of communication by sketches or diagrams that may help them in understanding the medical condition of the patient. If necessary, repeat information for them to retain it.
  - Conclude by delivering basic information about what was the initial condition of the patient and the treatment provided. Allot follow-up if required.
- *D—Deal with patient and family reactions*:
  - Response to any bad news (sudden/expected) must be expected. Initial cognitive coping mechanisms such as denial, anger, disbelief, and intellectualization are likely to occur. Be aware of the possibilities. Any intuition of possible suicidal ideation or intention should be noted and made known to other family members.
  - *Empathy*: Express your sadness at their loss. Do not overindulge in expressing emotions as this may entitle your weakness and emotional capability.
  - Avoid blaming other colleagues or staff for their shortcomings or knowledge.

- *E—Encourage and validate emotions*:
  - Extend an understanding of the family's reaction to the news. Ask for any emotional and spiritual needs, if required. Provide references, if required.
  - Establish a meeting with the patient and family members after the conversation. This helps family members to accept the loss and grief.

After Death: If Family is Not Present

- In many situations, such as road traffic accidents, the family may not be present with the patient. In the event of such a scenario, one must be careful about providing initial information to the relatives over the telephone.
- Introduce yourself, the name of the treating facility, and the patient's name. Confirm the name of the person and if he/she is a relative of the patient. Acquire information of what the relative/close friend already knows.
- Inform about the event leading to the ailing condition of the patient to the relative over the telephone. There is no clear-cut consensus on whether the news of death should be conveyed over the phone. However, it is advised to deliver the news of the death of a patient in person to the family. The relative should be asked to reach the hospital at the earliest and to drive safely during the commute. Confirm if the relative attending the call is an adult. If not, kindly request him/her to hand over the number of an adult who is in close relation to the patient.
- Confirm whether the relative has understood the information provided to him/her. Encourage any questions he/she might want to ask and answer them patiently. For medicolegal reasons, it is advisable to have such a conversation face to face.
- Ask the family member to meet you once he/she reaches the hospital. Encourage to bring any parent or spouse along with him/her. Provide directions and complete address of the hospital.

VIEWING OF THE BODY

- Prior to viewing, ensure that the appearance is presentable. Cover the patient with appropriate clothing and bedsheet.
- Blood should be cleaned and removed from all parts of the body. Jelly used for procedure such as electrocardiogram (ECG), defibrillator, and echocardiography must be wiped off.
- Life support, such as endotracheal tubes, central line, and cardiac monitors, must be disconnected and kept away from the patient. Make sure that secretions or blood spills are not present.
- Ensure that emotionally viable relatives do not view the patient as they may collapse on seeing the deceased patient.
- Heavily mutilated patients may have injuries at different body parts. Bandaging the injuries with clean dressing should be done.
- Explain to the family that the deceased may look different from their expectations.
- In the event of the death of a child, it is advisable to ensure that another family member is present along with the parents. Consolation of parents of young deaths is necessary. Always wrap the child in a clean blanket or bedsheet.
- Avoid using terms such as "it" or "body" for the deceased patient. Respect the dead and acknowledge the loss of the family.
- Reluctant and unwilling members of the family must not be forced to view the body. Only members of the family willing to see the deceased should be allowed in a private area away from other patients.
- Rather than disturbing the family, allow them to express their emotions by providing them space. Conclude by assuring them that every effort was put in saving the patient's life.

MEDICAL EXAMINATION: AUTOPSY

Once the news of death is delivered to the patient, there are many tasks to be completed. In case of medicolegal situations (such as traumatic brain injuries, mutilation, abuse, or suicide), it is mandatory to do autopsy of the patient. Family members need to be notified about the autopsy. In other cases, if the family insists on an autopsy, it should be carried out by informing the respective departments. A member of social services can assist the family with the paperwork and funeral home assistance. Articles and clothing on the patient's body should be handed over to the family members. Careful handover should be done in case of blood-soiled clothing, as this would be a hurtful experience for the family members.

ORGAN DONATION

Organs such as lungs, heart, liver, and pancreas should be recovered only if adequate tissue perfusion is present. Usually, it is done in patients declared brain dead in the intensive care unit. However, tissues and organs such as skin, bone, cornea, fascia, cartilage, veins, heart valves, and corneas can be harvested up to 24 hours, if the body was refrigerated 4 hours after death. Apart from patients with oncological ailments or infectious diseases, all patients up to the age of 80 years are suitable for organ donation. Organ procurements in the hospital have to be notified. Members from the organ procurement team must speak to the family members about organ donation, and necessary arrangements should be done.

ORGAN DONATION: DEATH OF A CHILD

- In recent studies, it is indicated that parents are more appreciative than overwhelmed when asked about organ donation of their deceased child, if approached at the right time and by skillful team members.
- In pediatric patients, the size of the organ poses a major concern for organ procurement teams. The donation can be taken as giving meaning to the death of the deceased. It should be considered as a life-giving measure for other pediatric patients suffering from acute, unanticipated, and tragic causes.
- Hence, timely notification to trained personnel should be ensured. It is advisable if the member of organ procurement directly speaks to the parents of the deceased child about organ donation after giving them adequate grieving time. Ideally, supportive staff such as a social worker, chaplain, and child life specialist should be present while talking to parents.

SUMMARY

Notifying death can be a daunting and difficult experience for emergency residents and physicians. However, with adequate training to reduce anxiety and education about the possible outcomes to be expected, negative impressions on the family can be avoided. Emergency doctors should follow an organized approach to breaking the news in a calm, composed, and professional manner. Careful consideration to the grieving process of the family members and assistance to survivors should be provided. Aftercare, including administrative help or paperwork, should be availed by family members. This helps in reducing the stress that the family undergoes after the death of a close one. Careful handling of pediatric death must be ensured. The key to an efficient physician is to provide a clear picture of the cause of death of the patient along with adequate care and compassion to the grieving family. This can reduce a large number of violent attacks witnessed in ED after the death of a patient.

23
CHAPTER

Brain Death

Bhawana Sharma, Devendra Richhariya

INTRODUCTION

Different countries produce comprehensive practical documents for the neurological determination of brain death; each describes the detailed systematic process and tests needed to confirm brain death. Individuals should obviously adhere to their own jurisdiction and legal protocol requirements. Despite much attention to the differences in codes of practice for determining brain death around the world, it is in fact the similarities that bind them. Neurological determination of brain death guidelines generally has fundamental clinical components—evidence of sufficient intracranial pathology to cause permanent coma, absence of reversible or confounding factors, absence of cortical or brainstem-mediated motor responses, absent brainstem reflexes, and loss of capacity to breath.

PATHOPHYSIOLOGY OF BRAIN DEATH

Regardless of the injury that causes alteration of the brain physiology, brain death occurs due to lack of blood flow to the brain. The common pathways involved in all are progressive intracranial hypertension, tissue damage, and edema (**Fig. 1**).

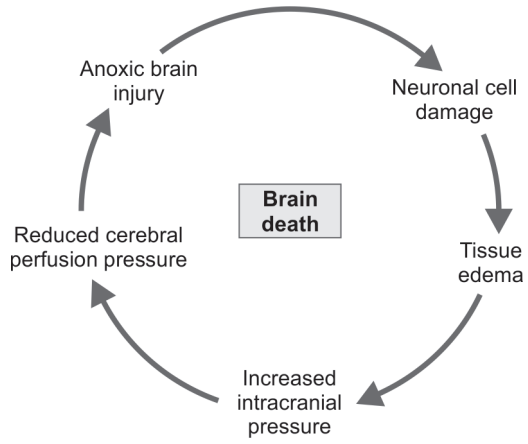

FIG. 1: Pathophysiology of brain death.

RECOMMENDATION

Australian and New Zealand Intensive Care Society (ANZICS) recommendations are as follows:

- *ANZICS recommendation 1*: Neurological determination of death is carried out by two doctors, who must each independently determine death according to the statement and meet the requirement of jurisdictional legislation.
- *ANZICS recommendation 2*: For neurological determination of death to take place, there must be the definite clinical neuroimaging evidence of acute brain pathology consistent with deterioration to permanent loss of all neurological function. In the cases of all hypoxic-ischemic brain injury, clinical history may alone provide sufficient evidence.
- *ANZICS recommendation 3*: There is a minimum 4-hour observation period prior to neurologic determination of brain death using clinical examination alone. Throughout this observation period, all preconditions are met, the patient has a Glasgow Coma Scale (GCS) of *3*, with pupils not reactive to light, absent cough/tracheal reflexes, and apparent apnea on the ventilator. Following an acute hypoxic-ischemic brain injury or hypothermia (<35°C) of duration greater than 6 hours, there should be a waiting period of 24 hours before determination of death using clinical examination.
- *ANZICS recommendation 4*: When imaging to demonstrate the absence of brain perfusion is required, it must be preceded by those parts of the clinical examination that are possible and responsiveness to all testable brainstem reflexes and breathing efforts must be absent.
- *ANZICS recommendation 5*: If the assessment of brain perfusion is required, three- or four-vessel angiography or radionuclide imaging is preferred. Computed tomography angiography (CTA) is acceptable if recommended radiological guidelines are followed. Magnetic resonance imaging (MRI) or angiography and transcranial Doppler (TCD) should not be used.
- *ANZICS recommendation 6*: Documentation of neurological determination of brain death should be made using a specific form to demonstrate explicitly that all criteria set out in this statement are met, whether or not donations occur. The same criteria should be listed in local hospital forms.

The international guideline development for the determination of brain death has been underway since 2012. *This group proposes a single operational unified determination of brain death based on cessation of brain function which occurs over two pathways, either permanent absence of circulation or subsequent to catastrophic brain injury. A harmonized international clinical practice guideline would reduce variation of practice between countries and improve public and professional confidence in the process. It seems unclear currently whether a worldwide consensus for either the definition or the criteria is achievable given complex challenges identified by the World Health Organization (WHO).*

DEFINITION

Brain death: A legal term (in most countries), defined as the irreversible cessation of the entire brain function that includes brainstem.

Medical and legal definitions: No standard definition exists internationally for the term "brain death." Medicolegal guidelines and definition of brain death are internationally inconsistent. Health care providers should know the local laws, institutional regulations, and guidelines before the declaration of brain death.

In 2014, a summary was published outlining the development of international guidelines for the diagnosis of brain death with the phrase "cessation of neurologic function" being used in lieu of brain death or brainstem death.

PREREQUISITES

Determination of brain death starts with documenting an irreversible and proximate cause for coma in a patient who is on invasive ventilator support with continued cardiac functions. A combination of the clinical history of the present illness, findings on clinical examination, radiologic imaging, and laboratory data is necessary to establish irreversibility and proximate causes. The patient's history and/or central nervous system (CNS) radiologic image findings should be suggestive of the mechanism of brain injury that may completely stop brain functions. The range of these clinical states may include circulatory arrest with no cerebral perfusion to a penetrating injury to the skull or a severe CNS infection with global cerebral edema with tentorial herniation. The patient's clinical examination with no sedative agents should be that of a comatose patient who is defined as having eyes closed and no appropriate interaction to external environmental stimuli. Hypothermia, CNS depressants, and neuromuscular blocking (NMB) agents may obfuscate the clinical examination and need to be systematically excluded. Furthermore, severe electrolyte or endocrine abnormalities may also impact a patient's mental status and need to be corrected before the diagnosis of coma.

After some prerequisites, *three essential steps* are mandatory for its determination (**Fig. 2**).

1. *Documentation of irreversible coma* due to a known proximate cause
2. *Documentation of absence of brainstem reflexes*
3. *Documentation of apnea—the apnea test*

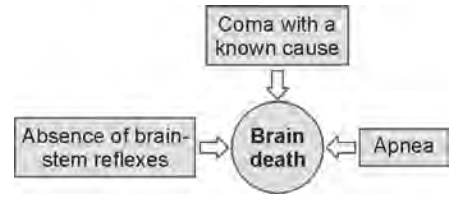

FIG. 2: Three essential steps in diagnosing brain death.

DOCUMENTATION OF COMA

Diagnosis of brain death by neurologic criteria based on current medical guidelines – Clinical, laboratory values, and radiological findings. The examination shows that the patient's eyes are not held open voluntarily and that no movements are made to verbal or noxious stimuli. A standard point of noxious stimulation includes nail bed, supraorbital, or temporomandibular pressure.

Confounders of brain death:

- Severe hypothermia, core temperature ≤32°C
- Severe hypotension—systolic blood pressure (SBP) <100 mm Hg
- Drugs—alcohol, poisons, recent sedation, NMB agents
- Severe dyselectrolytemia
- Hypoglycemia
- Acid–base abnormalities

Documentation of coma:

- Absence of motor response to a standardized painful stimulus
- Beware of local spinal reflexes causing spontaneous or stimulus-related motor movements

DOCUMENTATION OF ABSENCE OF BRAINSTEM REFLEXES

- Brainstem reflexes are lost in a rostral to caudal direction.
- Reflexes in the medulla oblongata are the last to cease.

Documented Tests

- Absent pupillary reflexes (nerves—optic and oculomotor)
- Absent oculocephalic movement—doll's eye reflex (nerves—vestibular part of vestibulocochlear, oculomotor, and abducens)
- Absent oculovestibular reflex—cold calorie test (nerves—vestibular part of vestibulocochlear, trochlear, and abducens)
- Absent corneal reflex (nerves—trigeminal and facial)
- Absent cough reflex (nerves—glossopharyngeal and vagus)

Pupillary Response (Cranial Nerve II)

Pupillary responsiveness should be assessed using bright flashlight. An ophthalmoscope should be used for magnification to look for the subtle pupillary response. The pupils are usually round or oval in mid position. Dilated pupils may suggest intact spinal sympathetic pathways or the release of stored norepinephrine from presynaptic terminals in the orbit. Infrared pupillometry may detect small pupillary responsiveness that may not be visible by the examiner.

Assessment of Eye Movements (Cranial Nerves III, VI, VIII)

Cervico-ocular Reflexes ("Doll's Eye Maneuver")

This maneuver can be performed only after the cervical spinal injury has been excluded. With the patient's eyelids held open, the head is rapidly turned 90° from the mid-line to the right and the left. If the patient is intubated, the endotracheal tube should be moved with the patient to avoid laryngeal damage or accidental extubation. The term "doll's eyes" refers to the expected conjugate horizontal movement of the eyes in the direction opposite to the head movement. This reflexive movement will only occur if the frontal cortex is not providing any input, such as in a comatose patient with intact brainstem reflexes. The absence of eye movements in a comatose patient during head movement is consistent with either upper brainstem dysfunction or a diagnosis of brain death.

Vestibulo-ocular Reflexes ("Cold Caloric")

Once the cervico-ocular reflexes are determined to be absent, or in circumstances in which these reflexes cannot be tested due to cervical spine instability, vestibulo-ocular reflexes should be assessed using cold caloric. First, the external auditory canal should be examined to ensure the absence of any obstruction. Given the clinical implications of diagnosing brain death, the presence of tympanic membrane perforation should not inhibit cold caloric testing. The patient's head end of the bed should be raised to 30°. Ice cold water of about 60 mL should be placed in a syringe and instilled into the ear while the patient's eyelids are held open. The amount of water is less important than its temperature; the goal is to decrease the temperature of the internal auditory canal. In a comatose patient with intact brainstem reflexes, the eyes should deviate toward the side of the cold-water stimulus. The absence of eye movement is present in a patient who is brain dead. The eyes should be examined for 1 minute after the ice water irrigation. After 5 minutes, the procedure should be repeated in the opposite ear.

Facial Sensation (Cranial Nerve V) and Facial Motor Response (Cranial Nerve VII)

Reflexes involving the cranial nerves V and VII need to be absent before the diagnosis of brain death can be made. The corneal reflex can be assessed by placing a gentle stimulus across the cornea of each eye individually to assess for a blink response. This can be accomplished with a wisp of cotton; however, some prefer a drop of saline to prevent the development of corneal abrasions, which may prevent tissue donation. A jaw jerk can also be assessed by the examiner striking his/her finger (cranial nerve VII) placed on the chin to assess for jaw closure (cranial nerve V). The absence of a grimace response to the noxious stimulus of the supraorbital ridge or temporomandibular joint should also be tested.

Gag or Cough Reflexes (Cranial Nerves IX and X)

The gag response may be difficult to establish in an intubated patient. Besides, the absence of a normal gag reflex in a significant proportion of healthy subjects renders this test less than useful in a comatose patient. So cough in response to deep endotracheal suctioning should be evaluated. By the neurologic criteria, the cough reflex should be absent to determine brain death.

DOCUMENTATION OF APNEA

Once the above-mentioned criteria are met, the physician should proceed to apnea testing to fulfill the diagnosis of brain death. An arterial catheter should be placed if one is already not in place due to the potential need of frequent arterial blood gas (ABG) analysis and hypotension during the apnea challenge. The patient's SBP must be ≥100 mm Hg with appropriate intravascular volume repletion and vasoactive drugs if required.

Apnea test: This should be done only after documentation of coma and documentation of the absence of brainstem reflexes.
Steps of apnea test:

- Preoxygenate with 100% oxygen for at least 10 minutes to obtain a PaO_2 of >200 mm Hg. Longer periods of preoxygenation may be required.
  Although the actual trigger for breathing during the apnea test is a decrease in the arterial pH, the test has traditionally been based on the rise in $PaCO_2$.
- Get an arterial blood gas.
- Disconnect the patient from the ventilator to prevent the false interpretation of artifactual breathing on the ventilator.
- Continue to oxygenate through an oxygen insufflation catheter which should be inserted in the endotracheal tube placed at the level of carina with the delivery of 100% oxygen @ 6 L/min to provide apneic oxygenation.

Those patients who have poor baseline oxygenation can be placed on 10 cm of H_2O continuous positive airway pressure (CPAP) or on an appropriate level to optimize their baseline oxygenation.

The patient is closely inspected for chest wall expansion, clavicle elevation, and abdominal excursions.

- To keep oxygen saturation > 95% (if SpO_2 <95%, abandon the apnea test)
- $PaCO_2$ is allowed to rise. If we assume a normal baseline $PaCO_2$ (35–40 mm Hg), the maximum respiratory drive is believed to occur at a $PaCO_2$ of 60 mm Hg.
- Repeat the ABG after 8–10 minutes.
- If an ABG shows a rise in $PaCO_2$ of 60 mm Hg or greater with continued apnea, the diagnosis of brain death is met.
- Alternatively, a rise in $PaCO_2$ by 20 mm Hg from its baseline level also meets the criterion. The rise in $PaCO_2$ and lack of respiration are documented.
- With an expected $PaCO_2$ increase of 3–6 mm Hg/min, a target $PaCO_2$ of 60 mm Hg should be observed within 8 minutes after discontinuation from the ventilator. Occasionally, it may take longer to establish this cutoff value. The rate of CO_2 production may be affected by the patient's core body temperature and hemodynamic status. Since pH is the main determinant of respiratory drive, an equivalent change in pH may be more specific than a change in $PaCO_2$.

The pH should primarily be considered in patients with an abnormal baseline $PaCO_2$ such as those with an underlying pulmonary disease. In the event, the apnea challenge cannot be finished due to cardiac arrhythmia, worsening hypotension,

or arterial desaturation and ancillary tests must be performed. Perform additional tests, which are optional in adults, recommended for age < 1 year. Some countries mandate this test by law to confirm brain death.

ADDITIONAL TESTS

Ancillary tests are necessary to declare brain death if the apnea challenge is difficult to perform or if there is a doubt regarding the reliability of parts of the neurological tests. The validity of these tests is yet to be determined. In many countries, these ancillary tests are required by law or left to the discretion of the physician. CT angiogram, electroencephalogram, Transcranial Dopplar and radionuclide imaging are some additional tests.

Conventional Cerebral Angiography

It remains the "gold standard" to know the intracranial blood flow. However, the specific radiographic features to define brain death are lacking. The absence of intracranial blood flow on angiogram at the level of entry of vertebral artery and carotid artery to the skull has been suggested to be consistent with brain death. The presence of contrast in the external carotid artery tree should be present to confirm appropriate contrast injection. In upward of 30% of brain-dead persons, there was a proximal opacification of the intracranial arteries observed with none having deep venous drainage.

Computed Tomography Angiography

This remains an issue of debate whether a computed tomography (CT) angiogram can be utilized as an ancillary test to declare brain death. The sensitivity for brain death seems to be the highest (99%) with the absence of opacification of the internal cerebral vein.

Transcranial Doppler Ultrasonography

This can be a useful tool for bedside assessment of cerebral blood flow (CBF), especially in an unstable patient in whom conventional angiography or CTA is not possible at that time. A specific pattern of oscillating flows or systolic spikes can be seen on TCD by experienced persons. Occasionally, absence of flow can also be seen. But a physician should be aware of the fact that in upward of 10% of patients, a thicker temporal bone window may not allow adequate insonation. TCD can be helpful in deciding the optimal time to send an unstable patient for ancillary brain death testing.

Radionuclide Imaging

Both planar scintigraphy and single-photon emission computed tomography (SPECT) are used in ancillary testing to diagnose brain death. Either of these radioisotopes, Tc-99m hexamethylpropyleneamine oxime (HMPAO) or Tc-99m ethylene cysteine diethyl ester (ECD), can be used. Intracranial blood flow cessation or brain death is diagnosed when there is an absence of radioisotope uptake into the brain parenchyma. Similar to other ancillary tests, "false-negative" cases for brain death have been reported in the literature.

Electroencephalogram

The "electrocerebral silence" on EEG may be consistent with brain death as per neurologic criteria. But EEG will be affected by some confounding factors, such as physical examination hypothermia, and effects of sedatives. Artifacts on an EEG can be produced by other electrical activities present on a critically ill patient. Limiting factors may include the availability of technical expertise. Many contemporary series of patients have shown a minimal difference between a clinical diagnosis of brain death and EEG findings.

OTHER TESTS

There is limited experience with MRI of brain so it cannot be recommended at this time. Somatosensory evoked potential (SSEP) can be absent due to severe drug intoxication or hypothermia. Therefore, SSEP should not be used for this purpose. Follow institutional protocols for certifying brain death. Most places mandate two sets of brain death tests. The second test is typically done in a minimum of 6 hours after the first test in adults to declare brain death. In neonates and pediatric group, this interval is 12–48 hours. There is no consensus about how long a patient needs to be observed before being certain that the brain functions have ceased irreversibly.

BRAIN DEATH MIMIC

Brain death mimic is important to differentiate various conditions (vegetative state, locked-in syndrome, coma from brain death) (**Table 1**). Brain death mimics can be roughly divided into two groups:

1. *Wrong-diagnosis mimics*: These are the most concerning. These are patients with an *unrecognized alternative diagnosis* which causes the patient to appear brain dead:
   a. Unrecognized intoxication (e.g., tricyclics, lidocaine, baclofen, barbiturates, paralytics, anticholinergics, organophosphates)
   b. Locked-in syndrome
   c. High C-spine injury
   d. Hypothermia
   e. Fulminant Guillain–Barré syndrome

   These patients have conditions which are often treatable and consistent with long-term survival. Accurate diagnosis is essential. One important clue to wrong-diagnosis mimics is that they are generally associated with *normal* neuroimaging.
2. *Wrong-severity mimics*: They do indeed have catastrophic, irreversible brain damage. Wrong-severity mimics have no likelihood of a meaningful recovery. However, they are not brain dead due to the persistence of some brainstem functions. An example would be a patient who has profound anoxic brain injury with marked cerebral edema. The patient has an isoelectric EEG for several days with no confounding factors (e.g., no sedation or hypothermia). The patient has no cranial nerve reflexes or responsiveness to pain. However, the patient does continue to generate a respiratory rate on apnea examination. This patient has no likelihood of awakening from coma. However, the patient

TABLE 1: Differentiating various conditions from brain death.

State	*Vegetative state*	*Locked-in syndrome*	*Coma*	*Brain death*
Awareness	Absent	Present	Absent	Absent
Sleep-wake cycle	Present	Present	Absent	Absent
Response to stimulus	±	Present (eyes only)	±	Absent
GCS	E4 M1-4 V1-2	E4 M1 V1	E1-2 M1-4 V1-2	E1 M1 V1
Motor functions	No purposeful movement	Volitional vertical eye movement or eye blink	No purposeful movement	None (reflex spinal movement)
Respiratory functions	Typically preserved	Typically preserved	Variable	Absent
EEG	Slow-wave activity	Typically, normal	Moderate to severely reduced	Severely reduced
Cerebral metabolism	Severely reduced	Mildly reduced	Moderate to severely reduced	Severely reduced
Prognosis	Variable	Depends on a cause/full recovery unlikely	Recovery/vegetative state/ death	Already dead

(EEG: electroencephalogram; GCS: Glasgow Coma Scale)

is *not* brain dead due to the absence of apnea. The injury is not quite *severe* enough to qualify for brain death.

MOVEMENT OBSERVABLE AFTER BRAIN DEATH

Brain death liberates the spinal cord from any supervision or suppression from the brain, causing spinal motor reflexes to run amok. This produces a variety of bizarre movements, often in response to stimulation. For example:

- *Triple flexion*: It is probably the most common movement observed. Stimulation of the feet causes flexion at the ankles, knees, and hips. This may appear to be a volitional withdrawal response to painful stimulation of the feet.
- *Myokymia:* It is localized quivering of a muscle (may involve facial or ocular muscles).
- *Lazarus sign:* It is flexion at the waist

These movements are alarming to family members and medical personnel who are not experienced with brain death. It is common for a brain death diagnosis to be inappropriately delayed or missed due to such movements.

BRAIN DEATH DECLARATION AND ORGAN DONATION

Who should Declare Brain Death?

Brain death should be declared by the medical superintendent of the hospital or an independent medical practitioner nominated by the medical superintendent, neurologist or the neurosurgeon nominated by the medical superintendent, or the treating doctor on duty. It should be assessed by two physicians and one of them must be consultant. No one should be from the transplant unit. Inform the family as soon as the patient is nearing brain death. Maintain the patient in a hemodynamically stable state. Approach for organ donation as per the regulation of the state law. If there is no transplant coordinator or grief counselor in the hospital, the neurosurgeon should also discuss with the family the option of the patient being an organ donor.

Brainstem Death and Indian Law

India enacted a law in 1994 to legalize the recognition of brainstem death. Maharashtra has recently mandated the notification of brain-dead cases. The Government Resolution underlines the responsibilities of hospitals registered under the Transplantation of Human Organs (THO) Act 1994, that is, they are authorized transplant centers. As a large number of brain deaths occur in hospitals not authorized to do transplants, the appropriate authority (Director of Health Services) has registered all hospitals in the state that have an operation theater and intensive care unit (ICU) as nontransplant organ retrieval centers (NTORCs). These hospitals are permitted to certify brain death as per the prescribed procedure and then conduct organ retrieval for therapeutic purposes; however, they are not permitted to perform an actual transplantation. Thus, it is now mandatory for all NTORCs and authorized transplant centers in the state to certify and notify the brain-death cases to the Zonal Transplantation Coordination committee. This is a strong step to streamline the procedure for cadaveric organ retrieval and transplantation. Medically and legally, the patient is dead, if brainstem death (brain death is used as a synonym for the latter) has been certified. The doctors involved in the diagnosis should in no way be connected with the transplant surgeries concerning the "brainstem dead" cadavers. The certification should be done on the laid-out forms (Form No. 8) as per the THO Act. The declaration of brain death must be recorded in the medical notes with the date and time. The legal time of death is the time at which the second prescribed clinical tests are carried out. Comprehensive reviews of brainstem death and brain death from an Indian perspective have also been documented.

CARE OF THE POTENTIAL ORGAN DONOR

"Care of the donor" is associated with "the care of multiple recipients." A brain-dead patient with a potential organ donor requires the similar intensity of care in order to preserve organ perfusion and improved quality of grafts. Improved quality of care and titration of inotropes and fluids with the use of invasive lines is mandatory in intensive care.

Potential donor: A potential donor is one who becomes brain dead due to a catastrophic brain injury, and the physician and the family expressed an intention to withdraw life support. The organ procurement organization initiates counseling the family by using "presumptive strategy" wherein grief counselors established communication with the family and explain that organ donation is the natural thing in the interests of the potential donor as well as the pool of recipients.

Pathophysiological Changes after Brain Death and its Importance in Organ Preservation

Fluctuating donor hemodynamics complicates the declaration time of brain death from the time of diagnosis. When the time to organ retrieval from the diagnosis of brain death is longer, the chances of hemodynamical instability are greater. Optimum donor care should be ensured in the ICU, in view of hormonal and inflammatory changes accompanying brain death to avoid graft dysfunction and chances of rejection. However, in the last two decades, outcomes have improved following transplant surgery due to increased awareness of donor management.

Cardiovascular System

In all patients with brain death, reflex hypertension and bradycardia (Cushing's reflex) occur due to medullary ischemia as a reflex attempt by the body to maintain the CBF. Following this, a period of intense vasoconstriction and tachycardia with increased circulatory catecholamines occurs, which can increase visceral and myocardial ischemia.

The effects of the catecholamine surge on the myocardium can be documented by the fact that 20–25% of brain-dead donors showed evidence of myocardial ischemia and 40% have echocardiographic evidence of myocardial dysfunction. Catecholamine surge contributes to the challenges in the maintenance of organ perfusion (reflex hypertension, bradycardia, myocardial dysfunction) in brain death. In order to maintain the organ perfusion management, include maintenance of BP with minimal use of inotropes, optimizing the fluid management.

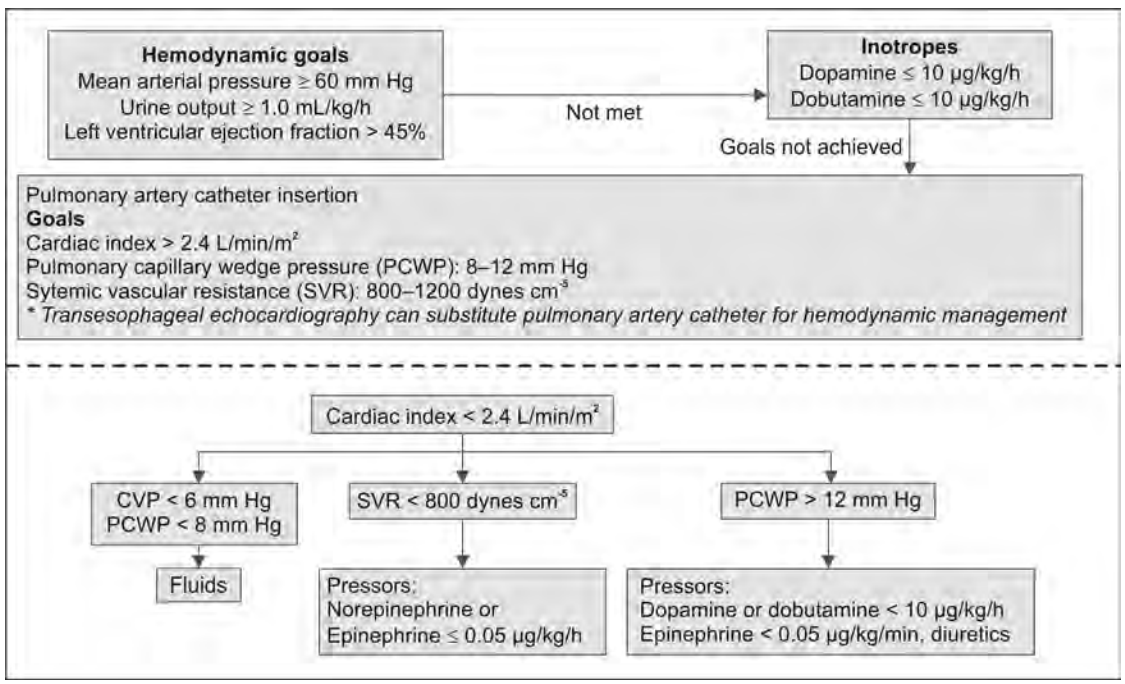
All potential donors should undergo an echocardiogram and pulmonary artery catheterization (PAC). It is indicated for donors with an ejection fraction (EF) <45%, more in the background of cardiac and lung transplants. The hemodynamic parameter should be maintained as shown in **Figure 3**.

Respiratory System

An endogenous epinephrine rise causes a rise in pulmonary hydrostatic pressure damage to the pulmonary endothelium resulting in pulmonary edema. The ventilatory management should include minimal FiO_2 needed to maintain a PaO_2 > 100 mm Hg, SpO_2 > 95%, $PaCO_2$ of 35–40 mm Hg, and pH 7.35–45. Earlier recommendations were to use liberal tidal volumes 8–15 mL/kg, but current ventilation strategies recommend similar ventilatory strategies used for acute lung injury (ALI). The use of PAC in intensive care for a brain-dead potential donor may restrict excessive fluid use and pulmonary edema.

Endocrine System, Stress, and Metabolic Responses

With brain death, the endocrine responses of the body are lost and the rationale for hormone replacement therapy for brain-dead patients. After brain death, the posterior pituitary function is lost early in comparison to posterior pituitary function with the occurrence of diabetes insipidus associated with polyuria and hypernatremia. As a replacement, arginine vasopressin and desmopressin can be given. Thyroid hormone level decreases and condition become similar to critical illness "sick euthyroid" state.



Hemodynamic goals
Mean arterial pressure ≥ 60 mm Hg
Urine output ≥ 1.0 mL/kg/h
Left ventricular ejection fraction > 45%
Not met
Inotropes
Dopamine ≤ 10 µg/kg/h
Dobutamine ≤ 10 µg/kg/h
Goals not achieved
Pulmonary artery catheter insertion
Goals
Cardiac index > 2.4 L/min/m²
Pulmonary capillary wedge pressure (PCWP): 8–12 mm Hg
Sytemic vascular resistance (SVR): 800–1200 dynes cm⁻⁵
* Transesophageal echocardiography can substitute pulmonary artery catheter for hemodynamic management
Cardiac index < 2.4 L/min/m²
CVP < 6 mm Hg
PCWP < 8 mm Hg
SVR < 800 dynes cm⁻⁵
PCWP > 12 mm Hg
Fluids
Pressors:
Norepinephrine or
Epinephrine ≤ 0.05 µg/kg/h
Pressors:
Dopamine or dobutamine < 10 µg/kg/h
Epinephrine < 0.05 µg/kg/min, diuretics

FIG. 3: Recommended hemodynamic parameters in a potential donor.

Other endocrine changes are a decrease in insulin levels, hyperglycemia worsening with stress, and alteration in carbohydrate metabolism. Insulin levels normalize subsequently with an increase in C peptide levels. A strict euglycemic state should be maintained as hyperglycemia-induced pancreatic cell damage may affect the pancreatic graft. Hyperglycemia can adversely affect the outcomes of renal transplantation.

Temperature regulation is also affected in a brain-dead individual displaying a pattern of initial hyperthermia followed by hypothermia. Lack of shivering, peripheral vasodilatation, and a decrease in the metabolic rate complicate the hypothermia. Hypothermia can worsen acidosis and coagulopathy and increase the risk for arrhythmias and cold-induced diuresis besides causing a leftward shift in the oxygen dissociation curve.

Systemic Inflammatory Response

A systemic inflammatory response mediated by inflammatory mediators from an ischemic brain, ischemic reperfusion injury, metabolic changes that occur during the catecholamine storm, and an inadequately restored cardiovascular state is quite severe after brain death. Increased plasma levels of interleukin-6 in the donor correlate with the poorer graft utilization and graft dysfunctions. After brain death, due to the release of tissue thromboplastin from the necrotic brain, tissue-disseminated intravascular coagulation occurs.

Protocols for Donor Management

The general principle of the "Rule of 100" is applied to maintain the circulatory and biochemical variables suggesting targets of SBP ≥ 100 mm Hg, urine output ≥ 100 mL/h, hemoglobin ≥ 100 g/L, PaO_2 ≥ 100 mm Hg, and blood sugar targeted at 100% normal. Other elements of donor management are listed below:

- *Temperature*: Prior to organ donation, the aim is to keep the core temperature > 35°C. Circulating hot air blankets, warmed intravenous fluids, and adjustments of ambient temperature may be used to achieve this goal.
- *Fluid management:* These patients often have polyuria and are severely dehydrated due to vasoplegic state which ultimately leads to central volume depletion. Traditionally among fluid therapy, crystalloids are the first choice and balanced salt solutions (Ringer's lactate, Plasmalyte-A, Ringer's acetate, half-normal saline with sodium bicarbonate) which do not produce hyperchloremic acidosis may be superior to normal saline. Hypernatremia should be corrected to avoid graft losses after liver transplant. Hydroxyethyl starches can damage renal epithelial cells and cause early graft dysfunction in the transplanted kidneys and are contraindicated in organ donors. There is little evidence to date supporting the use of gelatins in donors.
    - In the context of lung transplant, a fluid restrictive strategy with monitoring of filling pressures may be beneficial. Studies have documented the impact of fluid loading on outcomes in lung transplantation. This does not affect the quality of the renal graft for transplantation. Hemoglobin of 10 g/L could improve tissue oxygenation indices. Guidelines of critical care should be followed during the replacement of blood and blood products.
- *Inotropes and cardiovascular system*: Dopamine has beneficial effects on the renal graft and is the first choice of inotrope in hypotension unresponsive to volume. Although dopamine may predispose to arrhythmias and has no renal protective effect, the beneficial effect of dopamine is probably related to preservation injury and inflammation, donor cardiovascular effects, or recipient treatment. In transplanted hearts, noradrenaline doses >0.05 μg/kg/min adversely affect cardiac contractility and decrease the right ventricular performance.
- *Ventilatory management:* The principles are along the lines of management of ALI (low tidal volume 6–8 mL/kg, minimum plateau pressure, lung recruitment). The use of the lowest possible FiO_2 and optimal PEEP with a restrictive fluid strategy improves graft harvesting for lung transplants.
- *Replacement of hormones after brain death*: Standardization of hormone therapy after brain death in combination with a central venous pressure < 10 mm Hg significantly improved utilization of the heart and lungs for transplant without affecting other organ systems. The recommended replacements are:
    - Vasopressin 1 U bolus followed by an infusion of 0.5–4.0 U/h (desmopressin intranasally has a selective action on the V_2 receptors and a half-life varying from 6 to 20 hours)
    - Methylprednisolone 15 mg/kg immediately after diagnosis of brain death and 24th hourly thereafter
    - Insulin 10 U in 50% dextrose followed by an infusion to maintain blood glucose between 80 and 150 mg
    - Thyroxine (T4) 20-μg bolus followed by infusions of 10 μg/h. Tri-iodothyronine (T3) given as a 4-μg bolus followed by an infusion of 3 μg/h. T4 improves hemodynamics and prevents cardiovascular collapse in hemodynamically unstable organ donors.

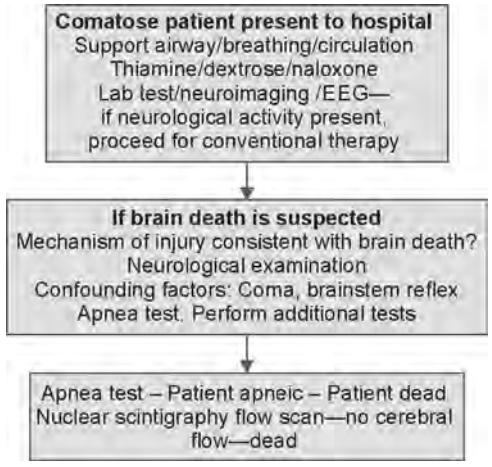
An analysis of 10 years of data of several hormone replacement modalities in the United Network for Organ Sharing (UNOS) data showed that the combination of thyroid hormone, corticosteroid, insulin, and antidiuretic hormone was the best for multiple organ procurement.

Other Concerns and Considerations

Donors with bacteremia or fungemia are not absolute contraindications to donations except overwhelming sepsis. However, infections with human immunodeficiency virus (HIV), herpetic meningoencephalitis, and T-cell leukemia-lymphoma virus should not go for organ donation. Transmission of HIV and rabies from infected donors has been documented.

SUMMARY

The ICUs are available to the wider population and more cities in India; a large number of seriously ill patients are now being



Comatose patient present to hospital
Support airway/breathing/circulation
Thiamine/dextrose/naloxone
Lab test/neuroimaging /EEG—
if neurological activity present,
proceed for conventional therapy
If brain death is suspected
Mechanism of injury consistent with brain death?
Neurological examination
Confounding factors: Coma, brainstem reflex
Apnea test. Perform additional tests
Apnea test – Patient apneic – Patient dead
Nuclear scintigraphy flow scan—no cerebral
flow—dead

(EEG: electroencephalogram)

FLOWCHART 1: Approach to suspected brain death.

revived. While many recover, a significant number end up being brain dead (approach to suspected brain-dead patient is shown in **Flowchart 1**). Brain death has created a new class of dead people who do not conform to the society's expectations of normal death and dying. Brain death also causes great stress for the family and friends. It is important to provide ample time to the family which helps them to adjust with the sudden tragedy and hopelessness of the situation. This helps them develop trust in their physician and in the diagnosis. An effective communication with the family members, as well as caring and providing support for them, is crucial before the request for organ donation is made. The only rational reason for continuing treatment after confirming brain death is for organ donation. Once the permission from family members is obtained, the transplant team takes over further care. The law in India is still not clear if the support system can be withdrawn once the family refuses organ donation.

24 CHAPTER

Organ Donation and Transplantation

Devendra Richhariya, Bhawana Sharma

INTRODUCTION

Over the years, the pattern of diseases has changed and so the treatment options are. With improved healthcare facilities, the survival of citizens of India has also improved. Healthcare facilities in India are mostly focused on particular problems such as diabetes, hypertension, obesity, and ischemic heart diseases, but the burden of chronic organ failure and end-stage diseases (end-stage renal disease and end-stage liver disease) is also rising at a significant pace. Treatment options of chronic end-stage diseases are limited, expensive, as well as resource-consuming; therefore, national apathy also coexists toward these diseases. The cure of the chronic end-stage disease is *"organ transplantation"* but majority of the patients cannot afford it. The benefits of transplantation are still far away from the reach of the large population of the country. Most of the patients with end-stage renal disease are on long-term dialysis and have poor quality of life. Dialysis facilities are expensive, limited, and not freely available in most centers; >90% of patients die within a month of the diagnosis. It has been estimated that a very small percentage of patients in India actually end up getting a transplant for end-stage organ failure. Similarly, in our country, with the enormous rise in end-stage liver disease and the absence of other definitive therapies, a pool of patients for liver transplants is also rising. Liver transplant is a highly skilled procedure and only few centers in India perform this.

The organ transplantation topic is always in the focus of the discussion in terms of ethical practice, especially in India where poor people are attracted to sell their organs for financial gains. In a country such as India where the prevalence of chronic end-stage disease is high and the cost of managing chronic illnesses such as end-stage renal disease is unaffordable by poor, e.g., limited facilities of free of cost hemodialysis or peritoneal dialysis, organ transplantation is the best mode to improve the quality of life. Patients who need organ transplantation are more than the available organs so transparency in the process of distribution is the key to the credibility and success of the organ transplant program along with social, cultural, religious, and political support.

HISTORY OF ORGAN TRANSPLANT: WORLDWIDE AND IN INDIA

In 1954, Dr Joseph Murray performed the first successful kidney transplant at Peter Bent Brigham Hospital in Boston. For the first time in 1962, immune-suppression drugs and tissue typing were also used for a human kidney transplant. In India, the first-ever renal transplant was done in 1965 at King Edward Memorial Hospital, Mumbai, from a deceased donor in a hypernephroma patient, while the first live donor renal transplant in India was done in 1971 at CMC Vellore. In India, the first kidney transplant was performed in the 1970s and these activities were picked up in the 80s and 90s as more centers were established and more trained staff started to be available.

In 1960, as an experiment, a liver transplant was performed from a deceased donor. The first successful liver transplants were done in the USA and the UK, respectively, in 1967 and 1968 from deceased donors, while in Australia (1989), the first successful liver transplantation was done from a live donor followed by in Japan (1994) and later by the USA (1999). In India, the first live donor liver transplant was done in 1998 from father to child.

In 1965, the term *"brain death"* was introduced and in 1968 it was defined as a complete cessation of mid-brain and cortical brain function.

Organ transplant in India is relatively new as compared to developed countries, although cornea (eye donation) from a dead patient is popular in the Indian society for the last few decades. Every healthy human being has two healthy kidneys and one kidney is sufficient for survival, so living donor kidney transplant is being performed frequently in India. Liver transplantation is also being performed from the living donors in which a part of the liver (250–650 g) is removed and transplanted in the patient suffering from end-stage liver disease (advanced cirrhosis and acute fulminant hepatic failure) and in the next 8 weeks' duration, the liver grows to normal size in both the donor and the recipient.

As live donors are not available to every patient and risk to life is also involved in donors along with various ethical issues, organ transplantation from cadaveric, deceased donors

is more relevant in India. In many states of India, it is claimed that deceased organ transplantation led to reduction in commercial transplantation. Retrieval of organs such as liver, kidney, and heart can also be done from the brain-dead patient (patient is certified brain death -heart beating and no question of survival of patients).

In 1994, the Transplantation of Human Organ Act (THOA) was passed in the Indian Parliament, which allowed the removal of organs such as liver, kidneys, and heart from a brain-dead patient for transplantation. One of the main aims of the act was to stop the illegal trade of organs for financial gain.

EVOLUTION OF LAW: TRANSPLANTATION OF HUMAN ORGAN ACT

As discussed earlier, the first kidney transplant in India was done in the early 70s and the activities picked up in the 80s. It is important to note that initially there was no law regarding human organ transplantation. Overseas patients rushed to India for transplantation from paid donors. Small hospitals along with some big private hospitals started performing the transplantation in substandard conditions resulting in poor outcomes. A significant section of nephrologists and transplant surgeons were also involved in unlawful activities.

The media reported these scams and medical bodies such as medical councils and other regulatory bodies had no answer. A section of the population started justifying "paid organ donation" by giving ideological rationale of free-market philosophy, while others advocated for regulations. However, at the ground level, it was realized that the donors should be protected from the middlemen in this "paid organ donation market"; on the other hand, studies also suggested the poor quality of life in unrelated donor transplantation. Success was also claimed by countries with the state-sponsored regulated model.

As a response to various controversies, the government of India in 1991 constituted a committee to prepare a report for all India legislation on organ transplant. The committee focused on brain death and suggested that human organ trading be made a punishable offense. In 1994, the government of India came up with THOA and enacted it in 1995. According to THOA, commercial trading in organs is banned. An unrelated donor is only permitted with permission of the authorization committee on the ground of altruism. Brain death is also legalized in India by THOA, so organs can be procured from brain-stem dead donors and deceased organ transplantation can be encouraged. The criteria for determining brain death have also been issued. According to the rules, brain death can be declared only in the state-recognized institution by four individuals unrelated to transplant and tests are to be done twice within a gap of 6 hours. THOA rules were also amended in the years 2008, 2011, and 2014.

CHALLENGES

Interpretation of the Transplantation of Human Organ Act

In THOA, brain death is defined for a specific situation and that is in the context of organ donation. The Act authorized only those institutions to declare brain death who are doing organ transplant. Later in 2011 Act amendment and rules in 2014, few other institutions who do not perform organ transplant have also been recognized to declare brain death. These are known as "nontransplant organ retrieval centers"; organs can be retrieved in these centers and then transported to transplant-recognized centers. A peculiar situation arises at the ground level if brain death is diagnosed and the family has not given consent for organ donation but instead asked for the handover of the body after removal of the ventilator; such a request is turned down as there are no instruction and guidelines in the Act. Because of problematic interpretation of the law, most of the time, relatives accused healthcare institutions and hospitals of keeping the dead body on ventilators and making money.

Ground Reality and Resource-constrained Scenario in India

The ground reality in India is different when it comes to deceased organ transplantation. Only major cities of India have modern state-of-the-art intensive care units, where "brain death" can be declared and the subsequent donation can be processed, and facilities to keep the brain-dead patient's organ working with mechanical ventilation and intensive monitoring. In a given scenario where ICUs are understaffed and nursing staffs are overburdened, another conflict of interest that arises is where to use resources, on a sick patient who needs life-saving care or on a brain-dead potential donor. A major change in attitude is also required as both conditions require the same attention. It has been observed that low priority is given to the process of declaring brain dead and taking consent from the families of potential organ donors.

Disparity in Organ Demand and Availability

The main issue of concern is the huge number of patients waiting for the transplant. Shortage of organs is a global issue and the only solution is deceased organ donation. The social worker of the hospital approaches the relatives of the patient who is declared brain dead and explains that three lives can be saved by donating two kidneys and one liver. Close relatives give written permission. Road accident fatalities in India comprise about 1.5% of the total fatalities and about 50% of death are due to head injuries. Even if 5–10% of these opt for organ donation, the problem of organ shortage can be solved.

Lack of Organizational Support, Educated Transplant Coordinators, and Effective Communication

Deceased organ transplant got a setback due to nonavailability of an adequate number of transplant centers, staffs, and educated transplant coordinators who have adequate knowledge of organ donation procedures and who could approach the family members of the brain-dead sympathetically and take consent. Many hospitals lack any protocol regarding the declaration of brain-death. They also do not have good dialysis backup, research, and health insurance plan. Even the medical fraternity has poor knowledge about organ donation.

Negative Coverage by the Media

Philosophy of altruism and mutual trust is the entire concept of the deceased organ transplant. Any negative propaganda breaks the trust and creates a hurdle for the whole process.

How to Encourage Deceased Organ Donation

The cost of maintenance is also an issue as most of the donors are in private sectors and how one can bill a family who has given consent for organ donation. Various incentives for the donor's family such as waiver of donor's hospitalization cost, providing preferences in a job, and children's education support should be included in the Act because the recipient and the hospital performing the transplant are the beneficiaries. Another thought is that any amount of compensation commodifies the Act and in an unequal Indian society, this will be a soft form of trading even in deceased donors. Political will is an important requirement for an accessible and affordable transplant to all end-stage organ failure patients. Frequent interaction between government and stakeholders and necessary legal and administrative help through regular orders are behind the success of a deceased organ transplant in the state of Tamil Nadu, especially in Chennai. Till date, Tamil Nadu, Andhra Pradesh, Maharashtra, Kerala, and Gujarat are the states where the highest number of deceased organ transplants is done.

Inequality in Recipient Pool and Transplant Pattern in India

In India, quality healthcare is largely owned by private sectors; the same is true for the organ transplant. Very small numbers of hospitals in public sectors are even doing the simple straightforward renal transplant. Similarly, <1% of public sector hospitals are doing liver transplant in India. Over the years, the deceased donor program poorly developed in India in comparison to the live donor liver transplantation because of no backup for end-stage liver diseases such as dialysis in end-stage renal disease. The high cost involved in transplantation along with very little funding by the government is another cause for poor progress in a deceased donor transplant.

As the deceased organ donation depends on the altruistic philosophy and, principally, organs do not belong to any hospital or city but belong to society, a transparent approach should be enforced by the state in distribution to a needful person. Instructions are clearly given in THOA about who can donate the organs but not about how the organ would be distributed to the needful person.

India is a vast country, and the deceased organ allocation policy differs in every state. It is not clear how an organ is allocated, severity-wise, waiting-period-wise, or institution-wise. A centralized approach for the allocation of the organ may also not work because of diversity in the country.

HOW TO CURB THE PROBLEMS

National Organ for Tissue Transplant Organization (NOTTO)

The National Organ for Tissue Transplant Organization was set up under the Director General of Health Services, Ministry of Health and Family Welfare, which evolved as a national network for organ sharing. The National Human Organ and Tissue Removal and Storage Network is a subdivision of this group which is expanding to other states as well for coordination and networking for retrieval and distribution of organs and tissues. This institution also maintains registry of organs.

Public–Private Partnership

A public–private partnership with the help of educated and effective transplant coordinators is significantly contributing to improving the organ procurement and transplant rate, such as in the southern states (Tamil Nadu, Andhra Pradesh, Kerala, Puducherry) where Multi-Organ Harvesting and Networking (MOHAN), a non-governmental organization, has been working since 1997. This organization also established the Indian Network of Organ Sharing (INOS) to promote organ sharing across the country.

Organ Transfer and Green Corridors

When donor and recipient are in different hospitals, or the transplant experts are not available where organs are harvested, organs are transported to other facilities. Road transfer is the conventional method in India for patient and organ transfer. Special road routes (Green Corridors) are created for the transfer of harvested organs where street signals are manually operated, stoppage at red lights are avoided, and traffic is diverted to ensure rapid transportation. If the distance is more commercial, airlines can be used for the transport of organs.

SUMMARY

India has a huge potential for deceased organ donation. If proper attention is given, it will fill the gap of organ demand within the country and provide an alternative to living transplant program. There is also a mismatch between potential donors and actual cadaveric donors. The actual decision is changed by the family members due to lack of awareness and miscommunication within family members or with hospital staff. That is why awareness needs to be generated among the general public toward deceased organ donation by nongovernmental organizations and religious leaders. Public awareness is the key to promote deceased organ donation.

The National Organ for Tissue Transplant Organization, a central organization, has to play a decisive role in coordinating the activities of deceased organ donation and make transplant accessible, ethical, and affordable in India. Effective communication between stakeholders is an important factor. Transplant coordinators and counselors should be involved in the early stage and at an appropriate time, a discussion about donation should be a part of the end-of-life care. Setting up more and more tissue banks with improved facilities for sterilization of preserved organs is the need of the hour.

Section 4: Prehospital and Disaster Management

25
CHAPTER

Ground Medical Transfer

GV Ramana Rao

WHAT IS GROUND MEDICAL TRANSFER?

Ground medical transfer refers to the transportation or movement of a sick/injured person, from one place to another under medical care. If the patient is moved from one place to another without any medical care, it is often referred to as "patient transport." It can be from home, workplace, or roadside to the hospital or from a lower level hospital to a higher level hospital. It can be elective or emergency transfer. Elective ground transport may or may not have a paramedic or medical oversight. A fine line of difference, hence, exists in the use of these terms; ground transport refers to physical movement while transfer refers to "movement with medical care." Ground medical transfer, emergency medical services (EMS), and prehospital care or out-of-hospital care are terms which have certain similarities and overlaps. Transport of critical patients has become a well-established practice of EMS worldwide and there is a growing need. Critically ill transfers demand the presence of doctors who can carry out detailed monitoring and advanced life support interventions. A critical patient during transfer is at a higher risk.

SALIENT HISTORICAL MILESTONES

At the global level, medical transfers of the modern era were created by Napoleon's doctor Jean Dominique Larrey in 1793, who established a system to transport and treat injured French soldiers. Mahatma Gandhi, during the Boer war in South Africa in 1892, started National Indian Ambulance Corps to help injured British soldiers. It had over 1,000 members as volunteers of stretcher bearers. Gandhi was bestowed with the title of "Kaiser-i-Hind" by the British for his ground medical transfers in Boer war. As recently as in 1966, a report titled "*Accidental Death and Disability: The Neglected Disease of Modern Society"* initiated organized EMS in the USA.

In India, Centralized Accident and Trauma Services (CATS), an autonomous body of the National Capital Territory of Delhi, has started ambulances services in 1991. The Hyderabad-based GVK Emergency Management and Research Institute was pioneered in technology-driven state-level "108" ambulance-based prehospital care services in public–private partnership framework in 2005. Apollo Hospitals in Hyderabad have started hospital-based ambulance services with a four-digit number 1066.

CURRENT CONTEXT

The 72nd World Health Assembly resolution (May, 2019) highlighted that timely care for the acutely ill and injured will save more than half of the deaths in lower- and middle-income countries. It emphasized the need for treatment with prehospital care and emergency care interventions. No one should die because of lack of access to emergency care as it is now an integral part of universal health care (UHC). The provision of emergency services is enshrined in India's Constitution. Failure on the part of any hospital to provide timely medical treatment to a person results in violation of the person's "right to life," as guaranteed under Article 21 of India's Constitution. Therefore, a big picture of the role of ground medical transfers should be at the forefront of the frontline healthcare providers and medical professionals involved with emergency care.

Ischemic heart disease (IHD), chronic obstructive pulmonary disease (COPD), and stroke are the top three causes of death in India (2017). Noncommunicable diseases (NCD) cause 55%, communicable diseases cause 33%, and injuries cause 12% of disease burden in India, measured in the units of disability-adjusted life years (DALYs) (2016). Road traffic accident-related deaths are highest in India (150,000 per year). About 40% of the deaths are due to hemorrhage. Maternal deaths and neonatal deaths are also important concerned areas. Tertiary-level institutional care can only increase survival chances during the obstetric and neonatal emergencies. Early recognition, early referral, and early interventions save lives, emphasizing the importance of ground medical transfers.

KEY PRINCIPLES GUIDING THE GROUND MEDICAL TRANSFERS

If ground medical transfers are assumed as a significant component of EMS, about one third of lives can be saved. A response time of 8 minutes or less in an ambulance and prehospital care has proven to increase survival rates among

cardiac arrest patients. In case of road crashes, if the victim can be transferred to a definite care facility in the first 60 minutes *(golden hour)* after the incident, a good proportion of lives can be saved, limbs can be saved, complications can be reduced, and the duration of the hospital stay can be reduced. The same analogy can also be applied in case of postpartum hemorrhage (PPH), ST-elevation myocardial infarction, stroke, traumatic brain injuries, high-risk newborns, snakebite victims, etc. The first 10 minutes, otherwise named *"platinum 10 minutes,"* after a trained professional reaches the emergency patient in the field are very critical for favorable outcomes. The principle being followed is *3As—assessment, analysis, and action*. If a paramedic is attending the patient, he/she is expected to obtain medical direction in all critical cases. Emergency care in ground medical transfers should always follow the *principle of "Do No Harm and Do Not Add Insult to the Injury,"* this being more applicable in the context of road accidents. Immobilization with a split, if not done in a fractured lower limb, and trying to transport the victim which is likely to result in vascular or neurological injury is a typical example. This can be grounded by ensuring quality of care using an evidence-based approach and scrutiny of documentation of transit patient care. These documents are often called *prehospital care records*. In multicasualty incidents, the practice of field triage and categorization of victims into red, yellow, and green (using triage tag) will confirm the most critical patient, who needs to be given the highest priority and immediate transport.

In most of the lower- and middle-income countries, the *"scoop and run model"* of out-of-hospital care is adopted, unlike the developed world where the *"stay and stabilize"* principle is often attempted. If basic life support competencies are within the scope of practice of an emergency medical technician (EMT), it is advisable to adopt "scoop and run" but if a highly trained advanced EMT is available or a trained physician is available in the ambulance, "stay and stabilize" can be followed. About 28% of the emergencies require advanced life support skills in out-of-hospital care scenarios. Before the transfer, make *sure that the "ACCEPT approach" (Assessment-Control-Communication-Evaluation-Preparation-Transportation)* is in place. Thus, the key principles universally applicable in ground medical transfers are as follows:

- Do No Harm and Do Not Add Insult to Injury
- What is not documented is not done
- Evidence-based, planned, logical, and critical actions
- Stabilization of the patient before transport
- Consent and counseling of family
- Triage
- If you do not control the situation, the situation will control you
- Rapid response and minimal delay
- 24 hours × 7 days in a week
- Near real-time communication between ambulance staff and hospital
- Estimated time of arrival (ETA) communicated in advance for preparedness
- Adopt "scoop and run" and "stay and stabilize" based on the competencies of the ambulance-based professional.

MODELS OF GROUND MEDICAL TRANSFERS

The major models of the ambulance services offered based on the ownership observed in the country at present are:

- Government-owned
- Private run ground medical services
- Public-private partnership (PPP)
- Private hospital-based
- Trust hospital/organization based

In the *government-owned model*, staff and ambulances are owned by the state government and the transfers happen between government institutions. The services are provided free of cost.

Private-owned ground medical services either own ambulances/employee, staff, or lease vehicles. Patient transfers happen from incident location as well as between hospitals of choice. It is a chargeable model.

Private hospitals with one or more centers keep a dedicated helpline number and required number of ambulances for ground medical transfers with EMTs/paramedics as per standards. In critical care transfers, use the services of emergency department (ED) residents/physicians. All the transfers are destined to their own private hospitals. Services are charged.

In the PPP model, the government awards services to the private organization through a fixed cost model by tendering process of per month per ambulance (PMPA) and signs a memorandum of understanding (MoU) mentioning the service levels. This model has become very popular in India in the last 10-year period. Staff and maintenance of vehicles are by the agency while the government monitors the services. Services are rendered free of cost to the citizens. Most of the transfers happen to government hospitals. Trust hospitals run few vehicles and enable services to the locals in a limited fashion.

Independent of the type of ownership, ground medical transfers attend to primary transfer from the field as well as secondary transfer between lower and higher level hospitals. The second cited services are also termed *interfacility transfers (IFT)*. Besides, *intrahospital transport* of emergency patient for diagnostics or special units is also an area which requires special attention.

While most of the public-accessed ground medical transfers, sometimes referred to as EMS or emergency medical services, are manned by a basic life support skilled EMT, it is preferred to have an advanced life support skilled EMT in the IFT ambulances. Private hospital-based ambulances involved with ground medical transfers are often manned by physicians or advanced life support skilled EMTs. In ambulances manned by either basic or advanced EMTs, medical oversight is mandatory. Use of drugs, advanced airway [endotracheal (ET) intubation], etc., requires guidance from qualified physicians.

BASIC TASKS AND TENANTS

In order to provide end-to-end ground medical transfer, *functional and critical* prerequisites are essential.

Functional prerequisites are:

- Telecommunication system for responding to calls in a timely manner
- Ability in delivering qualified providers to the scene
- Providing emergency care
- Transporting ill or injured to the appropriate hospital in ambulances

Critical elements needed are:

- Road ambulance
- Personnel—physicians or EMTs

- Equipment—basic or advanced life support
- Communication network in the form of mobile or radiofrequency handsets/internet

TYPES OF ROAD AMBULANCES

Based on the level of care, road ambulances in India as per the *National Ambulance Code* (AIS 125) are grouped into four types (**Table 1**).

TABLE 1: Types of road ambulance.

Type of ambulance	*Purpose*
Medical first responder	Will not have the capability to transport patients in a supine state or provide them medical care inside the vehicle
Patient transport vehicle	For the transport of patients who are not expected to become emergency patients
Basic life support ambulance	For the transport and treatment of patients requiring noninvasive airway management/basic monitoring
Advanced life support ambulance	For the transport and treatment of emergency patients requiring invasive airway management/intensive monitoring

Medical Equipment and Drugs

To assess, stabilize, and monitor the patient, appropriate medical equipment is a must. A list of medical equipment and expected tasks need to be a part of learning to optimize the usage in emergency care. The National Health Mission, Ministry of Health and Family Welfare, Government of India, has standardized the medical equipment for ambulances in India (**Box 1**).

- Patient transport equipment such as semiautomatic collapsible stretcher, spine board, scoop stretcher, and wheelchair are meant to be used in fixing, moving, and lifting the patient.
- Suction apparatus, manual/electrical as well as handheld, are needed to clear airway.
- Immobilization equipment in the form of splints, cervical collar.
- Vitals assessment equipment such as blood pressure (BP) apparatus, stethoscope, and pulse oximeter
- Diagnostic equipment such as glucometer
- Monitor
- Oxygen delivery system
- Wound care and nursing equipment
- Life support drugs
- Intravenous (IV) fluids
- Basic and advanced airway equipment
- Assisted breathing equipment such as bag-valve-mask (BVM) (adult/pediatric)
- Biomedical waste management
- Extrication equipment
- Telecommunication equipment

BOX 1: Standard list of essential equipment for ambulances.

Medical equipment

- Suction pump, portable electric
- Suction pump, foot-operated
- Suction pump, hand-operated
- Laryngoscope
- Flowmeter with humidifier bottle
- Oxygen cylinder "B" type
- Oxygen cylinder "D" type
- Bag and mask ventilation device (Adult)
- Bag and mask ventilation device (Child and neonatal)
- Trolley stretcher with back tilt facility and collapsible wheels
- Canvas stretcher, folding
- Stretcher scoop
- BP instrument aneroid
- Stethoscope
- Pneumatic splints
- Cervical collar
- First aid box
- Spinal board
- Double head immobilizers
- Fetal Doppler
- Portable hand-held glucometer
- Nebulizer (Electric)
- Automated external defibrillator
- Monitor
- Syringe pump
- Transport ventilator (Adult and pediatrics)
- Transport ventilator (Neonatal and pediatrics)
- (A) Intravenous, (B) Cutdown set, (C) Suture kit
- Pulse oximeter

(BP: blood pressure)

Drugs

- Adrenergic drugs
- Antiarrhythmic drugs
- Antihypertensive drugs
- Antiepileptics
- Antidotes
- Elements/Electrolytes
- IV fluids
- Miscellaneous

PLANNING AND COORDINATION

In order to plan and implement ground medical transfer services, a well-laid process needs to be established and adhered to. Globally, the "star of life" highlights the various phases of out-of-hospital medical transfer, namely early detection, early reporting, early response, on-scene care, transit care, and transfer to definite care. In the *Indian context unified emergency number 112 (108/102/104)* and state-level command and control centers (CCC) locate the emergency (SENSE), strategically placed ambulance reaches the emergency location quickly (REACH) and provides emergency care (CARE). A follow-up call after the transfer will document the status and satisfaction of services.

Planning for Patient Transfer

Transfer of patients is an important aspect of medical care. Transfer decision should balance risks and benefits. Staff, support equipment, standard treatment guidelines, and standardized communication are success factors. Out-of-hospital care protocols, applied during ground medical transfers, highlight initial assessment and immediate interventions. In addition, the role of direct medical oversight is also crisply documented for common emergencies. Protocols need revision based on the advances in medical technology. Expected complications during transfer are as follows:

- Pulmonary (hypoxia, pneumothorax, atelectasis, embolism)
- Cardiovascular (arrest, hypotension, hypertension, rhythm changes)
- Acid–base disorders (metabolic or respiratory alkalosis or acidosis)
- Endocrine (hypoglycemia)
- Infectious (risk for provider or patient)

Response Officers from the Command Center obtain the location, chief complaint, and communication details. "*On scene care"* focuses on scene size up, scene safety, triage, patient assessment, life support interventions such as CPR, use of AED, arrest of active bleeding depending on the need, fixing, moving, and lifting. "*Transit care"* focuses on stabilization of airway, breathing, circulation, monitoring, medical direction, documentation, use of drugs, reassurance, etc.

Prearrival information (PAI) to the receiving hospital is an important task of ground medical transfers with proven favorable outcomes. Destination determination (hospital selection) is conceptually dependent on the condition of the patient, facilities at the receiving hospital, and patient's choice. Good ground medical transfers or EMS system practice evidence-based protocols.

Patient handover or handoff activity at ED or a hospital follows the *acronym of SBAR (situation, background, assessment, and recommendation) or alternatively I-PASS (Illness severity, Patient summary, Action list, Situation awareness & contingency planning; and Synthesis by receiver).* Patient handover should include both *clinical handover and administrative handover* in the form of prehospital care record (manual or electronic).

TRAINING SCHEDULE FOR EMERGENCY MEDICAL TECHNICIAN

Hence, public access EMS system should have trained EMTs in the ambulance and qualified doctors in the state-level center for online medical direction. EMTs are trained for nearly 400 hours for basic life support skills and over 1,000 hours for advanced life support skills. Training of EMTs encompasses knowledge, skills, and attitude. Generally, EMTs are trained in institutional, hospital, and ambulance phases. Simulation education is extensively used in skill training. Simulation education using manikins ensures patient safety concerns and is considered as experiential learning. Even for assessment of skills, the Objectively Structured Skills Evaluation (OSCE) method is used for EMTs. In addition to the not-for-profit organization involved with EMS services, paramedical education and mainstream universities are also offering bachelor and postgraduate degrees and diplomas to EMS professionals (**Fig. 1**).

QUALITY ASSURANCE

The National Accreditation of Board of Healthcare Organizations and Hospitals (NABH) amply echoed the need for availability of ground medical transfers in all hospitals. Equipment, competencies, processes, communication, and care practices are also highlighted. Alignment of ground medical transfers, either public access or hospital-based, will not only save lives but also reduce cost barriers to institutional care. First aid at the incident by a trained bystander, prehospital care by ground medical transfers, and care continuum at the hospital are not only a concept of chain of survival but an opportunity to prove the fact that "a system saves lives."

SUMMARY

The medical team performing road transfer of patients should be highly qualified and competent within their respective field. A mix of medical teams exists, but is usually made up of doctors, paramedics, nurses, and driver. The medical team should ideally be made up of clinical specialists who have undergone extra training in the transfer of patients including postgraduate study. It may prove beneficial to have some heterogeneity within the medical team by mixing doctor/nurse or doctor/paramedic teams where each team member can bring his/her own specialist skills to the transfer and work together to provide optimal patient care. The skillset of the medical team should always match the potential needs of the patient. Road transfer of patients can be high risk for errors to occur such as airway problems, detached intravenous lines, equipment failure, etc., so the medical team should be competent in skills/treatment for problems, which may arise during transfer. Irrespective of the type of transfer, e.g., primary, tertiary or type of vehicle used, the medical approach to the

FIG. 1: Paramedic education schedule.

patient should be similar. Standard operating procedures are an excellent tool in the transfer of patients by road as it gives an objective guide and provides "checklists" to ensure essential tasks have been completed. Ambulance transport team is incomplete without a transport physician, just as an intensive care unit (ICU) would be incomplete without an intensivist. The advantage of a specialized transfer team is that it is more familiar with transport-specific procedures and equipment. Establishment of a specialized transfer team associated with a decline adverse events. Specialized teams are better able to stabilize the patient prior to the transfer. A specialized team better deals with logistic problems. "ACCEPT" approach should be adopted by the team before start: A-Assessment, C-Control, C-Communication, E-Evaluation, P-Preparation, and T-Transfer. Team must remember "6 R" for the safe transfer of the patient: The Right patient, at the Right time, by the Right people, to the Right place, by the Right transport, with Right care throughout.

26
CHAPTER

Air Medical Transfer

Saleh Fares, Michael J Nolan

INTRODUCTION

The use of rotary-wing and fixed-wing aircraft in the transfer of patients has increased in popularity in recent years. The utilization of helicopters as air ambulances is beneficial due to the speed of transfer of a specialist medical team to the scene of the patient and subsequent transport to a specialist hospital. This is especially important in urban areas where traffic congestion may hamper necessary resources. The use of a fixed-wing aircraft to transfer patients is required where the distance is greater and is advantageous due to the ability of longer distance and speed; however, disadvantages include secondary transfers from airport/landing strip to hospital. The air transfer of patients can generally be described in *three phases*:

1. *Primary transfer*: An air ambulance is used to transport a medical team to the scene of an accident or location of a patient. The patient is then transferred to an appropriate facility dependent on the specific patient requirement and local specialist centers. This air transfer is usually undertaken by a helicopter and flight times are usually short.
2. *Secondary transfer*: A fixed-wing or rotary-wing aircraft is used to transfer patients who require an advanced level of care. This transfer is usually from a clinic/hospital where medical treatment has been started but the patient requires treatment/intervention at a specialist facility. A fixed-wing or rotary-wing aircraft can undertake this.
3. *Tertiary transfer*: A patient is transferred by air from one facility to another, usually for definitive care. This includes international transfer of patients who require repatriation to their home country after illness/injury. This is usually undertaken on a fixed-wing aircraft including commercial jets.

DECISION FOR AIR MEDICAL TRANSFER

The decision to transfer a patient by air has several factors, including the current pathophysiology of the patient/intervention requirements, the training and expertise of the medical transport team, the location of the aircraft, and the distance to the patient and hospitals or facilities. Patients who have time-critical injury/illness and require life-saving interventions can benefit most from air transfer. These include conditions such as polytrauma, myocardial infarction, severe burns, surgery, premature neonates, intra-aortic balloon pump, extracorporeal membrane oxygenation, and many more. A "*doughnut model*" (**Fig. 1**) has been created to display the benefits of using different modes of transport for air transfer over variant distances. The area marked A will provide minimal assistance using air transfer (ground transfer is quicker), whereas area B is superior when using rotary-wing air transfer to transport an advanced medical team to the patient, where treatment/intervention can be initiated at the scene and en route to a specialist facility. Area C shows the distance that a rotary-wing aircraft will be time beneficial over other forms of transport. Area D is the distance where fixed-wing transfer would be the most beneficial regardless of necessary secondary transfers.

FLIGHT PHYSIOLOGY

The air transfer of patients creates many considerations for the medical team including the effects of altitude on the

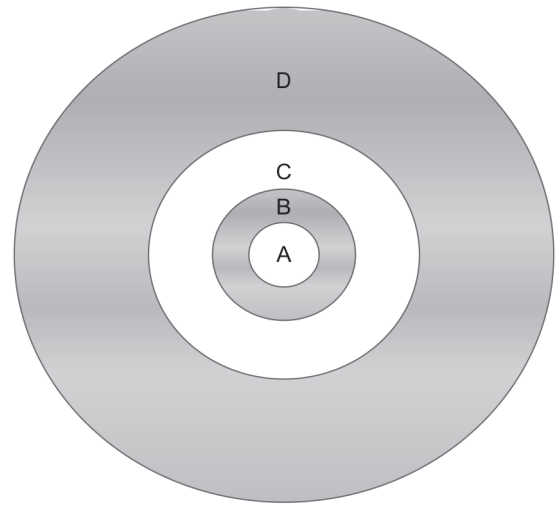

FIG. 1: Doughnut model of air transfer distances.

TABLE 1: Physiological impact of air transfer.

Effects of hypothermia	*Increase in oxygen demand and consumption*
Effects of hypoxic hypoxia	Oxygen saturation and ABG preflight may change at altitude
Effects of noise	• The patient may become panicked/distressed/combative • Monitoring audible alarms may not be heard • Communication with the awake patient may be difficult
Effects of vibration	• Increase in pain at fracture sites • May exacerbate nausea and vomiting • Higher amounts of analgesia and sedation are required • Inaccurate electrical artifacts on monitoring machines

(ABG: arterial blood gases)

TABLE 2: Comparison of ground and air medical transfer.

Ground medical transfer	*Air medical transfer*
Advantages	***Advantages***
• Door-to-door transfer • Rapid mobilization time • No landing zone required • Very few weather restrictions • Overall cost low and mostly affordable • Less physiological impact • More familiar environment for staff	• Rapid transfer • Consider where difficult road access • Can add few more medical personnel
Disadvantages	***Disadvantages***
• Motion sickness is a common problem • Traffic—major common problem	• Physiologic effect of high altitude • Assistance required for safe loading and unloading of patient • Runway is required sometimes • No night facility • Higher cost

physiology of the patient. Any medical crew involved in air transfer should have advanced knowledge of flight physiology in order to be aware and, subsequently, deal with any situations that may arise due to the stressors of flight. This is especially pertinent when transferring critically ill patients who may already be at the upper end of their physiological reserve as physiological deterioration may occur more rapidly from the stresses of flight (**Table 1**). These stressors would mainly be associated with fixed-wing transfer due to the higher altitude; however, patients transferred in helicopters may also suffer from the stresses of flight. It is important to note that these stressors are not limited to the patient but may also affect the medical crew. Some air transfer physiological considerations include the following:

- From sea level to 5,000 ft represents a significant change in barometric pressure and temperature for the patient
- Trapped air will increase 20% in size.
- The temperature will decrease by approximately 10°C.
- Ambient oxygen pressure will decrease by almost 17%.
- Arterial oxygen pressure will decrease by 23%.
- Alveolar oxygen pressure will decrease by 21%.
- Alveolar CO_2 pressure will decrease by 6.5%.

This will have a direct impact on air transfer patient care, and thus the medical crew must preempt these physiological changes that may occur and be prepared to treat accordingly.

STANDARDS OF CARE: AIR MEDICAL TRANSFER

It is important to discuss the advantages and disadvantages of the air and ground medical transfer in due course of planning (**Table 2**) to ascertain if air medical transfer would be beneficial in a particular case. The standards of care of the medical team will differ vastly across the globe. The medical team performing air transfer of patients should be highly qualified and competent within their respective fields. A mix of medical teams exists which is usually made up of doctors, paramedics, nurses, and respiratory therapists. There is no ideal medical team; however, it should ideally be made up of clinical specialists who have undergone extra training in the air transfer of patients including postgraduate study. It may prove beneficial to have some heterogeneity within the medical team by mixing doctor/nurse or doctor/paramedic teams where each team member can bring his/her own specialist skills to the transfer and work together to provide optimal patient care. The skillset of the medical team should always match the potential needs of the patient. Air transfer of patients can be high risk for errors to occur such as airway problems, detached intravenous lines, and equipment failure, so the medical team should be competent in skills/treatment for problems, which may arise during transfer. The patient should be examined thoroughly (airway, breathing, circulation); systemic examination before transfer and checklist can be used to confirm the availability of essential equipment for transfer according to the need (**Table 3**).

Irrespective of the type of transfer, e.g., primary, tertiary, or type of aircraft used, the medical approach to the patient should be similar. Standard operating procedures are an excellent tool in the transfer of patients by air as it gives an objective guide and provides "checklists" to ensure that essential tasks have been completed. This mitigates potential problems that may occur during flight where these tasks are difficult and sometimes impossible to carry out in a moving and sometimes cramped aircraft (**Fig. 2**). An example of this would be a patient who has suffered burns including facial/airway burns. During the assessment, it may be obvious that the patient has facial/airway burns but not displaying any symptoms of airway swelling or obstruction. However, problems arise during air transfer where the patient becomes distressed with respiratory difficulty, and impeding airway obstruction ensues due to swelling of the airway. It would prove beneficial to ensure that this potential complication is treated on the ground by identifying possible issues in flight and securing the airway beforehand with anesthesia and mechanical ventilation. This

TABLE 3: Checklist for air medical transfer.

Airway	*Safe/Secured by intubation*	*Yes/No*
Ventilation	• ETT confirmed (by X-ray) in right position	Yes/No
	• Paralyzed, sedated, ventilated	Yes/No
	• Comfortable on a transport ventilator	Yes/No
	• Confirmed by arterial blood gases	Yes/No
Circulation	• HR and blood pressure stable	Yes/No
	• Tissue perfusion adequate	Yes/No
	• Any obvious blood loss controlled	Yes/No
	• Have you checked hemoglobin?	Yes/No
	• Two types of venous access present?	Yes/No
	• Central and arterial line secured	Yes/No
Neurology	• Seizures controlled	Yes/No
	• Raised ICT managed	Yes/No
Trauma	• Protect cervical spine	Yes/No
	• Secure drain if pneumothorax	Yes/No
	• No intrathoracic/intra-abdominal bleed	Yes/No
	• All thoracic/abdominal/long bone/pelvic fractures are stabilized?	Yes/No
Metabolic	• Temperature adequately controlled	Yes/No
	• Acceptable acid–base balance	Yes/No
	• Acceptable range of blood glucose	Yes/No
	• Serum potassium, calcium	Yes/No
Monitoring device	• ECG	Yes/No
	• Blood pressure	Yes/No
	• Oxygen saturation	Yes/No
	• $ETCO_2$	Yes/No
	• Temperature	Yes/No

Make sure the following equipment are available on board:

Airway • Goeddel airways (assorted sizes) • Laryngeal masks (assorted sizes) • Tracheal tubes (assorted sizes) • Laryngoscopes (spare bulbs and battery) • Intubating stylet • Lubricating gel • Magill's forceps • Tape for securing tracheal tube • Sterile scissors • Stethoscope

Suction • Yankauer sucker • Suction catheters • Nasogastric tubes and drainage bag

Ventilation • Self-inflating bag and mask with oxygen reservoir and tubing • High-flow breathing circuit • Spare valves for portable ventilator • Chest drains (assorted sizes) • Heimlich flutter valves

Circulation • Syringes (assorted sizes) • Needles (assorted sizes) • Alcohol wipes • IV cannula (assorted sizes) • Arterial cannula (assorted sizes) • Central venous cannula • Intravenous fluids • Infusion sets/extensions • Three-way taps • Dressings • Tape • Minor instrument/cut-down set

(ECG: electrocardiogram; $ETCO_2$: end-tidal carbon dioxide; ETT: endotracheal tube; ICT: intracranial tension)

ensures a more comfortable environment to carry out this procedure and not in the back of an aircraft where conditions and space are limited.

The air transfer of patients is often most beneficial for critical care patients requiring specialist treatment/intervention. Whilst it is necessary to stabilize certain types of patients, it may also be required to expedite patient transfer to definitive intervention. This is the case in patients with noncompressible hemorrhage where the definitive treatment is surgery (penetrating/blunt injury). Minimal delay on the scene should be advocated and solutions for any issues that arise en route to definitive care should be instigated. The air transfer of patients in cardiac arrest should not be advocated due to several potential issues. The ability to perform cardiopulmonary resuscitation in the back of an aircraft is impractical due to limited space, crew restraint in the aircraft, and safety issues. Advanced life support treatment should be instigated according to standard operating procedures at the scene of the patient where space and resources may not be limited.

SPECIAL CONSIDERATIONS

During the air transfer of patients, there are some special considerations that clinicians must be aware of to mitigate problems due to altitude. Any patient who may have trapped air in pathological airspaces can have a possible catastrophic reaction to altitude. The conservative management of any condition with trapped air such as pneumothorax, intraocular air, and pneumocephalus must be handled with extreme caution. The insertion of chest drains in the restricted space of an aircraft if a patient deteriorates is impractical due to patient accessibility and limited space/resources. During the air transfer of psychiatric patients, special considerations are mandatory before placing the patient in the aircraft. The preferential use of ground transport is always advocated, but certain instances may arise where air transfer is the only option. Patients experiencing psychiatric illness may appear docile on the ground but become agitated due to the stressors of flight and the claustrophobic environment. This can have the potential to jeopardize the safety of the crew and the flight. All efforts must be made to carefully plan and adhere to local standard operating procedures (SOPs) whilst maintaining legal and ethical consideration in respect of pharmacological sedation of psychiatric patients.

RECENT ADVANCES

The most recent advance in the air transfer of patients is the increasing number of rotary-wing air ambulances. In the United Kingdom (UK), there are approximately 20 civilian air ambulances providing life-saving care to the public. Most of these air ambulances are funded by charity and rely on public donations. With the introduction of major trauma centers, injured patients may have to travel further to access this specialist facility. Air ambulance helicopters are the fastest way to deliver patients to life-saving specialist intervention

FIGS. 2A AND B: (A) Fixed-wing and (B) rotary-wing air transfer (limited space and access to the patient).

and play a key part in an increase in patient survival. Air ambulance faces few fatal crashes also, so regulations are required to increase the safety of air ambulance missions by implementing the latest technology and flight data monitoring systems to assist flying in challenging weather, at night, and in remote locations.

SUMMARY

The air transfer of patients poses risks for the patient, medical, and flight crew due to several reasons including altitude, environment, and severity of the patient's condition. Most situations that arise can be mitigated by careful planning and utilizing SOPs, which ensure that medical crews develop motor programs so that working in a changing environment can be completed safely and successfully. Below are some helpful rules for the air transfer of patients:

- Most complications that occur were not anticipated by the air medical crew. Large problems are usually small ones that were not planned for.
- The ability to competently deal with any situation that arises is mandatory. No one can run for help whilst in the sky!
- Make sure to spend extra time securing all tubes and infusion lines. These extra few minutes will pay off as loading/unloading patients can be haphazard for accidental removal.
- Treat the patient as well as the monitor. The environment of air transfer can be noisy and distracting. Ensure good clinical observation.

27 CHAPTER

Basic Concepts of Disaster Management

Venkat Changavalli, Devendra Richhariya

INTRODUCTION

The term disaster consists of two Latin words (dis—bad and aster—star/fortune). As the word itself suggests, it was considered as misfortune or punishment given by God and also considered the fact that these are not under human control. With time, these theories changed and now understood that these are not beyond the control of human and can be managed with appropriate planning.

In India, about 60% of land is vulnerable to earthquakes, 16% of land is vulnerable to drought, 12% of land is vulnerable to floods, and 8% of land is vulnerable to cyclones. These calamities result in injuries, deaths, and property damage and these cannot be managed by individual capacity through the routine measures. Preparedness is an integral part of a control program and is important for effective management of an incident to minimize losses to people and property, both in and around the facility. A comprehensive *disaster preparedness strategy* is required and components are as follows:

- Hazard, risk, and vulnerability assessments
- Response mechanisms and strategies
- Preparedness plans
- Coordination
- Information management
- Early warning systems (EWSs)
- Resource mobilization
- Public education, training, and rehearsals
- Community-based disaster preparedness

DEFINITIONS

Disaster, as per the Disaster Management Act, 2005, is defined as "A catastrophe, mishap, calamity, or grave occurrence in any area, arising from natural or man-made causes, or by accident or negligence which results in substantial loss of life or human suffering or damage to, and destruction of property, or damage to, or degradation of environment and is of such a nature or magnitude as to be beyond the coping capacity of the community of the affected area."

Any occurrence that causes damage, economic disruption, loss of human life, and deterioration in health and health services on a scale sufficient to warrant an extraordinary response from outside the affected area or community can be termed disaster. The United Nations International Strategy for Disaster Reduction (UNISDR) defines disaster as a serious disruption of the functioning of a community or a society causing widespread human, material, or environmental losses which exceed the ability of the affected community or society to cope using its own resources.

Examples of disaster:

- Road traffic accidents, air crash
- Bullet and blast injuries
- Collapse of a building
- Fire
- Communal riots
- Terrorist attacks
- Floods
- Earthquakes, tsunami
- Epidemics
- Nuclear/biological/chemical warfare

CLASSIFICATION OF DISASTERS

Disasters are classified into two major categories: (1) Natural and (2) Manmade (**Table 1**). Classification helps us in risk assessment of the disaster vulnerability and in building sufficient capacity to manage the disaster.

Risk factors for disaster: If the scale of hazard is too big, vulnerabilities are too high and capacity is insufficient to deal with it, the risk is too high, so emergencies cannot be managed locally, and the communities may not be able to handle the situation.

(Hazard + Vulnerability = Increase in disaster risk) and
(Increase in capacity = Decrease in disaster risk)

Hazard: A potentially damaging physical event, phenomenon, and/or human activity, which may cause loss of life or injury, property damage, social and economic disruption, or environmental degradation

Vulnerability: A condition or sets of conditions that reduce people's ability to prepare for, withstand, or respond to a hazard.

TABLE 1: Classification of disaster.

Manmade disaster	*Natural disaster*
• *Civil disturbances*: Riots, explosion, and demonstrations • *Warfare*: Conventional warfare (bombardment, blockage, and siege) • *Nonconventional warfare*: Nuclear, biological, and chemical warfare (NBC) • *Terrorism refugees*: Forced movement of a large number of people usually across frontiers • *Accidents*: Transportation calamities (land, air, and sea), collapse of building, dams, and other structures, mine disasters, fire, poison gas panic • *Technological failures*: Nuclear power station, leak at a chemical plant, breakdown of a public sanitation system	• *Meteorological*: Storms (cyclones, hailstorms, hurricanes, typhoons, and snowstorms) • Cold spells, heat, waves, droughts • *Topographical disasters*: Avalanches, landslides, and floods • *Geological disasters*: Earthquakes, tsunamis, volcanic eruptions • *Biological disasters*: Insects, swarms (locust) and epidemics of communicable diseases

Capacity: Those positive conditions or abilities which increase a community's ability to deal with hazards.

Risk: The probability that a community's structure or geographic area is to be damaged or disrupted by the impact of a particular hazard, on account of its nature, construction, and proximity to a hazardous area.

Features of disaster: Disaster disrupts a large number of people of a normal functioning society. It causes damage to property and loss of human life. Disaster management requires external help to manage the disaster. The following steps are important to minimize the losses:

- Reliable and early detection of an emergency and careful planning
- Coordination along with efficient trained personnel
- Resources for handling emergencies
- Appropriate emergency response actions
- Effective notification and communication facilities
- Proper training of concerned personnel
- Regular mock drill/rehearsal
- Regular review and updating plan

DISASTER MANAGEMENT CYCLE

Emergencies and disasters can strike without warning. Each individual with a disability has unique circumstances and needs. There will likely be problems with drinking water, electricity, and other utilities. When large-scale disasters strike, most assistance is provided by one citizen to another. Police, fire, or emergency medical service (EMS) resources will not be able to reach everyone right away. In the last few years, we have seen that disasters also simultaneously destroy health facilities, besides other infrastructures. *Disaster management* is a collective term encompassing all aspects of planning for preparing and responding to disasters. It refers to the management of the consequences of disasters. The fundamental of disaster management is to do the greatest possible good for possibly the greatest number of affected people. The disaster management cycle broadly has six phases covering predisaster [(1) prevention, (2) mitigation, (3) preparedness] and postdisaster [(4) rescue, (5) relief, (6) rehabilitation and reconstruction] responses (**Fig. 1**).

Response: Actions are taken immediately following the impact of a disaster when exceptional measures are required to meet the basic needs of the survivors.

Relief: Measures that are required in search and rescue of survivors as well to meet the basic needs for shelter, water, food and healthcare.

FIG. 1: Disaster management cycle.

Recovery: The process undertaken by a disaster-affected community to fully restore itself to the predisaster level of functioning.

Rehabilitation: Actions taken in the aftermath of a disaster to:

- Assist victims to repair their dwellings
- Re-establish essential services
- Revive key economic and social activities

Reconstruction: Permanent measures to repair or replace damaged dwellings and infrastructure and to set the economy back on course.

Development: Sustained efforts intended to improve or maintain the social and economic well-being of a community.

Prevention: Measures taken to avert a disaster from occurring, if possible (to impede a hazard so that it does not have any harmful effects).

Mitigation: Measures taken prior to the impact of a disaster to minimize its effects (sometimes referred to as structural and nonstructural measures). Structural and nonstructural measures undertaken to limit the adverse impact of natural hazards, environmental degradation, and technological hazards are as follows:

- Structural measures refer to any physical construction to reduce or avoid possible impacts of hazards, which include engineering measures and construction of hazard-resistant and protective structures and infrastructure, such as construction, hazard-resistant house construction, planting mangroves, drainage channels, and water conservation measures.
- Nonstructural measures refer to policies, awareness, knowledge development, public commitment, and methods and operating practices, including participatory

mechanisms and the provision of information, which can reduce risk and related impacts.

Preparedness: Measures taken in anticipation of a disaster to ensure that appropriate and effective actions are taken in the aftermath.

DISASTER RESPONSE MANAGEMENT

Disaster response is the immediate intervention or provision during the disaster or just after the disaster to preserve human life and provide basic needs to affected people. In view of the complexity of the disaster, response would vary and depend on the sudden/slow-onset disaster, place of disaster (rural, urban, mountain, coastal, marine), and magnitude of disaster (managed with local authority or need central government assistance).

Disaster responders: Responders can be divided into various categories such as immediate responders (community which includes family members, friends, and neighbors), core responders [police, fire services, EMS, district collector and National Disaster Response Forces (NDRF)]. Secondary responders are the civil defense special team, nongovernmental organizations, engineers, food and supply department.

Major response activities: Major activities for responders are search and rescue, which require especially trained persons who can rescue trapped people from the disaster area and collapsed structures, e.g., mountain rescue, air rescue, and sea mining rescue. Evacuation is an important activity which can be started before disaster in the form of early warning and moving the people to a safe area. Fire fighters are trained and well equipped to rescue people from car accidents, collapsed buildings, and other difficult situations.

Emergency medical treatment: Nearest hospitals are the first place where disaster casualties are received. A proper triage scheme, core medical emergency team with pediatric care units, is necessary to deal with mass casualties. Setting up mobile and field hospitals, placing first-aid equipment at community-level hospitals, etc., are important activities.

Ambulance services: Boat, ships, vans, etc., can be used for transporting injured and sick people. Ambulances can be used as mobile medical units outside the hospital to treat the people.

Restoration of important infrastructure: Water, sanitation, electricity, communication, repair of roads and bridges that connect the rural area to the urban areas, restoration of the functionality of healthcare centers and hospitals.

Tools for professionalizing disaster response: Various measures are implemented for streamlining the response such as setting up an *incident command system* (ICS), simulation and scenario analysis, exercise (tabletop and functional), mock drill, implementation of new innovations, and research.

INCIDENT COMMAND SYSTEM

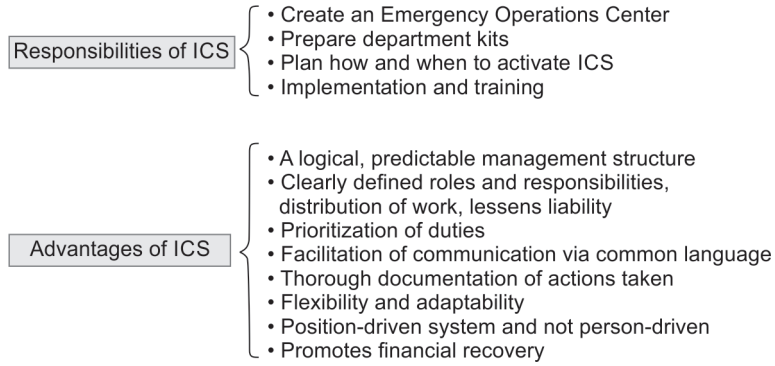
Incident command system (ICS) is an emergency management system that helps the primary responders, responding agencies, and personnel to unify services. Medical disaster can quickly lead to chaos and confusion and ICS provides medical facilities with an organized management structure that promotes immediate, focused direction of activities during a disaster and allows for prompt resumption of normal operations. Incident Command Center is headed by an Incident Commander whose responsibilities are administration, planning, finance, and arranging logistics (**Table 2**). Incident command is helpful in defining the role and responsibilities, prioritizing duties, and providing a predictable management structure (**Fig. 2**). The public information officer, safety officer, and liaison officer are the other important members of the ICS and their roles are clearly defined. An incident command organization chart is shown in **Flowchart 1**.

MULTIAGENCY COORDINATION DURING RESPONSE

Disaster is a complex situation, and a single-point contact mechanism is required for coordinated comprehensive relief operation.

TABLE 2: Overall responsibilities of the head of the incident command center.

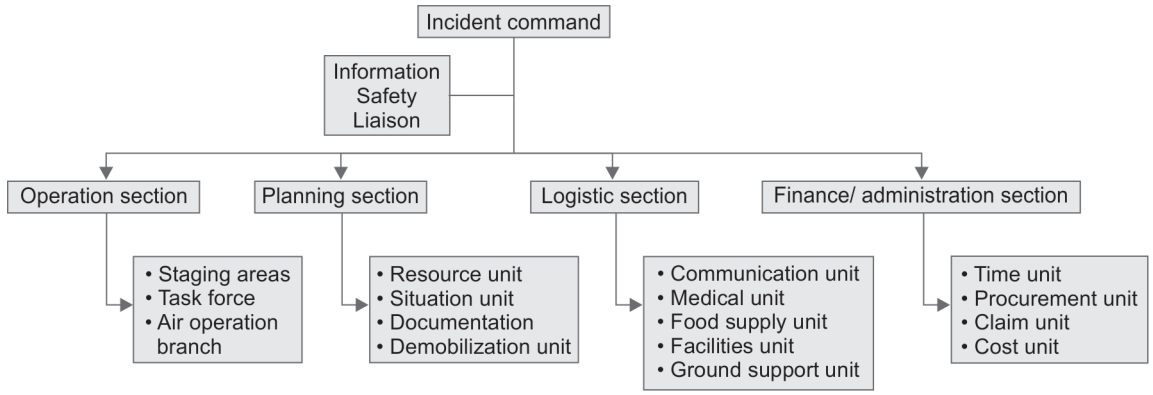
Logistic (provide support)	***Planning (prepare action plan)***	***Finance (cost accounting and procurement)***	***Operations (direct tactical action)***
Responsible for acquisition and maintenance of facilities, services, and personnel equipment materials	• Collect, analyze, and display information • Prepare an incident action plan • Maintain situation and resource status • Maintain incident documentation • Prepare demobilization • Promote continuity of operations	• Monitor incident costs • Maintain financial records • Administer procurement contracts	Carry out the medical objective to the best of their ability
Other important command staff			
Public Information Officer	***Safety Officer***	***Liaison Officer***	
Provide information to the news media; serves as the one central point for information dissemination	Monitors the facility and anticipates, detects, and corrects unsafe situations	Functions as an incident contact person for representatives from other assisting and cooperating agencies	



Responsibilities of ICS
• Create an Emergency Operations Center
• Prepare department kits
• Plan how and when to activate ICS
• Implementation and training
Advantages of ICS
• A logical, predictable management structure
• Clearly defined roles and responsibilities, distribution of work, lessens liability
• Prioritization of duties
• Facilitation of communication via common language
• Thorough documentation of actions taken
• Flexibility and adaptability
• Position-driven system and not person-driven
• Promotes financial recovery

(ICS: incident command system)

FIG. 2: Advantages of the incident command system.



FLOWCHART 1: Incident command organization chart.

Coordination is important: For prioritization of work, deploying resources in high-need areas, monitoring, evaluating population at risk.

Coordination facilitates assessment of roles, resource capabilities and also identifies gaps, overlaps and bottleneck. Coordination facilitates communication between various agencies.

Coordination barriers: Involvement of too many organizations and decision-makers which work for different priorities, expectations, and beliefs. Most of the time lack of resources and not possible to devote a person only for coordination, thus leading to ineffective coordination and leadership.

Coordination technique: Increase linkage and understanding between all responding agencies by promoting transparencies, involving right people or agencies, and allocating them appropriate role with written proceedings of coordination meetings. Have a rapid reporting system in place, know each other's strengths, respect each other, and acknowledge each other's contribution.

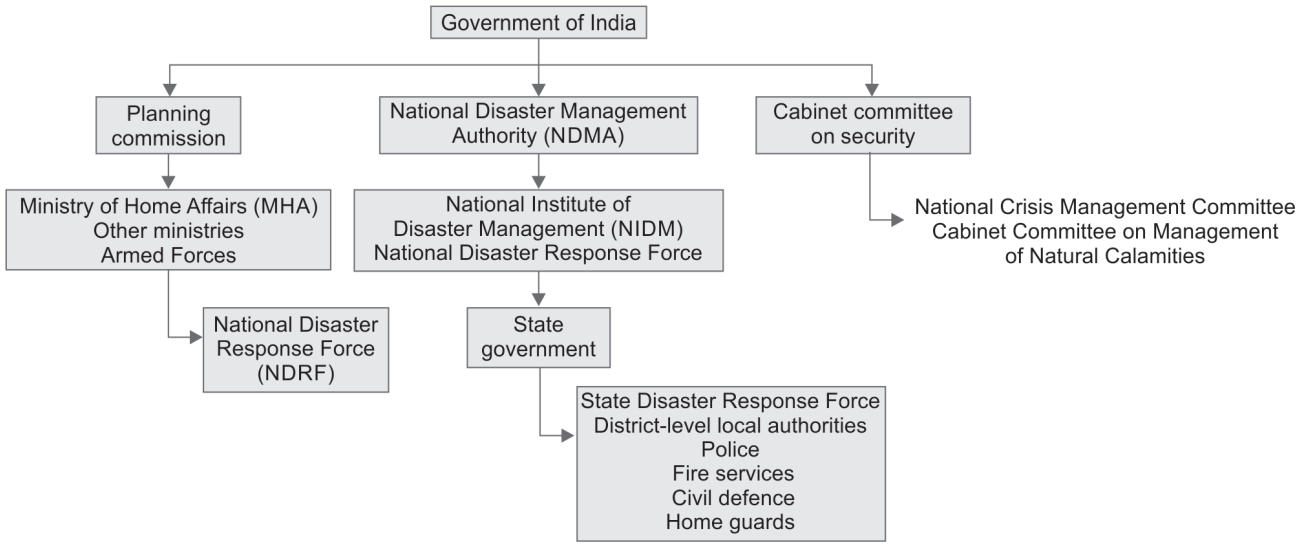
Role of Armed Forces, Paramilitary, and NDRF: The Indian armed forces are generally expected to call to intervene in specific tasks when any situation is beyond the capabilities of civil administration. Armed forces are positioned in various locations in the country and are always in readiness to respond to any situation. The armed forces and NDRF are disciplined manpower, show a high degree of professionalism, and are equipped with various machinery for restoration of immediate services and relief work. Armed forces, paramilitary forces, and national disaster relief forces provide various types of relief operations such as search, rescue and evacuation, medical aid, aerial dropping of food, setting up the relief camp, restoring damaged road and bridges, and restoration of essential services such as water and electricity.

The role of Indian armed forces in providing assistance to civil authorities in a disaster situation is well known. Armed forces provide assistance in disaster relief not only within the country but also in neighboring countries. The roles of police in disaster management are maintaining law and order, evacuation of the population, first-aid, record of lost and found people, identification and disposal of the dead, and guidance to other agencies. A specialist force that has been created to respond to disaster and a disaster-like situation in India is the *NDRF*. NDRF is equipped to assist state and local authorities in managing natural as well as manmade disasters. During nondisaster situations, NDRF provides community awareness education and disaster preparedness. Multiple agencies' coordination for disaster response in India is summarized in **Flowchart 2**.

EARLY WARNING SYSTEM FOR DISASTER

The role of any warning system is to inform vulnerable people about the possible threat of an impending natural hazard so that timely and appropriate action can be taken for the safety of life and property (**Table 3**). There are four elements of EWS:

1. Detection or risk knowledge
2. Monitoring and prediction



FLOWCHART 2: Multiple agencies' coordination during disaster response.

TABLE 3: Early warning system in India.

Hazard	*Nodal agency*
Cyclone	Indian Meteorological Department
Flood	Central Water Commission
Landslides	Geological Survey of India
Tsunami	Department of Ocean Development
Avalanches	Defence Research and Development Organization

3. Dissemination and communication
4. Response capabilities

An effective EWS for all hazards needs to be established which can give information about the more frequent hazard in that region as well as rare but most destructive hazard such as tsunami. Monitoring and warning service is an important part of EWS. Local warning procedures such as siren, drums, and bells are most effective at the time of emergencies.

Various technological advances to communicate early warnings need to be taken into account while designing the dissemination mechanism so that we can reach out to the last person and avoid failure.

ROLE OF TECHNOLOGY AS DECISION SUPPORT TOOLS

During critical hours of a disaster, quick and authentic information is required regarding the population likely to be affected, resource availability, critical infrastructure available, evacuation routes, and communication channels for effective decision-making. The National Informatics Centre officials support the administrators in managing the information.

Geographic Information System Role in Disaster Response

Geographic Information System (GIS) is a computer-based tool helpful in mapping and analyzing activities on earth, and GIS-based solution includes flood and earthquake damage assessment, emergency response planning, hazard mapping, and resource mapping. GIS integrates five key components: (1) Hardware, (2) software, (3) data, (4) procedure, and (5) people who manage the system. GIS is capable of capturing, storing, querying, analyzing, and displaying data. GIS is a powerful tool helpful in decision-making in all phases of the disaster management cycle.

Global Positioning System Role in Disaster Response

Global Positioning System (GPS) is a satellite-based navigation system helpful in locating the position anywhere on the earth. GPS is helpful in mapping of soil, vegetation type, endangered species, and wildlife habitat. It is helpful in the assessment of the damage after natural disasters such as fires, floods, and earthquakes.

HUMANITARIAN CONSIDERATION IN DISASTER RESPONSE

The most important part of disaster management is that all agencies taking part in rescue and relief work should respect all human beings and should not be looked down upon as helpless recipients of assistance. The responding agencies should ensure that assistance is given without any discrimination of nationality, race, religious belief, class, or political favor. The main issues during the response phase of a disaster are related to the evacuation of pregnant women, lactating mothers, elderly, and physically and mentally challenged.

CONDUCTING EXERCISE FOR DISASTER MANAGEMENT

"Practice makes a man perfect." Practice is an important aspect of the preparation process for disaster and a practical and cost-effective way to prepare for response and recovery. Exercise enables us to know the areas that need improvement and the operation plan that can be revised and training improves proficiency in executing these plans. Participants are placed in a simulated situation and required to function like a real

event. Preparedness and operational plan are tested by doing the exercise. The main reasons for conducting the exercise are as follows:

- To test and evaluate plans, policies, and procedures
- To detect planning and procedural weakness
- To detect gaps in resources
- To improve coordination and communication within the organization
- To clarify and train the individuals in their role and responsibilities
- To improve individual performance

Four types of exercise are helpful:

1. Drill
2. Tabletop exercise
3. Functional exercise
4. Full-scale exercise

Drill: Drill is a coordinated supervised activity to test a single specific function. In this, there is no need to activate the whole machinery and the role is to practice and perfect one small part of the response plan and put tight focus on the potential problem area. Drill activities may range from simple operational procedures to more elaborate communication and command post drill. Four components of the drill are as follows:

1. Preparation for drill
2. General briefing to participants
3. Use of audiovisual aids
4. Monitoring of exercise

Tabletop exercise: This is an analysis of an emergency situation in an informal and stress-free environment. A group of participants examine and resolve the problem through constructive discussion. The exercise starts with reading out a small hypothetical emergency and then the facilitator leads the tabletop discussion. The discussion-generated problems focus on how participants would respond in real emergencies. Participants are allowed to take their time in arriving at a conclusion. Tabletop exercise usually lasts for 1–4 hours or more. The advantages of tabletop exercises are as follows:

- Provide a low-stress discussion of coordination
- Provide a good environment for problem-solving
- Provide opportunities to various agencies to know each other and coordinate well
- Provide good preparation for functional exercise

Full-scale exercise: A full-scale exercise coordinates the several activities of the disaster management cycle, tests several emergency functions, and activates an incident command system or emergency operation command; thus, a scale exercise simulates a real event as closely as possible.

The following measures are taken for realism:

- On-scene action and decision
- Simulated victim
- Search and rescue requirements
- Communication devices
- Equipment deployment
- Actual resource and personnel allocation

The exercise begins with a description of events in the form of mock emergencies such as a collapsed or a burning building, a simulated chemical spill on a highway, or a terrorist attack. The incident command center or emergency operation center (EOC) is activated. The responder has to take action and one or more controllers manage the exercise. All the stakeholders such as policy personnel, coordination personnel, operational personnel, and field personnel take part in the full-scale exercise. At the end of the exercise, debriefing and evaluation are conducted.

PREPARING THE EMERGENCY DEPARTMENT FOR MASS CASUALTIES

Hospital Disaster Management Committee:

- Medical Director
- Medical Superintendent
- Additional Superintendent/DMS
- Heads of departments such as Emergency, Surgery, Orthopedics, Medicine, and Laboratory Radiology
- Heads of operation theater (OT), Security, Store/logistics in-charge
- Blood Bank Officer
- Nursing Superintendent
- Ambulance

In-hospital challenges during disaster management:

- Additional bed space
- Biological warfare/Chemical warfare
- Temporary isolation ward
- Barrier nursing, universal precaution
- Additional OT tables
- Cancel routine/Elective surgery
- Monitor consumption of essential drugs and supplies
- Ensure adequate supply
- Documentation including medicolegal record (MLR)
- Crowd management
- Media management
- Proper identification, tagging documentation of dead
- Creating temporary morgue
- Maintaining the essential services, water power supply, emergency lights, and waiting area

Creating the additional capacity for disaster:

- Utilize all available beds
- Additional bed capacity: Vacant beds, daycare beds, preoperative beds, trolley beds, folding beds, floor beds
- The patient whose elective surgery is planned can be discharged, patients requiring domiciliary/outpatient department (OPD) care.
- Utility areas (side rooms, galleries, seminar rooms, etc.) can also be used.

Logistic support system for EOC: There should be separate stock for routine day-to-day emergencies and for disaster. Inventory should include:

- All essential medicines
- Dressing materials
- Splints
- Disinfectants
- Vaccines
- Emergency trays
- Surgical supplies
- Resuscitation room
- Resuscitation kit

- Electrocardiogram (ECG), defibrillator
- Ventilators
- Suction machine
- Oxygen
- Endotracheal (ET) tubes
- Stretchers
- Wheelchairs
- Linen, blankets, etc.

MASS CASUALTY MANAGEMENT

Establishing the Emergency Operation Center

It serves as a central command post during a disaster, generally established outside the emergency department (ED), should be large enough for key people and support staff, and should be located in a safe area (**Table 4**).

How to activate and when to activate ICS:
- Determine who will activate the ICS
- Notification to hospital personnel
- Briefing all core members regarding assignments and clear immediate direction
- Activation of ICS should be announced using standardized codes, such as "disaster code"

Mass casualty: When an unexpectedly large number of injured/ill persons need emergency medical care at the same time, it is referred to as mass casualty. The aim in a mass casualty situation is to "do the best for the most, not everything for everyone" and "doing the best for the most."

Goal: To apply trauma triage principles in multiple patient scenarios

The grading of the mass casualty is done as follows:
Grade I: 10–15 victims
Grade II: 16–30 victims
Grade III: >30 victims

TABLE 4: Sequence of activities in the emergency department during mass casualty management.

Assignments	*Strategies*	*Coordination*
• Assembly of team • Roles and responsibilities • Personal protection equipment distribution	• Patient identifications • Triage tagging • Documentation	• With command center • Use of mobile
Mass casualty—triaging and treatment		
• Victim identification • Rapid vitals assessment and physical examination • Tagging according to triage categories • Care priorities • Documentation • Disposition • Regular communication with the emergency command center		
Debriefing		
• Evaluation of triaging decisions and evaluation of strategies • Assessment of medical and diagnostic performance • Discussion about communication and management skills		

Disaster triage: The objective of disaster triaging is focused on the critically ill patients and saving the maximum number of lives with limited medical resources and doctors.

Simple Triage and Rapid Transport System Principle: *Tag—Treat—Transfer….*

The objective is to locate, identify, and tag priority-1 patients who require immediate care and transportation. "Triage tags," applied to patients, make one's task of sorting much easier. It is of four different colors: red, yellow, green, and black. Fold the triage tag to show appropriate color on the outside. Priority patients are those with a good chance of survival.

Simple Triage and Rapid Transport System (START) focuses on three areas:
1. Respiration
2. Pulse rate and quality
3. Mental status

Goal: Correction of life-threatening condition: Airway or breathing problem and profuse bleeding

How to identify so many unknowns:
- Name
- Mass Unique Health Identification (UHID)
- Marks of identification—tattoo, scar
- Belongings—purse, clothes, DL, ID
- Typical injuries—amputation

Mass casualty incident: Situation may be one or combination of biological, nuclear, fire chemical, explosion, or natural event and natural disaster with mass casualty incident.

Chemical and Radiological Disaster

Disasters such as earthquake, landslide, road traffic accidents, and hurricane are more common than chemical and radiological disasters but it is essential to have planning for chemical and radiological events because they have the potential for major disruption to clinical care and create hazardous consequences such as chaos and confusion. Hospitals should have a trained emergency team to deal with chemical and radiological exposure (**Table 5**). A decontamination area with shower and place for stocking of antidotes for toxicants should be within the ED (**Table 6**). The components for chemical and radiological management (disaster management cycle) are the same as any other disaster (already discussed earlier). Decontamination of radiological activity is to be dealt in the same way as chemical activity. Clothes should be removed and after showering, the patient should be scanned by radiation detector equipment.

Common challenges in a chemical event:
- Failure to identify the offending agents for hours or days
- Medical team gives only supportive care (act blindly initially)
- Mistaken diagnosis
- Inadequate resources in the ED for effective management of large number of chemical exposure victims
- Medication errors
- Chaotic and confusion in society

Offending chemical agents can be identified with the help of the following observations:
- Vital signs
- Mental status

TABLE 5: Common clinical features of chemical and radiological exposures.		
Toxins	***Common features***	***Examples***
Irritant gases	Irritation of eye, ear, nose, throat, wheezing, breathlessness, chest pain, and tightness	Ammonia, chlorine, nitrogen dioxide, phosgene
Chemical burns	Painful skin, mucous membrane irritation	Hydrochloric acid
Organophosphate	Pinpoint pupil, eye pain, breathlessness, wheeze, sweating, drooling of saliva, vomiting, diarrhea, seizure, coma	Organophosphate, carbamates insecticides
Solvent	Headache, nausea, confusion, syncope	Paint thinners, lubricants, methylene chloride
Metabolic poisoning	Unconsciousness, hypotension, cardiac arrest	Cyanide, hydrogen sulfide
Radioactive material	Vomiting, delayed onset of skin manifestations	

TABLE 6: Recommended stock of antidotes in the emergency department.	
Atropine 1 mg/mL	16 mg
Dextrose 50%	100 mL
Diazepam 5 mg/mL	40 mg
Hydroxocobalamin plus sodium thiosulfate	4 kits
Methylene blue	8 units
Naloxone 1 mg/mL	16 mg
Pralidoxime 1 g vial	10 mg
Prussian blue 500-mg capsules	12 capsules

- Pupil size
- Involvement of mucous membranes
- Lung findings
- Skin examination where the skin has to be looked for burn, moisture, color

SUMMARY

Return to normal activity as soon as possible is the important goal for effective disaster management. A detailed after-action report is helpful in the improvement of a disaster management plan. Revision of disaster management plan and regular mock drills should be conducted.

CHAPTER

Mass Casualty Management

Saurabh Dalal

INTRODUCTION

Mass casualty management (MCM) is the exercise of saving "maximum number of people in minimum time, with minimum resources"; therefore, this chapter is dedicated to save lives on a mass scale. The MCM comes into play "when a mass casualty incident (MCI) has occurred during any mass gathering."

"What is exactly a mass gathering?" "It is the influx of large number of people to any mass gathering events that may give rise to specific public health risks" as defined by the World Health Organization (WHO). Further, when we come to breaking up the jargon, we need to understand what exactly does an "MCI means." "MCI basically creates stress, even in those hospitals which have adequate resources, because by definition 'mass casualty' is an occurrence which is beyond the resource capacity of the health facility at the given time."

Mass casualty incident could lead to an event resulting in illness and/or injuries that disrupt the routine functioning of the nearby hospital/health facility/locality/jurisdiction and/or of the whole region. As per the WHO, MCI is "any event resulting in a number of victims large enough to disrupt the root cause of emergency of health-care services." As observed in the past few decades, MCIs have been characterized by quantity, severity, and diversity of patients who can rapidly overwhelm the ability of local medical resources to deliver comprehensive and definitive medical care. These MCIs have been occurring more frequently in recent decades and can affect countries of all socioeconomic backgrounds. So, therefore, preparedness toward MCM needs to be well in place, in the community as well as by the authorities, because the community is, in any case, the first responder; therefore, they need to be confident in any given situation.

BACKGROUND

In order to understand the history of MCM, we need to understand the kind of MCIs that have been taking place in the history. During the last century, events creating a large number of casualties have been infrequent but with depressing repetition, which has absorbed the attention of the world community. In these years, nations have increased to sufficient population densities and have developed technologies of sufficient power to create the conditions for sudden catastrophe, whereby in a relatively brief time span an enormous number of people may be killed or injured.

When discussing nuclear war, reference to precedent may admit sources of serious error, since in terms of the scale of effects, this disaster would depart fundamentally from anything the world has yet experienced. Yet people still struggle to comprehend what nuclear war might mean, if only to give better warning now. As part of this attempt to make real the unimaginable, it is instructive to inquire into how massive numbers of casualties have been managed in the past. The perspective taken here is the organization of medical response. Wars and major civilian disasters provide the context and the time frame dates from the US Civil War.

The current theory of MCM rests on the concept of triage, according to which casualties are sorted into categories by severity of injury and treatment plans assigned to each based on an assessment of transport availability and resources. The word is said to derive from the French *triage*, meaning the process of sorting by quality, and its use in the wool and coffee trades during the eighteenth and nineteenth centuries carried the distinct connotation of separating higher from lower quality.

Although the process of prioritizing military casualties on the basis of wound severity has been traced to Baron Dominique Jean Larrey, surgeon-in-chief of Napoleon's Russian Campaign, the term *triage* was first applied in this context during the World War I. The British Expeditionary Force used *triage* to mean *division into three*: (1) Those who could withstand travel back from the front, (2) those who required immediate surgery, and (3) those whose injuries were so severe that they would be left to die. The US military command currently prefers the term *sorting*, but in all other respects it relies on the concept of triage in its protocols for MCM. The main causes apart from natural disasters are manmade disasters such as terrorist bombings and accidents:

- Planned events such as sporting and mass gathering events
- Conventional, which usually have some level of recurring frequency (transportation incidents, burn, and severe weather events)
- Chemical, biological, radiological incidences

- Nuclear agents from an unintentional or accidental release or act of terrorism
- Catastrophic health events (nuclear detonation, major explosion, major hurricane, pandemic influenza, or others)

In India, the National Disaster Management Authority guidelines on medical preparedness and MCM serve as a basic framework for managing mass casualties; several capacity-building activities and mock drills have been carried out across the country in accordance with the guidance.

CASE STUDIES

Mass gathering events pose critical health challenges, especially for the control of diseases. The rising population, better connectivity, and scope of travel have increased the frequency and magnitude of mass gatherings and underscored the need to shift the discourse from reacting to the public health issues they throw up to taking active steps in preventing them based on evidence through research.

Kumbh Mela: The Largest Human Gathering on the Planet

One of the largest human gatherings in India, the *Kumbh Mela*, is a religious event in India that constitutes the largest number of people gathered at a specific place and at a specific time. Understanding the *Kumbh Mela* can highlight the health challenges faced and provide crucial lessons for the management of mass gatherings. The investigations undertaken at the recent *Kumbh Mela* in the city of Allahabad have showcased what kind of mammoth efforts are undertaken to manage such big events without any accidents. Many in-depth studies on the *Kumbh Mela* have generated evidence for context-specific measures to address the complex health challenges of mass gatherings.

Kanpur Rail Accident Tragedy

One of the recent examples of efficient MCM was the accident of the Patna–Indore Express, in which as many as 142 people were killed and >200 injured when 14 coaches of the train were derailed in the Kanpur Dehat district of Uttar Pradesh on a Sunday; this was one of India's worst train accidents of the decade. The derailment happened at 3.10 AM near Pukhrayan, about 100 km from Kanpur. Most of the 500 passengers on board were sleeping and some of the shocked survivors recalled how they got jolted out of their slumber by a violent thud.

- Army initiated the rescue operations throughout the night and recovery vehicles were deployed to clear the wreckage. A team of doctors and paramedics were also deployed at the spot to help in rescue operations.
- Two NDRF teams from Varanasi and another from Lucknow were also rushed to the accident spot.
- Medical assistance of all kinds was offered. Rail mobile medical units were also rushed to the site. All the injured were rushed to hospitals; immediate medical help and hospitals like King George's Medical University in Lucknow were kept on standby.
- The primary care on-site and first aid were carried out after extrication from the coaches. This was a classic case of a mixture of multiple mortalities and morbidities in the rural Indian context and reiterated need of pan-nation preparedness for all hazards, both natural and manmade.

Tughlakabad Hazardous Gas Leak Tragedy, New Delhi

Hazardous material is commonly referred to as HAZMAT or dangerous goods by the industry and these are chemicals that can constitute a health hazard or physical hazard. In the early hours on May 6, 2017, the driver of a truck carrying a container with 80 drums of an agrochemical pesticide powder observed leakage from some containers. A total of six drums had sprung leaks and, at 7:30 AM, local laborers spread soil over the ground spill and poured water to wash the crystals away. This triggered a chemical reaction that caused the release of toxic fumes. The chemical cloud was carried by winds into a local school where students inhaled the gas and developed burning sensations in the eyes, breathlessness, pain in the abdomen, and nausea.

The school principal alerted local authorities at 7:43 AM and evacuated all the students. The NDRF, Police, Fire, and medical services responded and evacuated the affected children to nearby hospitals. A total of 578 symptomatic girl students and 37 teachers were shifted to local hospitals and treated. Scrutiny of the Material Safety Data Sheet (MSDS) identified that the HAZCHEM was 2-chloro-5-(chloromethyl) pyridine (60%) ($C_6H_5Cl_2N$, commonly known as CCMP), an organic corrosive, an acidic compound, and a pesticide intermediate.

The key aspect in such a massive accident was on-time and on-site triage. A total of 578 symptomatic girl students and 37 teachers were shifted to local hospitals. About 310 were sent to the Hakim Abdul Hamid Zamia (Majeediya) Centenary, 66 to the Apollo Hospital, 171 to Okhla ESI, 65 to the Batra Hospital, and 3 to the AIIMS Trauma Hospital where they were given first aid and discharged after 6–7 hours of observation. Of those affected, 378 had burning sensation of the eyes, 164 had spasmodic cough and breathing difficulty, 51 had abdominal cramps and nausea/vomiting, and 22 developed a mild skin rash. The symptoms were mild and responded to symptomatic treatment. No specific antidotes were necessary, and all the school children were discharged in the same evening. This event reemphasized the focused capacity building within the communities and health systems to deal mass casualties effectively.

INNOVATION AND BEST PRACTICES

The MCM is an innovation from the war-room science to civilian science. It is being developed as a structured tool globally to recognize the effort of preparedness and thus provide the right thrust or mix of all the elements of authority/science/response mechanisms and equipment and to save maximum lives, with a minimum number of resources in minimum time. This has emerged as a management tool for emergency medicine practice. Most recently, post-Sendai framework, the mass casualty and public health events are addressed under a combined Health Emergencies and Disaster Risk Management Framework and Public Health Emergency Preparedness and Planning initiative.

It is important to look at how the concepts of first responders, triage, prehospital care, and MCM have linked together in the hospital disaster management planning, particularly look at the surge capacity in times of need and activate the incident response system (IRS) to prevent anarchy. This customized approach to trauma and injury whether in the case of bomb blast, CBRN (chemical, biological, radiology, and nuclear) or a simple chaos caused by stampede all are MCIs

but have different approaches to deal with in case of school bombings; similarly, there is a very specific response to be tailored. Therefore, in the dearth of basic MCM training, we find it difficult to work in sync with emergency room physicians; this absence of skills leads to increased casualties. There are very few examples where the amalgamation of "lessons learned" have been brought into future use.

The counter-strategy to MCIs will be to develop MCM tools like trauma systems based on data-intensive models integrated with a decision support system, to make sure that victims of mass casualty get on-site care, and also replicated at each level of the healthcare system, i.e., from a smaller to a larger setup and even during transport. The most recent initiatives such as the World Health Emergency programs and WHO Emergency Medical Teams (EMT) should be widely endorsed and training to different cadres should be provided. The EMTs are an important part of the global health workforce and have a specific role. Any doctor, nurse, or paramedic team coming from another country to practice healthcare in an emergency needs to come as a member of a team. This team has quality, training, and equipment/supplies so it can respond with success rather than impose a burden on the national system. The EMTs strive for self-sufficiency, a quality of care that is appropriate for the context, with credentials that meet the minimum acceptable standard of the WHO.

BRIDGING THE GAP

In our country, till date spiritual festivals/gatherings were treated as "confusion" and nonfocused or rather random steps were being taken to provide health security, but lately these events, whether road-shows by Kavadiyas, which is visible on state/national highways in north-India, or the *Kumbh Melas* organized every 3 years, have been treated in a cautious manner with government agencies working along with global security agencies/disaster management planning agencies to draw up plans to respond to any mishaps. New innovative approaches such as two-seater fire extinguisher bikes were introduced for easier access.

The mantra/process of *"triage, treat, and transfer"* is being followed for MCM, but in order to sustain any process we need to have a framework. The framework on which the MCM rests is the IRS certified by the National Institute of Disaster Management (NIDM) in India. This framework outlines the role and responsibility of each of the components in the response chain right from administration, community, healthcare professionals to organizers of the event.

INCIDENT RESPONSE SYSTEM

The IRS (**Flowchart 1**) is an effective mechanism for reducing adhoc measures in *response*. It envisages a composite team with various sections to attend to all the possible *response* requirements. The IRS designates officers to perform various duties and get them trained in their respective roles. No matter what forms government and public administration take, the National Emergency Management Systems should include:

- Identification of lines of authority, from the national to the local level
- Financial arrangements for funding emergency work
- Arrangements to ensure that government and community activities are maintained (e.g., creation of parallel or "hardened" communication systems to take over if normal voice or data transfer systems are affected)
- National stockpiling of appropriate resources (including provincial or state and local prepositioning of stockpiles)
- Database of national experts for advice on specific problems
- Protocols and formal arrangements for coordinated efforts with other countries or between provincial/state governments within the country.

NATIONAL EMERGENCY OPERATIONAL AND PREPAREDNESS STRUCTURE

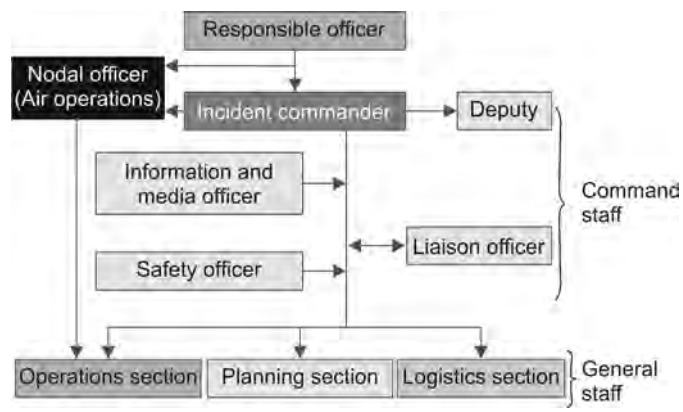
The MCM concept has travelled a long way, from being an ad hoc understanding to an integral part of any medium to large event. The three core issues in terms of managing any mass gathering would be (1) surveillance, (2) response, and (3) the system's ability to rapidly detect and implement appropriate and commensurate measures to contain/minimize the impact on the health system (**Flowchart 2**).

The system is helpful in maintaining the state of alertness for prolonged periods of time throughout the mass gathering. The local medical services and hospital system are able to manage large number of patients in case of emergency. Ultimately, food and water safety, i.e., the ability of the local infrastructure to ensure safe preparation of food and its delivery including safe water to attendees of mass gatherings, is also a key aspect that needs to be looked at from a preparedness and public health perspective to prevent any adverse events of mass poisoning.

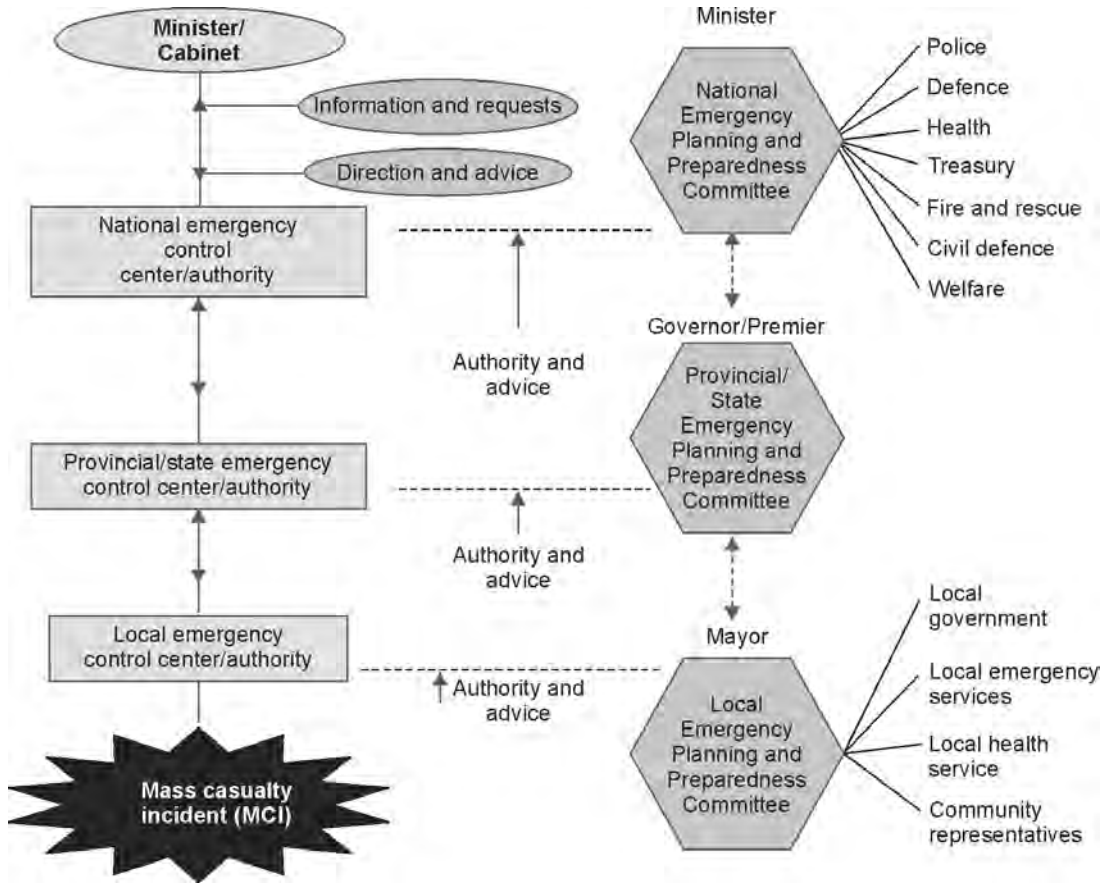
Bridging the gap between the healthcare system and the hospital and from policy to patients'/mass gathering perspective is key for safer future. Till date, random preparedness was being undertaken globally on mass gatherings, but formal steps have been initiated by public institutions such as WHO and other global bodies to come up with structured response mechanisms to develop a culture of focused response.

WAY FORWARD

The way forward on MCM would necessarily include sustainability element in the system. Therefore, specific MCM



FLOWCHART 1: Incident response system.



FLOWCHART 2: National emergency operational and preparedness structure.

response plans for each of the genres should be created/planned. Further, creation is not the "key to success"; rather practicing those plans in the form of drills at regular intervals is the approved way forward, to bring in the concept in the form of "a natural response" among the community.

Sensitive response plans such as radiation emergencies should be regularly rehearsed and documented and well exhibited in the designated area. Another sensitive area for preparation is terrorism; globally, this form of human casualty has presently become a part of our daily lives in many countries. Therefore, a district-/state- and national-level plan should be created and disseminated among the teams so that during the activation phase, everyone is clear about his/her roles and responsibilities. In the public services of our country such as airlines, railways, roadways, and general traffic, the partnership of trauma with MCM is key to success, especially in metros. We need to localize the global perspectives and carry forward the management implications of this partnership, so that resources are directed where they are required to essentially save lives in times of chaos.

SUMMARY

When an unexpectedly large number of injured/ill persons needs emergency medical care, at the same time it can be termed as "mass casualty situation". The aim in a mass casualty situation is to "Do the best for the most, not everything for everyone" and "doing the best for the most". Main goal of mass casualty management is to apply triage principles in multiple patient scenarios.

In other term exercise of saving "maximum number of people in minimum time, with minimum resources", is "MCM". The MCM comes in to play "when a MCI has occurred during any mass gathering". The MCM is transformed from the war-room science to civilian science. Over the time MCM developed as a structured concepts internationally to recognize the effort of preparedness, and thus provide the right guidelines of all the elements of authority/science/response mechanisms and equipment to save maximum lives with minimum number of resources in minimum time. Mass casualty management has emerged as a management tool for emergency medicine practice.

Preparedness for Chemical, Biological, Radiological, and Nuclear/Energetics Disasters

29
CHAPTER

Shaza Karrar, Mohammad Anzal Rehman, Saleh Fares

INTRODUCTION

As far back as ancient times, the capacity for offensive agents and vectors to precipitate massive, population-wide losses to human life has been evident. One of the earliest accounts of an infectious epidemic describes the plague of Athens in 430 BC, where an unknown disease characterized by fever, pustular rash, and diarrhea resulted in the death of up to 100,000 people under siege in the city of Athens. Over the years, a multitude of mediums capable of producing mass casualty have been discovered, classified as chemical, biological, radiological, nuclear/energetics, and commonly grouped under the acronym CBRN/CBRNE. CBRN emergencies can present as natural phenomena or accidents that arise secondary to nonadherence to contaminant guidelines or negligence, such as the coolant system failure that resulted in a reactor explosion at the Chernobyl Nuclear Power Plant in 1986. However, during the past 100 years, the world has seen an unprecedented increase in chemical, biological, and nuclear agents being implicated in acts of terrorism, leading to the realization of their potential as weapons of mass destruction (WMD). There is no doubt that CBRN threats are a clear and present danger in modern civilization. In the year 2020, the global pandemic caused by the novel coronavirus, SARS-CoV-2 (severe acute respiratory syndrome-coronavirus-2), also known as "Coronavirus disease 19 (COVID-19)," showcased the unprecedented breadth and devastation that can be associated with these events. Therefore, all healthcare providers must equip themselves with the tools needed to recognize, prevent, and manage these low-probability, high-impact occurrences and their catastrophic consequences.

CBRN PREPAREDNESS AMONG EMERGENCY PROVIDERS

Healthcare providers in the prehospital and emergency department settings are uniquely integral to CBRN incidents, representing the frontlines of defense in disaster management. However, several studies evaluating preparedness among emergency workers around the world found that a large number of providers were not confident in their ability to adequately manage CBRN incidents, with various training simulations highlighting significant gaps in awareness and proficiency in these scenarios.

One proposed explanation for the prevalent gaps in knowledge and preparedness is the general lack of prior staff experience with these events as well as a relatively low integration of formalized training in CBRN preparedness in most healthcare institutions. An online survey assessing training among 1,028 Emergency Medical Services staff in Canada revealed that only 63% of providers received some form of training to work in a contaminated environment.

Fortunately, over the past decade, several training tools, exercises, and guidelines have been proposed and successfully implemented by hospitals to improve staff awareness and optimize institutional response to CBRN events. Furthermore, international societies such as the World Association for Disaster and Emergency Medicine (WADEM) have made significant progress in promoting high-impact disaster awareness and preparedness at a global scale.

All emergency healthcare providers should strive to update individual and institutional awareness of CBRN incidents. The integration and practice of regular, standardized training exercises in the acute care setting are useful in optimizing the local emergency response against potential high-impact threats.

APPROACH TO A CBRNE INCIDENT

The potential threat of a CBRNE incident holds a frightening risk of infrastructure and environmental destruction, large-scale mortality and morbidity, and a devastating economic impact. A CBRNE incident occurring would have severe implications on a broad national level. These include, but are not limited to, loss of life, a threat to public health safety, political and psychosocial repercussions, and burdens to the healthcare systems. Additionally, these agents may cause extensive contamination prolonging their associated harm. Hence, it

is necessary to establish a strategic response and develop effective countermeasures and protocols to help mitigate risk, minimize the potential loss of life, and collaboratively manage a CBRNE incident if it ever materializes.

CBRNE weapons and warfare have urged international efforts to enforce laws and treaties to monitor and regulate the existing CBRNE risks. Covering international treaties would go beyond this chapter's scope; therefore, the aim of this chapter will be on the approach and preparedness for a CBRNE incident and later on converge to each weapon preparedness, risk stratification, and management depending on its nature. The primary purpose of a CBRNE disaster preparedness approach and possible associated mass casualty training is to take all the necessary measures of mitigating the potential risk of an incident in order to prevent it and, in case it occurs, to have a strategic, controlled, and effective response to minimize its implications.

Before we go further into CBRNE preparedness, we must understand the value of disaster risk stratification and management as an initial approach to better identify opportunities for hazard reduction and mitigating losses. Disaster Risk Management, henceforth, should be a structured and systematic approach to enable any organization or healthcare system to consolidate efforts, allocate resources, and aim for minimal losses. Disaster management at a larger scale aims to diminish potential losses, ensure a rapid medical response to victims, achieve effective recovery, decontaminate, and minimize further harm from the incident. The disaster management cycle demonstrates the ongoing process to reduce the impact of a disaster incident, react during and immediately following a disaster, and take steps to recover after a disaster has occurred (**Fig. 1**). All four phases of the disaster management cycle do not always occur in this particular order; often these phases overlap in the cycle and the length of each can differ significantly depending on the severity of the incident. Each CBRN threat differs substantially concerning its weapon nature and potential risk and associated damage. Hence, the disaster management approach would address each weapon's nature to encounter its specific potential risk and response. A brief overview of each phase definition is given in the following text, and later, we will review each specific weapon disaster management approach.

FIG. 1: Disaster management cycle.

MITIGATION

Mitigation represents measures taken to prevent and reduce the impact of the disaster. For example, it may include building codes and zoning, vulnerability analysis, public education, and prevention.

PREPAREDNESS

Preparedness constitutes response planning, training, and educational activities. For example, formulating preparedness plans, disaster response drills, mock codes, and developing warning systems set up before a disaster could occur. Preparedness training theoretically and practically, as well as research, is an integral component of combating the evolving threat of a disaster and CBRN incidents.

The abruptness of such incidents may prohibit response activation, which poses a serious challenge. Therefore, training through mock drills and exercises needs to be conducted to hone the responder's skills and reflexes to decontaminate and remove victims from the agent's source promptly.

Part of preparedness would consist of efforts taken to recognize a potential event via identifying indicators and triggers. Indicators are measures or predictors of changes in demand and resource availability, while triggers are decision points to respond to these indicators that require adaptations in terms of contingencies, crises, and return toward the conventional system.

Mitigation and preparedness phases are usually developed and enhanced in anticipation of a disaster incident. Developmental efforts would play a key role in involving a contribution from the community, healthcare systems, humanitarian organizations, prehospital, and police or military authorities, encompassing all relevant parties to be involved in the immediate response and long-term recovery phase.

Appropriate preparedness in these two phases significantly enhances response and recovery phases in the cycle, better warnings, and reduced vulnerability or prevention of disasters during the next cycle. It may include reshaping public policies, plans, and modifications in causes of such incidents or mitigating potential live risks.

RESPONSE

CBRN Scene Management

Response encompasses the efforts utilized to minimize the hazards created by a disaster. Effective scene isolation mitigates consequences by restricting access to and from the incident scene and controls the movement of contaminated victims, providing a safe parameter for responders to manage and contain the incident, and prevent any further release of the contaminant substance.

In the view of an incident, an emergency response or incident response team would be the first to respond to the incident scene. The first person on-scene would typically serve as an incident commander until relieved by a senior. He/she would take appropriate measures of equipping personal protective measures, report to supervisory personnel

on the nature of the incident and potential threats, initiate decontamination measures, and set up evacuation procedures and triage of victims. A defined Incident Commander would activate emergency response teams and mobilize all response efforts and local recourses to the scene, further restricting access to the surrounding areas of risk and evaluating the severity and impact of an incident and its required safety measures.

The first emergency response team at the scene usually approaches the scene with caution parallel to wind directions, assesses the scenes, establishes incident command, recognizes indicators of the nature of CBRN weapon used and hazardous materials of harm. Furthermore, they would estimate the number of casualties, carry out primary triage and decontamination procedures, and approximate needed resource requirement and allocations.

In a mass casualty due to a CBRN incident, before detecting and analyzing the weapon/agent utilized, incident zoning, triage, decontamination, and treatment of victims take priority. Several triage systems can be applied to CBRN casualties, none of which are standardized globally. It is essential to utilize a triage and decontamination system that is simple, direct, easy to follow, and available to medical recourses. More on triage systems is delved into in the mass casualty section of this chapter.

CBRN incidents can occur due to industrial disasters, occupational exposure, natural catastrophe, warfare, or acts of terrorism. These incidents present different challenges for all responders, necessitating the rapid decontamination and treatment of a significant number of casualties while taking critical measures to ensure the well-being of the personnel managing the incident.

The detection following a CBRN incident is part of a triad of actions consisting of detection, identification, and monitoring. Specific devices designed to detect gas, nuclear agents, and radiation are available for detection utilization. The ability of devices to detect all CBRN agents does not exist. Therefore, it is essential to identify incident variables that should be detected and organized according to the devices and personal protective equipment (PPE) required.

Personal Protective Equipment

All scene responders must take appropriate measures to protect themselves before entering the contaminated area. The use of PPE to protect the airway, skin, and eyes is an indispensable component of emergency response. Limitations to the use of PPE are restriction of physical activity, dehydration, heat-related illness, and psychological effect. These limitations can be avoided by training emergency personnel to use PPE appropriately (**Fig. 2**).

Level A PPE should be used when the highest level of respiratory, skin, eye, and mucous membranes protection is needed. A typical Level A conveys a chemical-resistant fully encapsulated suit, overgloves, and boots integrated into the suit. Respiratory protection is a self-contained breathing apparatus. Level A protection is required for entry into an unknown hazardous environment.

Level B PPE is used when the highest level of respiratory protection is needed, but lesser protection to skin and eyes is needed. It represents a chemical-resistant hooded suit, double gloves, overboots, and a self-contained breathing apparatus and may be used for decontamination procedures for an unknown substance and for entry into hot zones where the agent is not caustic.

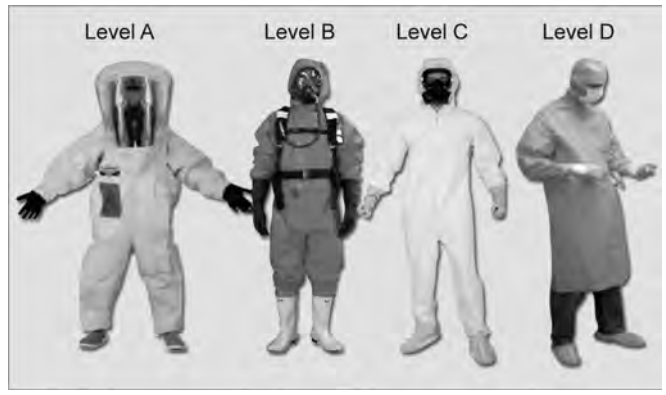

FIG. 2: Personal protective equipment levels. ***(For color version, see plate 1)***

Level C PPE is utilized when the type of airborne substance is known and identified, similar to Level B, but uses an air-purifying respirator instead of a self-contained breathing apparatus. Level C PPE can be used only after the hazardous substance has been identified and upon verification of adequate oxygen in the environment.

Level D PPE is used for droplet precautions and consists of a gown, head cover, mask, gloves, and shoe covers. A more enhanced mask with a higher filtration rate can be utilized in the case of a known airborne substance.

CBRN SCENE MANAGEMENT ZONES

When it comes to a CBRN incident site zoning, a clean treatment zone needs to be set up, at least 300 yards upwind of the contaminated scene; this is referred to as the cold zone. The contaminated area is referred to as the hot zone. What separates the cold and hot zones is a warm zone, utilized for decontamination. A warm zone is usually set up several 100 yards away from the hot zone and 50 yards from the cold zone. All responders must leave the hot zone via specially designated pathways into the warm zone where they will be decontaminated.

No medical care is provided within the warm zone awaiting the decontamination process. Therefore, before leaving the emergency care area, the patient must be stabilized to the extent that his/her condition will not deteriorate during the decontamination process. After receiving emergency care, a casualty must go through the decontamination station before receiving more definitive care in a clean environment. Decontamination takes 10–20 minutes.

Decontamination Considerations

Each CBRN incident type necessitates a distinctive triage system and decontamination principles that naturally go along with each other. These principles consider command control, planning resources, task forces, decontamination operational sites, and allocations. Decontamination decreases the risk of incident-related contaminants to victims and health providers and personnel. Generally speaking, delaying the stabilization of critical victims for decontamination should not put a victim at additional risk. Qualified triage personnel would determine the priority of stabilization efforts and decontamination. Hence, these two processes are designed along and parallel to

each other to reduce the risk of contaminants while ensuring safety and safe treatment or stabilization of causalities. General principles of decontamination would include promptness of initiation and priority and necessity when it comes to victims or location.

Chain of Custody and Evidence Documentation

Maintaining a documented chain of custody is of high importance to stratify future risk and perpetrators. It would include process and procedures and digital fingerprints. In principle, the chain of custody does not interfere with the response efforts, triage, treatment, or decontamination procedures.

RECOVERY

Recovery constitutes the restoration efforts and allocated resources utilized in returning the community to normal. Recovery may include temporary housing of affected victims and involved personnel, expanding medical care capacity and services, rehabilitation, reconstruction, and restarting regular services.

CHEMICAL AGENTS

Chemical agents are described as toxic compounds that were designed to cause injury or death. Their appeal as easily synthesized substances that, once disseminated, carry with them the potential to generate large-scale casualties made them a popular agent of warfare in the First World War, being responsible for over 1.3 million casualties and approximately 90,000 deaths over a 4-year period.

In the years that followed, the devastating loss of life attributable to chemical warfare, as well as rising frequencies in their use for acts of terrorism, culminated in the enforcement of the Chemical Weapons Convention (CWC) in 1997 which effectively prohibited the use, development, acquisition, stockpiling, or transport of chemical weapons and/or their precursors. However, despite this, the threat of attacks using these agents looms ever larger, and emergency providers must be prepared to combat their potentially hazardous effects.

Chemical warfare agents usually exist in solid or liquid form. However, these substances are oftentimes very volatile and allow for extensive dispersal through aerosolization and conversion to gaseous forms. Key features responsible for determining the potential harm from these agents include their inherent toxic capacity, route of entry in humans, mechanism of action, stability, and miscibility (ability to mix with solvents or thickeners). The various types of chemical agents can be classified based on their physiological effects on humans. **Table 1** outlines some of the more prominent chemical agents identified over the years with their relevant mechanisms of toxicity, route of exposure, and clinical characteristics.

Chemicals are usually introduced into the body by inhalation, absorption, ingestion, or inoculation, rapidly acting or with delayed effects. The principles of management after exposure to chemical agents center around the removal of the patient from further exposure to the toxin; attention to airway, breathing and circulation (ABCs); prior to evacuation; and during decontamination. Rapid identification of the offending agent based on history and/or examination can allow for the initiation of specific antidotes for reversal of symptoms as outlined above. Therapeutic measures are otherwise largely supportive, depending on the organ system affected, and include antibiotic coverage to prevent secondary bacterial infection where appropriate.

Once again, it should be emphasized that triage be performed at every echelon of medical care, preferably several times, because the health status of some chemical casualties categorized as "delayed" may change within a short time and develop unanticipated life-threatening conditions such as severe bleeding.

BIOLOGIC AGENTS

Microorganisms are abundant in nature worldwide, and the vast majority of species present no risk of harm to humans. However, various pathogenic strains do exist and have been known to cause illness or even death. Biological agents represent a subgroup of these disease-causing microorganisms unique for properties such as enhanced toxicity, environmental stability, transmissibility, and host susceptibility to the exposure that enables their implication in population-level morbidity and mortality.

The characteristics that allow biological agents to induce mass casualty may be a consequence of their natural propensity for disease and transmission. An example of this was the emergence of the novel strain of *SARS-CoV-2* in Wuhan, China, in 2020. An alarmingly high rate of transmission and uncertainties surrounding effective management strategies contributed to the rapid evolution of COVID-19 from a localized outbreak to a worldwide pandemic.

Unfortunately, biological agents can also be intentionally manipulated to target specific individuals and populations, with emerging techniques, to synthesize easily and artificially augment agents to permit improved infectivity and survivability raising concerns for their use as agents of bioterrorism and warfare in the future.

Biological agents can be grouped into four main categories, namely (1) bacteria, (2) viruses, (3) fungi, and (4) toxins, as outlined in **Table 2**. Several attempts have been made to classify these agents based on the burden of their disease. The US Centers for Disease Control and Prevention (CDC) categorizes biological agents as A, B, or C based on their relative risk to national security as well as ease of production and/or dissemination. Other guidelines, such as the European Directive 2000/54/CE, classify pathogens from groups 1 to 4 in increasing order of risk or hazard to humans, with decreasing order of availability of effective preventive or management strategies. Although most national guidelines may prove useful when developing local defense strategies against biological agents, several inconsistencies among different risk classifications reveal opportunities for improved collaboration and global consensus on standardized methods of evaluating biological agents.

As evidenced in **Table 2**, many biological agents, while reserving their high transmission rates, may not produce symptoms until several days, making it especially difficult to respond to incidents of disease spread. Therefore, some of the key factors contributing to an effective defense strategy against biological events center around establishing techniques to detect and diagnose the presence of disease rapidly.

TABLE 1: Classification and characteristics of chemical agents.

Agent class	*Examples of agents*	*Mechanism of action*	*Route of exposure*	*Clinical characteristics*
Nerve agents	• *G-agents*—Sarin, cyclosarin, tabun, and soman • *V-agents*—VE, VG, VM, VR, and VX	Inhibition of acetylcholinesterase leads to the accumulation of acetylcholine in the body	Inhalation or skin	• *Symptoms*: Miosis, hypersalivation, runny nose, diaphoresis, bronchospasm, muscle excitation, arrhythmias, seizures, respiratory paralysis • *Management*: Supportive ± seizure control. Atropine + pralidoxime
Vesicants (blister agents)	• *Mustards*—mustard gas, nitrogen mustard • *Arsenicals*—Lewisite *Phosgene oxime*	• *Mustards*—DNA alkylation leads to cell death • *Arsenicals*—enzyme inhibition causes NADPH and glutathione oxidation, resulting in disruption of metabolism and cell death • *Phosgene oxime*—unknown	Inhalation or skin	• *Onset*: Hallmark of mustards is postexposure latency (symptom-free period) for several hours. Arsenical exposure—immediate pain • *Symptoms*: Corneal irritation/erosion, skin erythema/blistering, rhinorrhea, hoarseness of voice, cough. Phosgene oxime causes wheals followed by eschars (no blisters) • *Management*: Mainly supportive. No antidote for mustards or phosgene • *Antidote for arsenicals (Lewisite)*: Dimercaprol/British Anti-Lewisite (BAL)
Blood agents (cyanogenic agents)	Hydrogen cyanide, cyanogen chloride	Inhibition of cytochrome oxidase in cells, preventing oxygen utilization	Skin, inhalation, or ingestion	• *Symptoms*: Confusion, nausea, weakness, cyanosis, CNS excitation followed rapidly by depression, convulsions, coma, and cardiorespiratory arrest • *Antidotes for cyanide toxicity*: Hydroxocobalamin, sodium nitrite followed by sodium thiosulfate
Choking agents (pulmonary agents)	Phosgene, diphosgene, chloropicrin, chlorine	• Chlorine—acidification of gas causes irritation/necrosis of respiratory tract mucosa/lung tissue→pulmonary edema/ARDS • Phosgene/diphosgene—disruption of alveolar surface tension→pulmonary edema	Inhalation	• *Symptoms*: Nose and throat irritation, dyspnea, wheezing, cough with increased secretions, hypoxia on room air is a sign of ARDS-such as lung injury • *Management*: Mainly supportive with high-flow oxygen/mechanical ventilation as needed. Possible role of corticosteroids, bronchodilators and/or inhaled sodium bicarbonate
Incapacitating agents (tear gases)	Chloroacetophenone (CN), O-chlorobenzylidene malononitrile (CS), oleoresin of capsicum (OC), and dibenz [b, f]1: 4-oxazepine (CR)	Direct toxicity, possibly through NADH-dependent receptors of skin and mucosa	Inhalation or skin	• *Symptoms*: Lachrymators—conjunctivitis, tearing of the eye, blepharospasm • *Sternutators*: Sneezing, upper respiratory tract irritation • *Vomiting agents*: Nausea/vomiting • *Management*: Immediate decontamination + supportive treatment

(ARDS: acute respiratory distress syndrome; CNS: central nervous system; DNA: deoxyribonucleic acid; NADH: nicotinamide adenine dinucleotide hydrogenase; NADPH: nicotinamide adenine dinucleotide phosphate hydrogen)

Various tactics are used to decrease the spread of infection from potential secondary aerosolization. Three basic methods of decontamination are (1) physical removal, (2) chemical deactivation, and (3) biological deactivation of the agent. Biological deactivation has not been developed to the point of being practical.

Effective management policies will undoubtedly address triage, workflow, medical supplies, equipment delivery, and manpower. Public health education and safety programs should be incorporated to raise awareness of the extent of disease and risk of transmission. Disease-prevention techniques should focus not only on reducing exposure and

TABLE 2: List of major biological agents with clinical characteristics of their associated diseases.

Agent/Disease	*Route of exposure*	*Clinical characteristics*
Bacteria		
Bacillus anthracis/ Anthrax	Inhalation, direct contact, and ingestion	• Symptoms begin in 2–5 days • *Cutaneous*: Vesicular ring→ulceration→black eschar, lymphadenitis, edema • *Inhalation*: Initial flu-like illness, followed by fever, dyspnea, respiratory distress, cyanosis • *Gastrointestinal*: Fever, nausea/vomiting, hematemesis, bloody diarrhea, dysphagia • All forms can also lead to meningitis and death • *Antibiotics*: Ciprofloxacin, doxycycline, amoxicillin • *Prophylaxis*: Ciprofloxacin licensed vaccine available
Francisella tularensis/ Tularemia	Bite from arthropod vector, direct contact, ingestion, and inhalation	• Symptoms begin in 3–6 days • Fever, chills, headache, malaise, ulcer at the site of infection can lead to lymphatic infiltration • *Antibiotics*: Aminoglycosides (streptomycin, gentamicin) • *Prophylaxis*: No fully licensed vaccine available
Yersinia pestis/Plague	Bite from arthropod vector, inhalation, and ingestion	• Symptoms begin in 2–6 days • Fever, chills, headache, pain at the bite site, lymphadenopathy, cough, bloody sputum • *Antibiotics*: Streptomycin, gentamicin, doxycycline, ciprofloxacin, chloramphenicol • *Prophylaxis*: Tetracycline, streptomycin, chloramphenicol. No effective vaccine available
Burkholderia mallei/ Glanders	Direct contact and inhalation	• Symptoms usually begin in 1–14 days • Fever, headache, lymphadenopathy, chest pain, mucosal inflammation and/or necrosis, cutaneous ulcers, dyspnea, cough, mucopurulent sputum • *Antibiotics*: Limited efficacy. No FDA approved treatment regimen available • *Prophylaxis*: No effective vaccine available
Brucella/Brucellosis	Inhalation, direct contact, and ingestion	• Symptoms begin in a few weeks up to several months • Fever, arthralgia, headache, malaise, night sweats, and cough • *Antibiotics*: Rifampicin, doxycycline, streptomycin • *Prophylaxis*: No vaccine available
Viruses		
Ebola/Marburg virus, arenaviruses, flaviviruses, tick-borne viruses/hemorrhagic fever	Direct contact, various vectors, inhalation	• Symptoms begin in 2–19 days • Fever, myalgias, fatigue, headache, nausea, vomiting, encephalopathy, thrombocytopenia, bleeding, DIC, shock • *Treatment*: Mainly supportive. Ribavirin useful in some cases • *Prophylaxis*: General lack of available effective vaccines (except in cases of tick-borne virus, yellow fever, and/or chemoprophylaxis
Variola major virus/ smallpox	Direct contact	• Symptoms usually begin after 10–14 days • Fever, rash (macules→papules→vesicles→pustules→scab/scarring), sepsis • *Treatment*: supportive • *Prophylaxis*: Vaccine available
Venezuelan equine encephalitis virus (VEEV)/Encephalitis	Mosquito vector, inhalation	• Symptoms begin in 1–5 days • Fever, vomiting, diarrhea, encephalitis, convulsions, coma • *Treatment*: Supportive • *Prophylaxis*: No FDA-approved vaccine available
Nipah virus/ Encephalomyelitis	Direct contact, animal reservoir	• Symptoms begin in 4–21 days • Fever, headache, myalgia, cough, encephalitis, coma • *Treatment*: Mainly supportive. Ribavirin useful in some cases • *Prophylaxis*: No vaccine or chemoprophylaxis available

Continued

Continued

Agent/Disease	*Route of exposure*	*Clinical characteristics*
Toxins		
Clostridial toxins	Ingestion	• *Clostridium botulinum*: Blurred vision, paralysis, dry mouth, mydriasis. Treatment: Antitoxin • *Clostridium perfringens*: Abdominal pain, diarrhea. Treatment: Supportive
Staphylococcus enterotoxin B (SEB)	Ingestion	• Abdominal pain, nausea, vomiting, diarrhea • *Treatment*: Mainly supportive
Abrin/Ricin	Ingestion, inhalation	• *Abrin*: Abdominal pain, vomiting, diarrhea, pulmonary edema, hemolysis • *Ricin*: Vomiting, diarrhea, gastrointestinal bleeding, hypotension, pulmonary edema • *Treatment*: Supportive, no effective treatment available
Fungi		
Coccidioidomycosis/ Valley fever	Inhalation of spores	• Symptoms begin in 7–21 days • Fever, night sweats, fatigue, cough • Immunocompromised individuals at greater risk of infection • *Treatment options*: Fluconazole, itraconazole, amphotericin B • No vaccine available

(FDA: Food and Drug Administration; DIC: disseminated intravascular coagulation)

transmission but also on exploring options for vaccines and prophylactic treatment.

RADIATION/ENERGETICS

Events associated with the exposure of humans and the environment to dangerous levels of radiation are rare. However, their destructive potential for harm to exposed humans and the environment, coupled with their long-term implications in exposed populations and infrastructures, make them genuinely formidable threats. In 1998, the International Atomic Energy Agency (IAEA) and World Health Organization (WHO) recognized important concepts in managing radiation accidents and published guidelines in their Safety Reports Series.

Radioactive material exposure health risks to responders depend on several factors, such as the amount of radiation received, known as the dose, and the length of time over which the dose is received.

To best respond to radiation threats, it is essential to assess the severity of the inciting event as well as the risks associated with exposure. The International Nuclear and Radiological Event Scale (INES), outlined in **Figure 3**, is a tool used to categorize radiation events into one of seven levels based on radiation dose, radiological barriers, and controls, consequences to affected people and the environment, including *potential* repercussions covered under "degradation of defense in depth."

Individuals may be exposed to a radiological dispersion device (RDD), also known as a "dirty bomb," which would produce injuries from heat, force of the explosion, debris, and radiological dust. Radiation that was dispersed with or without an associated explosive component results in either direct (blast injury) or indirect trauma (projectiles), flash, and/or thermal burns, with subsequent radiation sickness. Upon confirming the initial fatalities after an explosion, the future radiation can be determined. This will be dependent upon the grade of radioactive material and the amount that has been released.

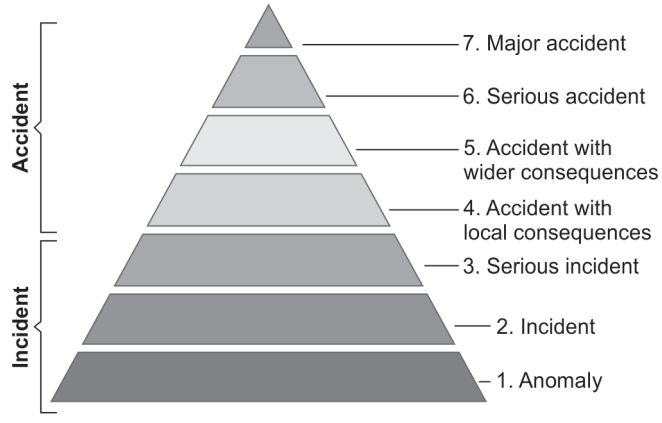

FIG. 3: International Nuclear and Radiological Event Scale (INES).

First responders to the scene are prompted to utilize time, distance, and shielding (TDS) to reduce or eliminate radiation exposure. A further threat to first scene responders to a dirty bomb incident is the possibility of a secondary explosive device planned against the first responders.

The initial triage of patients should attempt to ascertain the extent of exposure, associated injuries, and the degree of internal and external contamination. An RTR system consists of Radiation-specific TRiage, Treatment, and TRansport sites, designed to support medical care following a nuclear incident. Its goal is to characterize, organize, and efficiently deploy appropriate material and personnel assets as close as physically possible to various categories of victims while preserving the safety of responders. After an incident is characterized and safe perimeters are established, RTR sites should be determined in real time, based on the extent of the destruction, environmental factors, residual radiation, available infrastructure, and transportation routes. Such RTR

sites are divided into three types depending on their physical/situational relationship to the incident: (1) RTR1 sites are near the epicenter with residual radiation and include victims with blast injuries and other major traumatic injuries, including radiation exposure; (2) RTR2 sites are situated in relationship to the plume with varying amounts of residual radiation present, with most victims being ambulatory; (3) RTR3 sites are collection and transport sites with minimal or no radiation present or exposure risk and a victim population with a potential variety of injuries or radiation exposures.

Symptoms of exposure are influenced by factors such as the type of radiation, total dose amount and rate, individual susceptibility, and surface area irradiated. Clinical signs may include nausea, vomiting, and erythema within the first 48 hours of exposure, a latent phase with no apparent symptoms, followed by the manifestation of disease days to weeks postexposure in the form of various hematopoietic, gastrointestinal, cutaneous, and neurovascular syndromes. Management involves decontamination measures such as removal of contaminated debris, washing of skin and nasal passage, wound debridement and irrigation, internal decontamination with chelating agents, antibiotic coverage as well as appropriate surveillance, testing, and supportive therapy as needed.

MASS CASUALTY TRAINING

Mass casualty incident (MCI) is defined as an incident that could potentially overwhelm, exceed, or threaten the local capacity of response available due to the severity of the incident and the number of casualties. In an MCI, multiple organizations are augmented by protocols and measures to maintain an effective emergency response.

Decontamination, triage, and rescue of casualties are considered the cornerstone of the initial assessment of a CBRN incident, followed by appropriate evacuation of the public at risk and warning systems, which further contribute to saving lives and mitigating exposure risks.

The management of casualties resulting from exposure to a CBRN incident requires appropriate triage assessment and categorization. Separating minor injuries significantly reduces the burden on the healthcare system and prioritizes life or limb-threatening casualties in need of rapid medical care. Furthermore, it rationally distributes these casualty burdens to an appropriate complexity level of care hospitals and healthcare facilities.

During a suspected radiation hazard, responders should be provided ionizing radiation dose estimating devices for use in medical triage and diagnosis of potentially exposed casualties. When it comes to biological incidents, the first indication of exposure may be immediate as in biological toxins or delayed, making it difficult for responders to evaluate possible exposure with victims who may present with delayed onset of symptoms. Some potential biological agents are transmissible among humans and may spread fast after the initial attack; this may become a vital triage planning consideration.

In addition to hot, warm, and cold zones mentioned previously in the chapter, in a CBRN MCI, the incident field triage site should be divided into zones that are conducted at three levels. These consist of (1) on-site triage, (2) medical triage, and (3) evacuation triage. A triage officer would be appointed to each level/zone.

Onsite Triage Hot Zone—Level 1

At this zone, the first responders carry out a rapid categorization of victims with potential life- or limb-threatening injuries needing immediate medical care. First responders can utilize the Simple Triage And rapid treatment (START) protocol for the primary triage during the initial response phase (**Flowchart 1**). Emergency care administered by START teams is restricted to positioning airways, controlling hemorrhage, and elevating the patient's feet. All casualties will be tagged according to the severity of their conditions and placed into one of the following four categories:

1. *Immediate—red tag color*: Victims with spontaneous breathing upon airway positioning, or respiratory rate over 30 per minute, or a capillary refill >2 seconds, or absent radial pulse, or cannot obey the command. These victims can be helped by immediate intervention and transport.
2. *Delayed—yellow tag color*: Victims who are not in immediate or minor category. These are generally nonambulatory; their transport can be delayed, as, despite possible life-threatening injuries, they are not expected to deteriorate significantly over several hours.
3. *Minor—green tag color*: Walking wounded who can assist in their own care. These victims are ambulatory with relatively minor injuries and are unlikely to deteriorate over several days.
4. *Expectant—black triage color*: No ventilation despite airway positioning. These victims have either expired or are unlikely to survive the severity of their injuries. Pain and palliative care should be provided to them.

It is also essential to move casualties triaged as black triage color, who are deceased or unsalvageable, to a site that is easily seen by the public or other casualties. The deceased has to be kept there until law enforcement authorities have acquired a chain of custody evidence, and the living casualties have been evacuated from the scene after decontamination. Deceased casualties require thorough decontamination before they are moved to the morgue or are deemed ready for release.

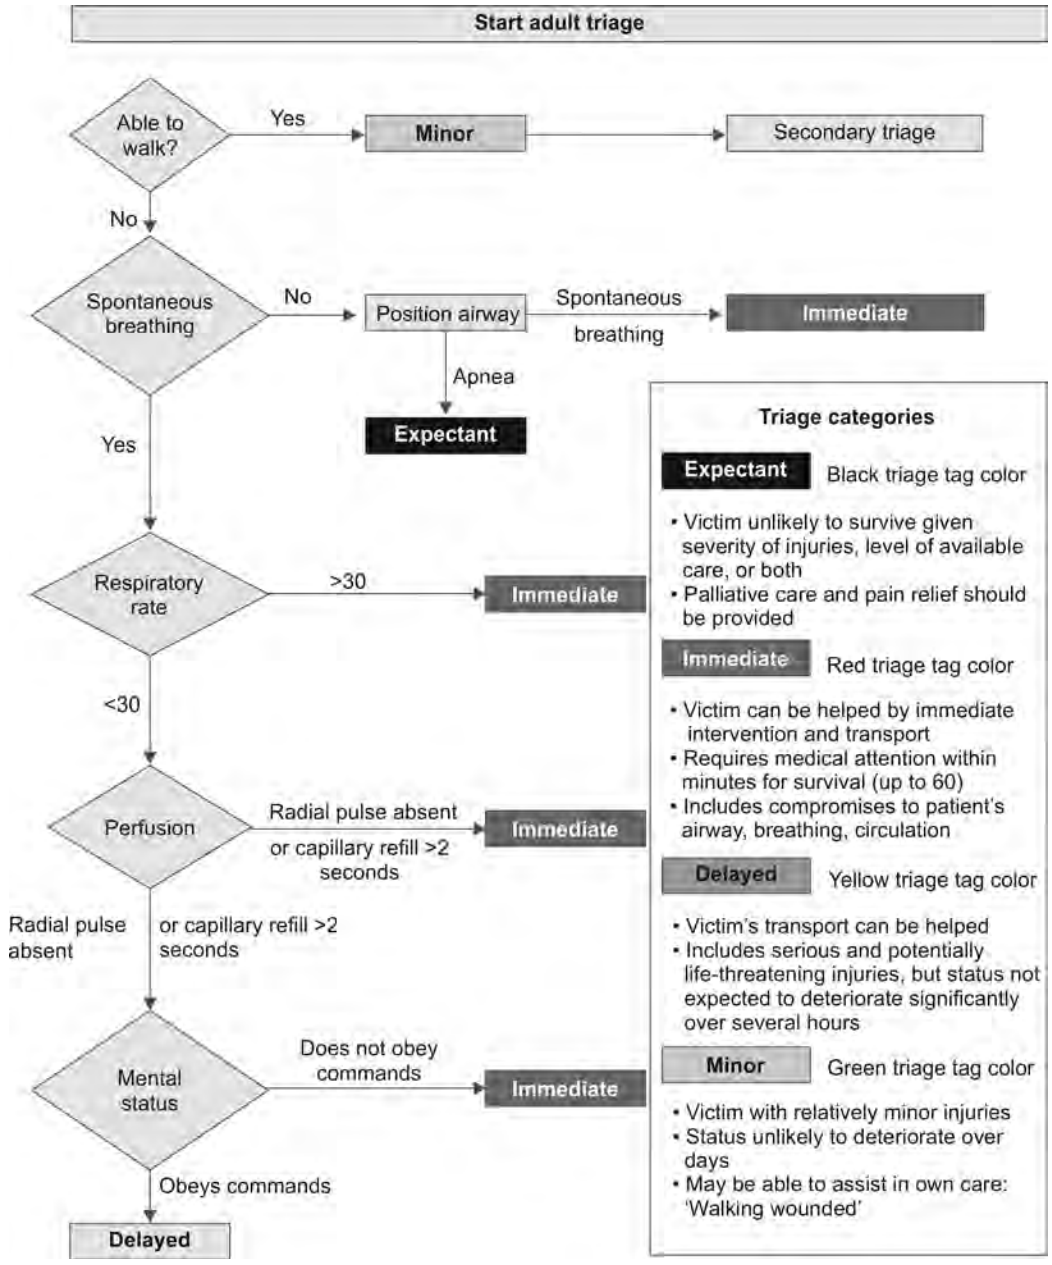
Several triage tools have been developed, including START, Jump START (pediatrics), care flight triage, SALT (Sort, Assess, Lifesaving Interventions, Treatment/Transport), MASS (Move, Assess, Sort, Send), and STM (Sacco Triage Method) models. Supportive evidence for the use of one triage algorithm over another is limited, and the development of effective triage protocols is a vital research priority. Currently, the presence of a standardized MCI triage system that is well validated, reliable, and uniformly accepted remains a significant gap.

Medical Triage Cold Zone—Level 2

This zone carries on a rapid categorization of victims by the most experienced medical personnel available to identify the medical care level needed. Responders assigned to the medical triage zone will perform a *secondary assessment* and complete any required information on the triage tag. Emergency personnel is not required to follow the START protocol during secondary and subsequent triage.

Evacuation Triage Zone—Level 3

This zone assigns priorities to disaster victims requiring urgent transfer to hospitals by air or land according to the severity of the injury and available resources.



(START: simple triage and rapid treatment)

FLOWCHART 1: START adult triage algorithm. ***(For color version, see plate 1)***

Evacuation can help decompress the disaster area and provide further care to critical casualties to off-site medical facilities. On the other hand, there could be several reasons that may delay the evacuation of some casualties; these may include contaminated victims, casualties with transmissible disease, and unstable patients.

SUMMARY

Over the last few decades, more and more sources capable of inducing mass casualty have been identified, grouped under common acronym CBRN/CBRNe (chemical, biological, radiological, nuclear/energetics). CBRN emergencies can be present as natural phenomena or can occur due to negligence and nonadherence to guidelines. The world has witnessed an unprecedented rise in chemical, biological, and nuclear agents being used as an act of terrorism. Undoubtably in modern civilization, CBRN threats are a clear and present danger. Meanwhile various studies evaluated preparedness for disaster among healthcare facilities and found that a large number of providers were not confident in their ability to adequately manage CBRN incidents. In various mock drills and training simulations, significant gaps in awareness and proficiency in these scenarios were also highlighted. Thus, all healthcare providers must take steps to update themselves with the tools needed to identify, prevent, and manage these low-probabilities, high-impact disasters, and their catastrophic consequences. Over the last few years, various hospitals successfully implemented several training tools, exercises, and guidelines to improve staff awareness and optimize institutional response to CBRN events.In the acute care setting integration and practice of regular and standardized training exercises are useful in optimizing the local "Emergency Response" against potential high-impact of CBRN.

30
CHAPTER

Military Medicine

Ahmed Humaid, Saleh Fares, Abdulla Alhmoudi

INTRODUCTION

Military medicine is a broad branch of medicine which encompasses many aims, from treating traumatic injuries of those in active battle to caring for the mental health of service personnel and their families. Historically, military medicine has been more focused on ensuring good health amongst soldiers. Many died from communicable diseases rather than injuries sustained on the battlefield. For example, during the American Revolution in the 1700s, approximately 90% of soldier deaths were attributable to poor sanitation.

Improvements in general public health and modern medicine have rendered this less of an issue. Contrastingly amongst active-duty American personnel between the years 2006 and 2018, only 17.5% of deaths were from illness. Within this group, the highest cause of death was accident (31.9%), followed by self-inflicted injury (23.2%). Only 21.6% died of wounds sustained in active combat. As public health has improved through time, so have modern methods of warfare. The treatment of the injured soldier will very much depend upon the injuries he has sustained.

We are no longer seeing a majority of penetrating injuries. The rise of the roadside improvised explosive devices in both the Afghanistan and Iraq wars has led to increased blast injuries and blunt trauma. Given the stressful nature of these situations, a standardized approach by which to structure initial care is beneficial and has been shown to improve outcomes. This standardized approach has not only improved outcomes within military medicine, but also improved care in civilian trauma. A good example of this is the use of the tourniquet for a major hemorrhage from a limb. This was first researched and applied in combat situations before being implemented more widely in general trauma care.

TACTICAL COMBAT CASUALTY CARE PRINCIPLES

Tactical combat casualty care (TCCC) was the first set of battlefield trauma care guidelines. It was the result of the Naval Special Warfare biomedical research program that it was realized that the most common cause of preventable death amongst injured service personnel was external hemorrhage; however, the use of tourniquets was actively discouraged. The resulting set of guidance was put together comprising a phased approach to care on the battlefield as laid out in **Table 1**.

TABLE 1: Phases of tactical combat casualty care.

Phase	*Tactical situation*	*Aims*
Care under fire	Personnel engaged in combat with the ongoing threat	• Return fire and take cover—superior firepower prevents further wounds/casualties • Direct casualty to self-aid and continue combat or take cover as able • If able, stop life-threatening hemorrhage or place in the recovery position if airway or consciousness impaired
Tactical field care	No longer engaged in a hostile situation	• Field triage (see **Fig. 1**) • Disarm casualty with altered mental status—preventing further injury/casualties • Structured assessment using the acronym MARCH as outlined in *approach to injured soldier* • Perform secondary survey and treat other wounds if able
Tactical evacuation	Transportation available to a higher level of medical care	As per tactical field care, however, increased resources may mean better ability to treat and monitor certain conditions, e.g., traumatic brain injury

(MARCH: massive hemorrhage, airway assessment, respiratory assessment, circulatory assessment, and hypothermia)

FIELD TRIAGE

Field triage is used to identify the priority for the treatment of mass casualties. **Figure 1** shows how they are sorted to ensure that those who need immediate life-saving intervention receive this promptly, whilst identifying those less severely injured who can wait. Traumatic arrest in the context of the battlefield is unlikely to be survivable. Diverting resources when under fire, or in the context of mass casualties to the arrested patient, is likely to result in further deaths. If resources permit during tactical evacuation, it may be that more specialist interventions, such as resuscitative thoracotomy (RT), could be considered.

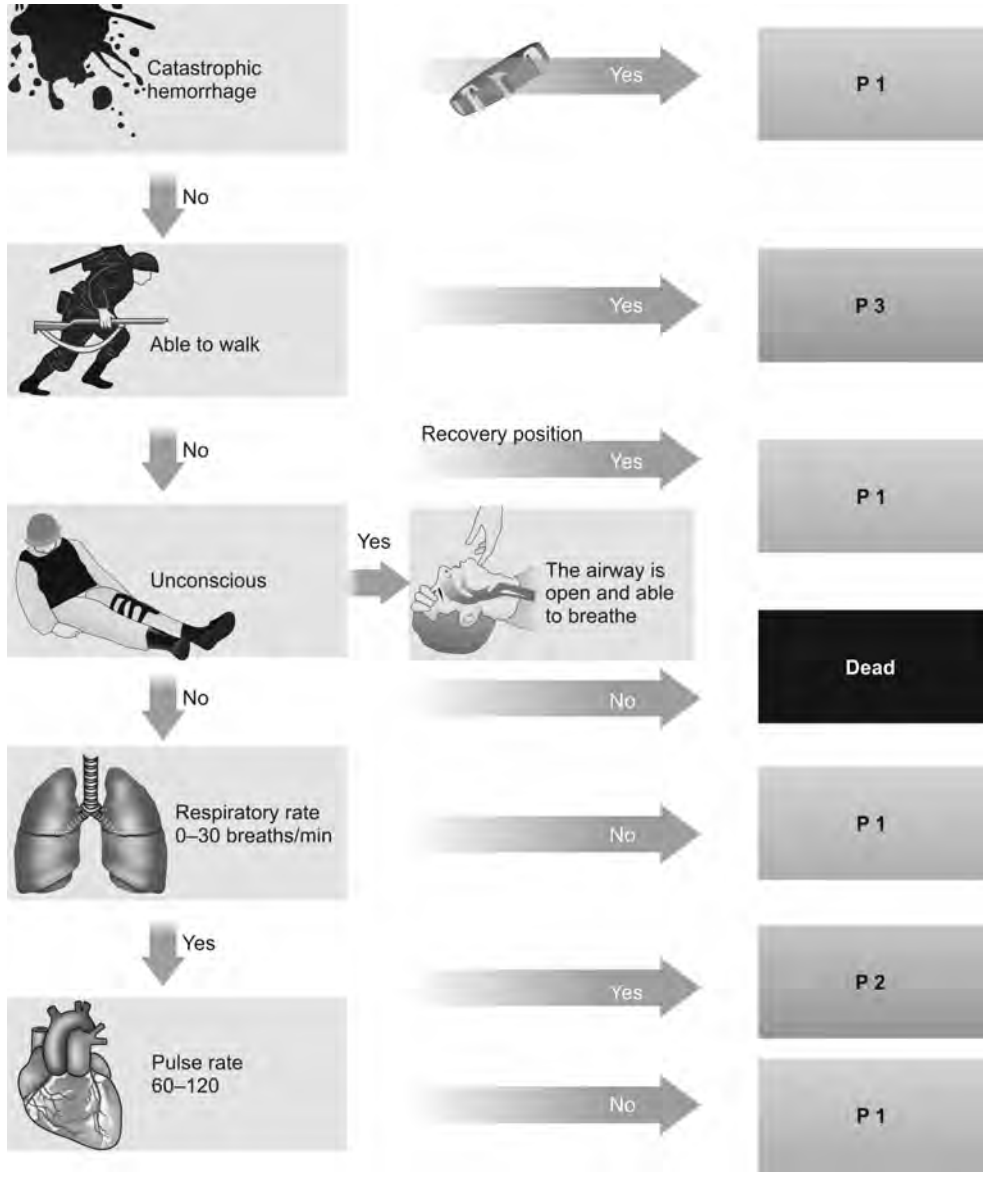
APPROACH TO THE INJURED SOLDIER

During the tactical field care phase of TCCC, a primary survey can be conducted of the patient. Help provided will be limited by resources available to attending medics, though the standard kit carried by forward surgical teams is extensive. **Table 2** is an example of the kit you would expect one of these teams to carry. Though this may vary it gives an indication as to the capabilities of these prehospital responders.

The primary survey has been modified for military medicine to prioritize the treatment of massive hemorrhage—by far the leading cause of preventable death. The acronym MARCH (Massive hemorrhage, Airway assessment, Respiratory assessment, Circulatory assessment, and Hypothermia) is used as a hierarchical structure to approach, with each section having to be corrected before moving on to the next. This is outlined below:

Massive hemorrhage (M): Control any bleeding. This can be done in a number of ways based on anatomical location:

- If from an extremity, apply a tourniquet or direct pressure.
- Bleeding from a junctional anatomic area, i.e., the junction between limb and torso may be better managed by specialized junctional tourniquets as hemorrhage



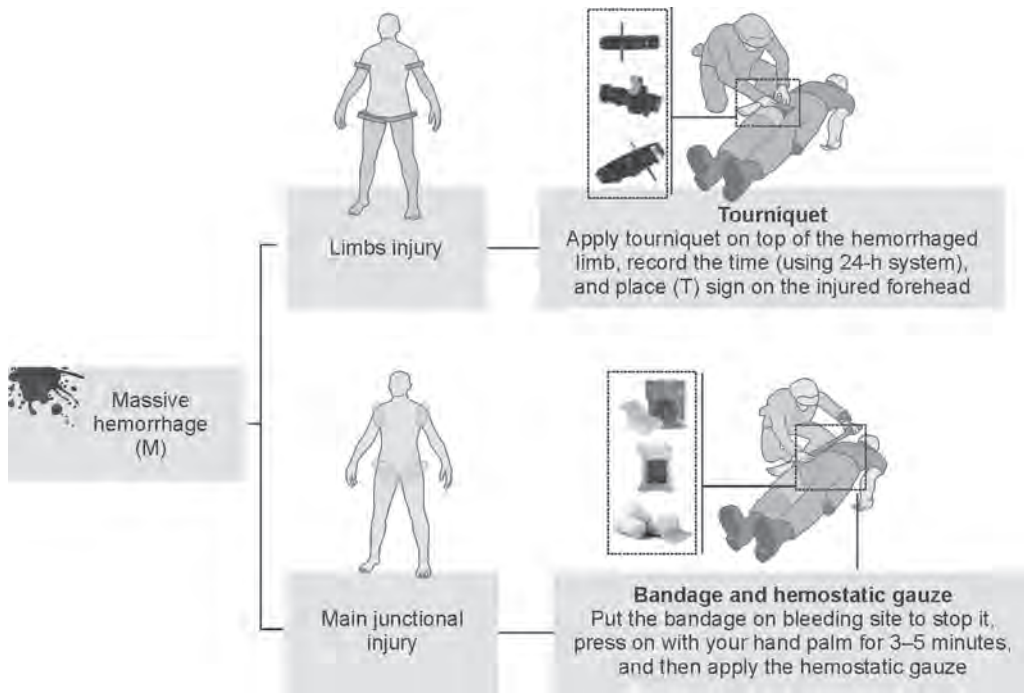
[P1 (Priority 1): immediate life-saving interventions required; P2 (Priority 2): interventions can be delayed but urgent care required within 2 hours; P3 (Priority 3): requires medical intervention that can be delayed without risk to patient]

FIG. 1: Field triage of mass casualties.

TABLE 2: Example kit carried by forward surgical teams.

Combat application tourniquet	*Method for securing tube (e.g., tape)*	*Adhesive on way flutter valve/seal*	*Wound antibiotics of choice (multiple doses)*
Gloves (multiple, sterile, and nonsterile)	Surgical airway kit	Hemostatic bandage	CNS wound prophylactic antibiotics of choice
Protective eyewear	Cleaning swabs	Large dressings	Morphine
Headlamp	Stylets	Skin stapler	Lidocaine with epinephrine
Stethoscope	CO_2 monitoring (colorimetric indicator sufficient)	Benzoin swabs to aid adherence of dressings	Acetaminophen
Red, green, blue, and yellow safety light sticks	Finger pulse oximeter	Hypothermia prevention kit	SAM/Traction splints
Cervical spine immobilization collar	Suction device	IV fluid administration kit	Needled (multiple gauges)
Nasopharyngeal airways	Thoracotomy kit	IV/IO access kits	Sharps bin
Multiple endotracheal tubes including intubation kit	Thoracostomy tube and kit	IV fluids of choice	Indelible marker
Laryngeal scopes (×2) with replacement	Scalpel	Fluid warmer	Mass casualty patient cards
Bag valve mask	Forceps	Pressure bag	Burns dressings
Suction device	Trauma shears	Syringes (multiple sizes)	Sterile water

(CNS: central nervous system; IO: intraosseous; IV: intravenous; SAM: structural aluminum malleable)



Massive hemorrhage (M)
Limbs injury
Tourniquet
Apply tourniquet on top of the hemorrhaged limb, record the time (using 24-h system), and place (T) sign on the injured forehead
Main junctional injury
Bandage and hemostatic gauze
Put the bandage on bleeding site to stop it, press on with your hand palm for 3–5 minutes, and then apply the hemostatic gauze

FIG. 2: Methods of achieving hemostasis depending upon the anatomical site of injury.

is unlikely to be amenable to standard tourniquets or hemostatic agents.

- For torso injuries, hemostatic agents can be used for the direct packing of wounds. If pelvic fractures are suspected, application of a pelvic binder may be helpful in stemming internal blood loss.

Figure 2 illustrates some of the ways in which hemostasis can be achieved through adjuncts, as described above.

Airway assessment (A): Ensure a patent airway. Airway adjuncts can be used; however, in the context of mass casualties, a secure airway is preferable. Cricothyroidotomy is used with greater frequency than in civilian medicine. This has the benefit of greater certainty of correct placement of the tube within the trachea when compared to endotracheal intubation. C-spine immobilization can be considered; however, in the context of care under fire, it is likely to take time which could result in

further casualties. Consideration should be given to a tactical situation when considering immobilization.

Figure 3 illustrates basic airway maneuvers and adjuncts which can be used to secure the airway, and the order in which they should be employed.

Respiratory assessment (R): In the context of trauma, impaired breathing is likely due to hemothorax, pneumothorax, or tension pneumothorax. Ensure that any open chest wounds are sealed with a vented dressing and have a low threshold for needle thoracostomy.

Circulatory assessment (C): Hemorrhagic shock should be treated with permissive hypotension. Casualties are likely to be suffering from acute traumatic coagulopathy and guidance is aimed at preserving the initial clots formed. Aggressive resuscitation may lead to increased bleeding by disrupting these clots. As such, systolic blood pressure should be maintained at around 90 mm Hg.

Tranexamic acid is widely used outside of military medicine in the context of trauma. Its administration within the 1st hour has been shown to significantly improve outcomes in this context. Intraosseous (IO) access is an effective method by which to gain access in patients with poor perfusion quickly.

Hypothermia (H): Prevention of hypothermia is essential. This contributes to traumatic coagulopathy and greater mortality.

Following this, a secondary survey can be performed. If safe to do so, the patient should be exposed and all other injuries identified and tended to. Ensure constant reassessment of the situation and flexibility to move back to the *MARCH algorithm* if there is deterioration.

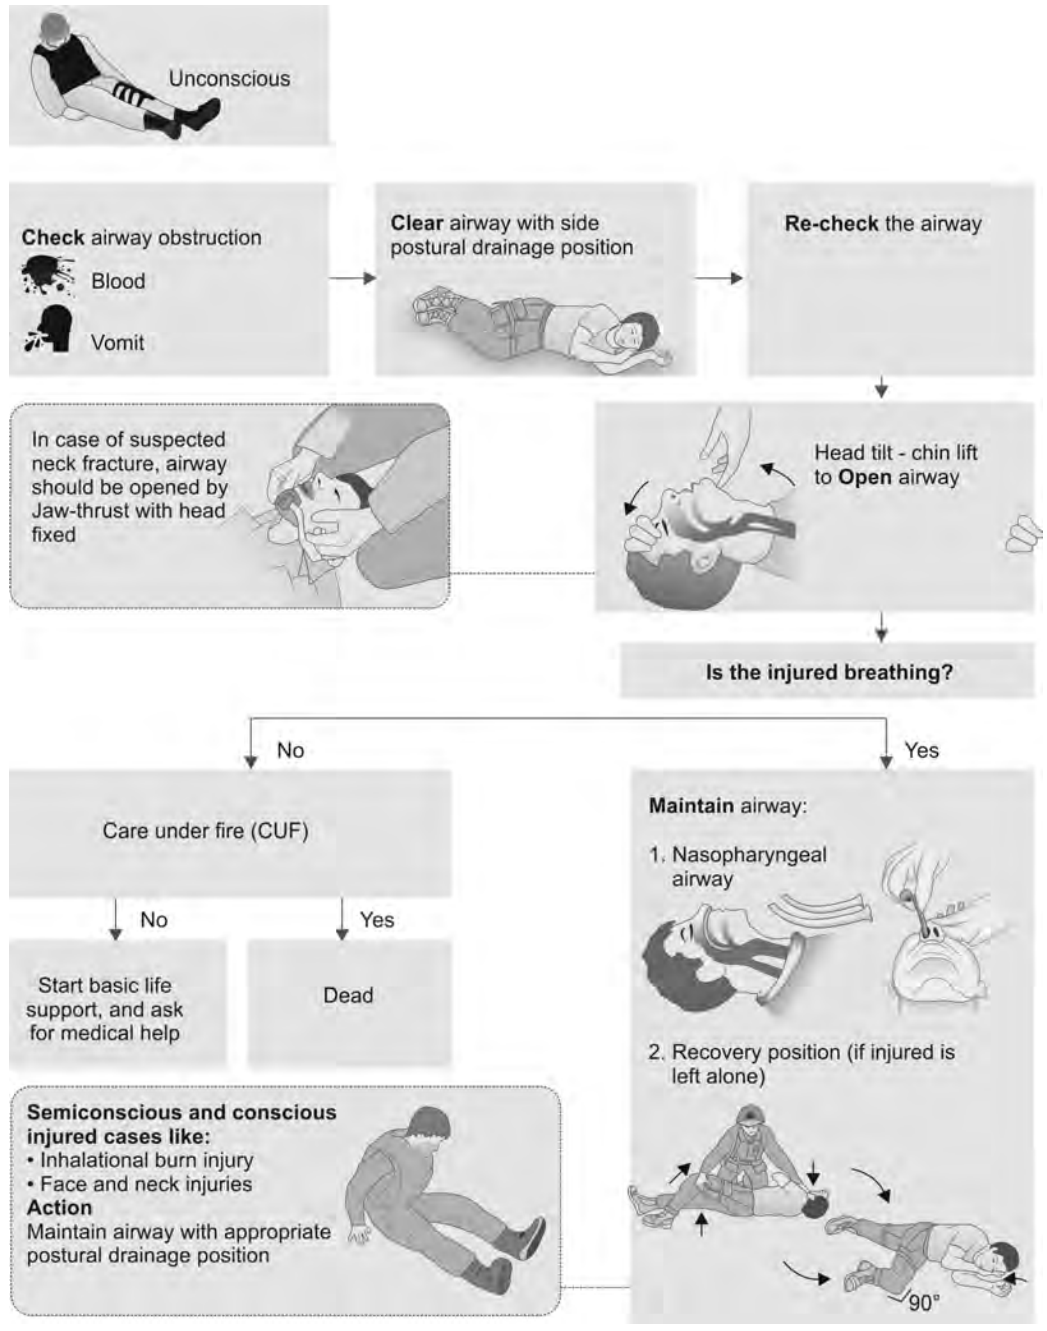


FIG. 3: Methods of positioning and use of airway adjuncts.

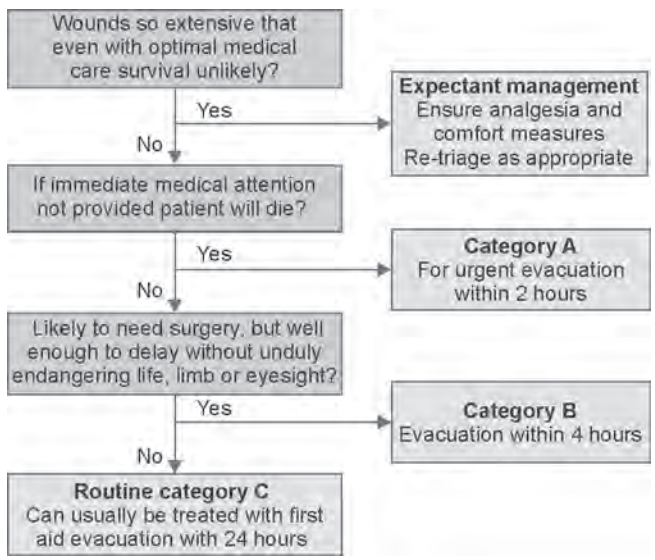
MEDICAL EVACUATION

Medical evacuation (MEDEVAC) is considered a crucial step in the care of any injured patient. It refers to the medical care provided during the movement of injured patients from the point-of-injury (POI) to a higher level of care. The purpose of the MEDEVAC is to take the right injured patient, at the right time, to the right medical facility, using the right transportation method, and providing the right en-route care (**Flowchart 1**).

Ensuring timely evacuation of the patient has been shown to vastly decrease patient mortality. The introduction of "the golden hour," meaning ensuring the transport of a patient for more definitive care, has been incorporated into both battlefield care and civilian trauma medicine, generally improving outcomes.

MEDEVACs are integral to ensuring the safe transport of the patient to each level of care. When it is being conducted to transfer specific patients, who are more likely to survive transport, it is referred to as tactical MEDEVAC. When MEDEVAC is performed to move patients out of operation theatres, thereby decreasing workload in these areas, it is referred to as strategic MEDEVAC.

The evacuation process is most successful when it is taken as a system-wide approach with integrated levels of care. This includes having trained prehospital care providers, well-equipped transportation methods and medical facilities, organized policies and procedures, and robust governance with clear command and control structures, to mention but a few. Several models exist utilizing different resources. There are numerous ambulance types with different capacities and capabilities. Similarly, helicopters (such as the Black Hawk) and fixed-wing aircraft (such as the C-130 or C-17) play a vital role in transporting casualties within the operation theatres as well as strategically.



Wounds so extensive that even with optimal medical care survival unlikely?
Yes
No
Expectant management
Ensure analgesia and comfort measures
Re-triage as appropriate
If immediate medical attention not provided patient will die?
Yes
No
Category A
For urgent evacuation within 2 hours
Likely to need surgery, but well enough to delay without unduly endangering life, limb or eyesight?
Yes
No
Category B
Evacuation within 4 hours
Routine category C
Can usually be treated with first aid evacuation with 24 hours

FLOWCHART 1: Prioritization of evacuation of casualties.

During any MEDEVAC, necessary equipment must be available to ensure the delivery of the best care possible. Every member of the evacuation team must be familiar with everything, well trained on when and how to use it, and know the location to find it.

Medical care during evacuation requires special education and training. There are different levels of providers, ranging from basic to advanced, or even subspecialized. Similarly, special teams are usually tasked with evacuating critically ill patients. Those teams are usually formed by emergency or critical care physicians, nurses, respiratory therapists, and occasionally paramedics. Examples of this include the Critical Care Air Transport Teams (CCATT) in the United States or the Medical Emergency Response Team (MERT) in the United Kingdom.

Survival of the casualty does not only depend on medical care at POI but also on the intermediate and longer term care, including rehabilitation. The surgical teams responding are traditionally split into four "roles," each having their own priorities for management based on the resources available to them. They are outlined in **Table 3**.

Working in austere environments (including safety issues, limited resources, and unfamiliar surroundings) poses several challenges to care providers. Other challenges include dealing with injured patients in contaminated areas or managing a large number of casualties.

When the transportation is made by nonmedical vehicles with no en-route medical care, with a purpose of rapidly evacuating the casualties to a medical facility, it is known as casualty evacuation (CASEVAC). There are numerous types of MEDEVAC and CASEVAC options, with several advantages and disadvantages. This is beyond the scope of this chapter.

CHALLENGES AND INNOVATIONS

Long gone are the days where soldiers could expect to die from minor wounds which become infected. Military medicine has moved on with rapidly administered broad-spectrum antibiotics.

More modern innovations largely target improving survival in battlefield trauma care. The widespread adaptation of the TCCC guidelines reduced battlefield-preventable deaths significantly. Interventions such as extremity and junctional hemorrhage largely contributed to this.

A widely recognized ongoing challenge is reducing death from *noncompressible torso hemorrhage (NCTH).* NCTH is defined by high-grade injury present in one or more of the

TABLE 3: Four roles in the care of casualties.

Role	*Location*	*Time from injury*	*Aims*
1	Point of injury/aid station	Within the 1st hour	Basic first aid, immediate life-saving measures, and triage
2	Forward surgical teams	Within the 1st hour	Ability to provide triage and damage control resuscitation (DCR), with some capability for damage control surgery (DCS)
3	Combat support hospital	24–72 h	Capability for more advanced diagnostics and treatment, including DCS
4	Usually, country of origin or designated hospital	>72 h	Definitive medical care for those whose needs outstrip role 3. Highly specialized input of care

following anatomic domains: pulmonary, solid abdominal organ, major vascular or pelvic trauma plus hemodynamic instability. It carries the highest mortality rate of potentially preventable death in military trauma.

In patients with hemorrhagic shock, the goal is to enable casualties to survive long enough to reach the care of a surgeon capable of performing damage control surgery (DCS). Fluid resuscitation using nonblood products is known for its detrimental effects of dilutional coagulopathy and hence must be avoided. Whole-blood transfusion, or packed red blood cells (pRBC) and plasma in a 1:1 ratio are the best options but most often not logistically possible. *Freeze-dried plasma (FDP)* as a resuscitative fluid has re-emerged as the fluid of choice for hemorrhagic shock at the POI, in both prehospital civilian and military trauma. Studies on the use of FDP showed positive effects on volume expansion and coagulation profiles. It was also shown to reduce the use of pRBC units required when used early during the evacuation of traumatic hemorrhagic shock patients in prehospital settings. FDP has logistical benefits as it can be stored at ambient temperatures for 2 years with preserved efficacy. Each bottle of powdered plasma is easily reconstituted with 200 mL of sterile water before transfusion. These advantages make it an ideal choice for role-1 and role-2 levels and also during helicopter evacuation.

Resuscitative endovascular balloon occlusion of the aorta (REBOA) is a less-invasive option for mechanical homeostatic control of NCTH compared to RT with aortic cross-clamping. Studies have shown mortality benefits with REBOA compared to RT for the control of NCTH. However, it is important to note that REBOA does not serve to replace RT in the setting of thoracic injury, but is currently only generally used for infradiaphragmatic injuries. REBOA has been used in military medicine with success by trained personnel; it should be considered when the casualty presents in a periarrest state, if surgery is likely to be delayed, or where the single operating table is occupied by another case. The placement of REBOA can be done by emergency physicians who are trained and able to maintain their skills as long as a surgeon is immediately available for DCS.

Another area of innovation in battlefield trauma care is optimal analgesia with minimal risks. In an attempt to simplify the battlefield analgesia options, pioneered initially by TCCC, the protocol shown in **Table 4** was devised.

TABLE 4: Triple analgesia option for battlefield pain relief.

Injury severity	*Pain relief*
Minor pain, able to engage in ongoing combat	Oral *acetaminophen* 1,000 mg and *meloxicam* 15 mg
Moderate-to-severe pain, but neither shocked or with respiratory difficulty and unlikely to develop either condition	Transmucosal *fentanyl citrate* 800 µg
Severe pain with either shock or respiratory distress	*Ketamine* 100 mg intramuscularly, 50 mg intranasally, or 20–50 mg intravenously

It is worth noting that nonsteroidal anti-inflammatory drugs (NSAIDs) are not recommended in trauma settings due to their significant cyclooxygenase-1 (COX-1) inhibition causing inhibition of platelet function. However, meloxicam is a selective NSAID that works 90% on COX-2 inhibition; hence, it is preferable in this context.

SUMMARY

Ongoing research in military medicine has a number of challenges to address, this being one small part. However, owing to its very nature, research in military medicine can be difficult. Documentation is likely to be inaccurate in the heat of battle and conducting high-quality randomized control trials poses its own difficulties. The use of large trauma registries has sought to minimize some of these challenges as well as the use of telecommunications. There continue to be high-quality research driving improvements not only in battlefield care but also in general trauma management. Off of the battlefield, there has been greater awareness placed on the psychological impact of trauma in service personnel. This has led to public support groups and funding for psychotherapy. This is likely to continue to pose a future challenge, with the survival rates of trauma patients improving.

31
CHAPTER

Basic and Nondefinitive Airways

Advait Thakor

INTRODUCTION

The human body requires a continuous supply of oxygen (air) and a continuous removal of carbon dioxide to properly function. This is accomplished by a patent airway and adequate ventilation. The airway consists of the upper airway and the lower airway. The upper airway extends from the mouth and nose to the laryngeal inlet. The lower airway extends from the laryngeal inlet to the bronchioles in the lungs. The most common causes of airway obstruction in patients presenting to the emergency department include—infections of the oral cavity, trauma, and burns (**Table 1**).Emergency physician should be able to recognize the features of airway obstruction. The management of airway and ventilation is necessary to provide adequate oxygenation to the patient and is an essential skill to be mastered by emergency physicians. The gold standard for a definitive airway is endotracheal intubation. However, there are basic skills required to be learnt for achieving proper airway management viz.

TABLE 1: Causes of airway obstruction.

Congenital	• *Obstruction above the larynx*—choanal atresia, micrognathia, and Treacher Collins syndrome • *Obstruction at the level of larynx*—atresia and webs • *Tracheal level*—web and tracheomalacia
Infections	*Nose*—septal abscess rhinosporidiosis *Oral cavity*—peritonsillar abscess, infection of floor of mouth *Pharynx*—adenoids retropharyngeal abscess *Larynx*—epiglottis laryngeotracheobronchitis diphtheria *Neck*—Ludwig's angina
Trauma	Maxillofacial trauma, neck trauma, laryngeal trauma, and burn scaring
Tumors	Papilloma, cysts, hygroma, benign tumors (may cause both internal or external narrowing)
Others	• Radiation—edema of surrounding tissue • Pregnancy, obtunded patient, obese individuals

- Basic airway positioning maneuvers
- Suctioning
- Supplemental oxygenation
- Use of airway adjuvants such as oropharyngeal airway (OPA) and nasopharyngeal airway (NPA)
- Bag-valve-mask (BVM) ventilation
- Supraglottic airway devices (SADs)

HOW TO RECOGNIZE AIRWAY OBSTRUCTION IN AN EMERGENCY DEPARTMENT?

Recognition of an *"obstructed airway"* is the first step toward successful airway management. Unobstructed respiration is always "quiet," it is never silent or noisy. Total respiratory obstruction may usually have a "silent" (due to absence of breath sounds and movement of air) presentation. Partial respiratory obstruction is noisy, snoring which may be due to tongue fall. Gurgling sounds due to collection of fluids/secretions in the pharynx. Stridor manifests due to glottic or supraglottic obstruction. Tachypnea may be an early sign of airways and ventilatory compromise. Severely compromised airways may lead to the use of accessory muscles of respiration, sternal retraction, cyanosis, anxiety, sweating, tachycardia, etc. The presentation may be (1) sudden in onset with complete obstruction, (2) gradual onset with partial obstruction, and (3) progressive and recurrent.

AIRWAY POSITIONING MANEUVERS

The principle behind airway maneuvers is that a patient should have an airway as open as possible. This is most efficient when the head of the bed is elevated to at least 30°, if possible. In order to maximize the patency of the upper airway, the external auditory meatus of the patient should be aligned at or above the sternal notch. The maneuvers are:

Head tilt-chin lift: This is done by tilting the head back by giving pressure on the forehead and lifting the chin with the other hand so as to open the airway ***(Fig. 1A)***. *Caution: It should not be done in patients with suspected cervical spine injury.*

Jaw thrust: The aim of this maneuver is to open the airway with minimum movement of cervical spine. The clinician stands behind the patient and places his hands on each side of the face such that the fingertips are at the angle of the jaw on the mandible. The jaw is lifted without tilting the neck causing forward displacement of the jaw which moves the tongue forward (**Fig. 1B**).

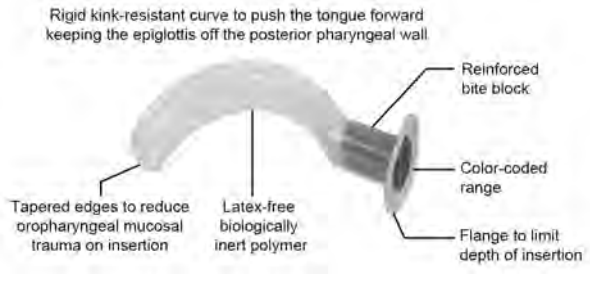
AIRWAY ADJUNCTS

Oropharyngeal Airway

The OPA (oral airways) helps to maintain or open the airway by preventing the tongue from covering the epiglottis. This happens when a person becomes unconscious which causes the jaw to relax and the tongue falls back obstructing the airway. It also helps to make BVM ventilation more effective especially in cardiopulmonary resuscitation. OPA is made up of rigid material and can be divided in various parts to facilitate airway as shown in **Figure 2**. Various sizes of OPA are available (**Fig. 3**) and a proper-sized OPA estimated by the method shown in should be used. Sizing of the OPA—the flange should be approximated, externally, to where it is abutting the lips, and the tip should be able to reach the angle of the mandible (**Fig. 4**).

There are two techniques to use the OPA: (1) open the mouth and with a tongue depressor, push down the tongue toward the floor of the mouth, and insert the OPA directly into

FIGS. 1A AND B: Head tilt-chin lift and jaw thrust maneuvers.
Courtesy: Dr Amit B Nabar.



Rigid kink-resistant curve to push the tongue forward keeping the epiglottis off the posterior pharyngeal wall
Reinforced bite block
Color-coded range
Flange to limit depth of insertion
Tapered edges to reduce oropharyngeal mucosal trauma on insertion
Latex-free biologically inert polymer

FIG. 2: Oral pharyngeal airway (OPA).

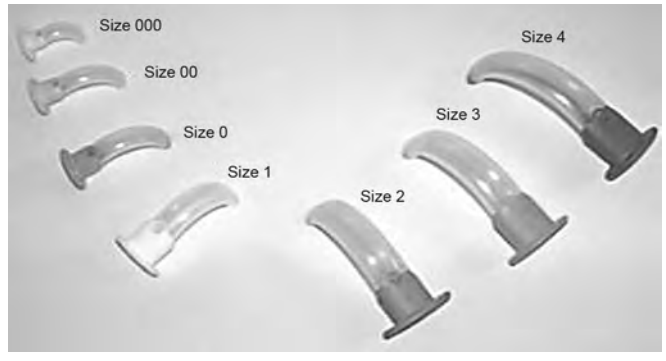


FIG. 3: Various sizes of oropharyngeal airway.

FIGS. 4A TO C: Estimation of (A) correct size; (B and C) Correct technique of placement of oropharyngeal airway.

the mouth over the tongue; and (2) open the mouth and with the tip pointing cephalad toward the roof of the mouth, and insert the OPA in such a way that the concave part of the OPA faces the palate. Advance the OPA and rotate it 180°. *Caution: A proper-sized OPA should be used as a small airway would cause obstruction by pushing the tongue back and a larger airway may induce laryngeal spasm. OPA use is contraindicated* in the presence of gag reflex and if foreign body in the airway.

Nasopharyngeal Airway (Also Called Nasal Airway or Nasal Trumpet)

It is a hollow noncuffed tube which is soft, flexible, and available for various sizes (**Fig. 5**). It is inserted nasally along the floor of the nasopharynx going beyond the base of the tongue to maintain a patent airway. *Sizing the NPA and placement*—the proper size of the tube is measured from the tragus to the tip of nostril. The diameter of the NPA should be less than that of the nostril. A well-lubricated NPA is inserted with the bevel facing the septum of the nose. The NPA is advanced gently along the floor of the nose. The flange should rest on the nostril and may be secured (**Figs. 6A** and **B**). *Caution: If resistance is felt, no force should be used.*

Advantages of NPA:

- It can be used in semiconscious patients with intact gag reflex and cough reflex.
- It can be used in patients with trismus.
- It can be used with patients with wiring of the jaw.

FIG. 5: Nasopharyngeal airway.

Contraindications to use of NPA:

- Patients with central facial trauma
- Patients with suspected skull fracture
- Patients with coagulopathies
- Patients on anticoagulants
- Patients with history of recent transsphenoidal surgery, recent rhinoplasty, or septoplasty

SUCTIONING

The upper airway may be obstructed by material in the airway such as blood, blood clots, vomitus, foreign bodies, etc. In such situations, it is imperative to remove the material from the oropharynx. This requires a properly functioning suction usually with a Yankauer cannula (**Fig. 7**). In case the material is very thick and viscid, it may have to be removed by detaching the tip of the suction cannula and using the tubing directly. Alternatively, a gauze piece held in a Magill's forceps can be used to remove the thick material in the oral cavity. Magill forceps are also useful for removing solid foreign bodies especially in children. *Caution: Keep a watch on the oxygen saturation while suctioning.*

BAG-VALVE-MASK VENTILATION

Once the airway is clear and maintained by maneuvers or airway adjuncts, check the breathing. If the breathing is inadequate or absent, pulse oximetry shows a falling reading, the patient needs to be assisted by BVM ventilation. A BVM is a system comprises a self-inflatable bag with a face mask with a one-way valve, a reservoir bag and an inlet to connect to a source of oxygen.

Parts of the Bag-valve-mask System

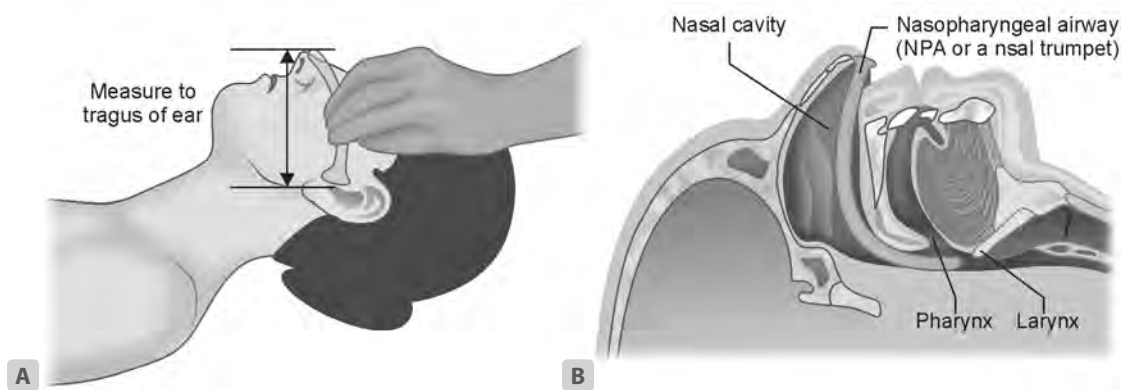
Various parts of the BVM system are shown in **Figures 8A** and **B**.

Face Mask

It is usually transparent and has a cushion at the face end which can be inflated to ensure a proper seal. It is molded so as to minimize dead space.

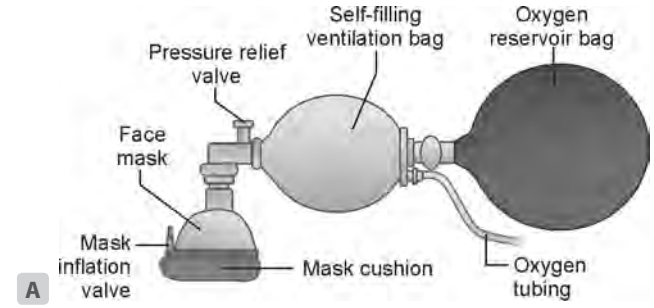
Valve

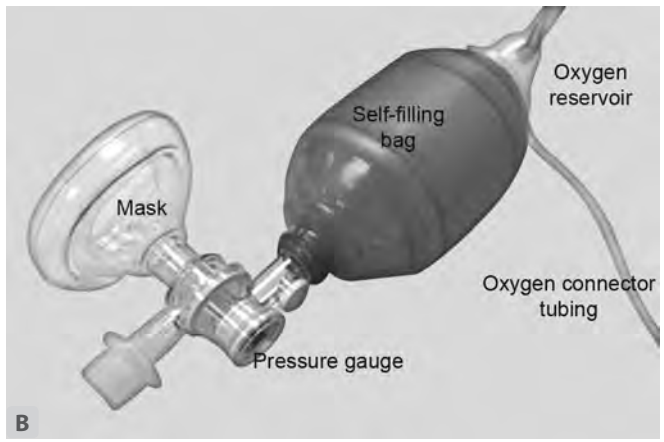
It is a nonrebreathing valve which prevents the exhaled air to go back into the bag. Some valves have a built-in pressure gauge



FIGS. 6A AND B: (A) Estimation of correct size; (B) Placement of nasopharyngeal airway.

FIG. 7: Yankauer suction cannula.





FIGS. 8A AND B: (A) Parts of bag-valve-mask system (BVM); (B) BVM with pressure gauge.

(**Figs. 9A** and **B**). A positive end-expiratory pressure (PEEP) valve can be attached to the exhalation port in some systems.

Bag

It is a self-inflating bag which reinflates after compression. It is usually available in various sizes (e.g., Laerdal™ 240 mL for infants, 500 mL for children, and 1600 mL bag for adults).

Reservoir Bag

It is almost equal to or more than the self-inflating bag so as to give 100% oxygen if required.

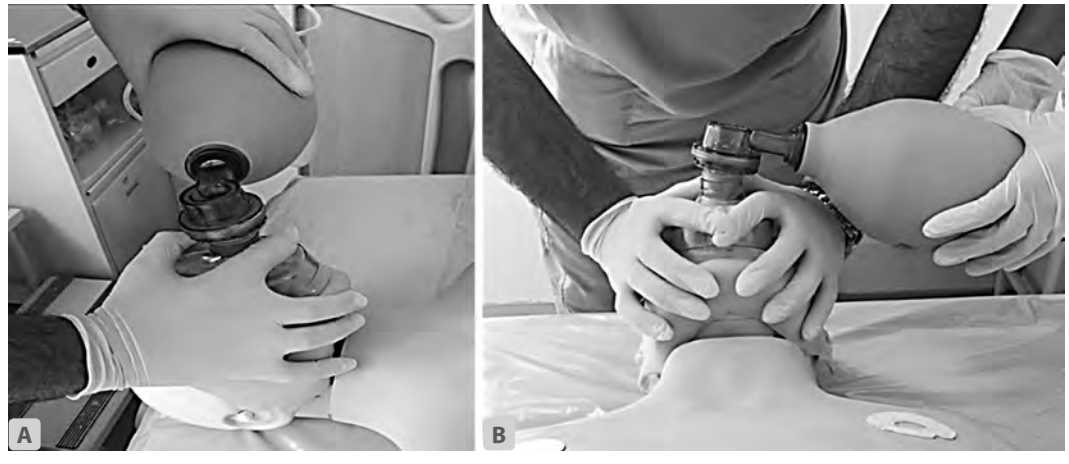
Use of Bag-valve-mask System

It is very important to properly use the BVM system so that adequate ventilation of the patient can be done. The mask has to fit properly to the face of the patient.

The C-E technique of holding the mask achieves this. Herein, the user makes a C with his thumb and first finger and grasps the body of the mask whereas his middle, ring, and little finger form an E to grasp the ramus of the mandible and lift it onto the mask.

Caution: The thumb and index finger forming the C should not push down the body of the mask on the face else there is a chance of the tongue falling back. The three other fingers forming an E should be on the bony part of the mandible and not on the soft tissue.

A single person can follow the above method; however, if there are two persons available, the BVM can be held by one person using both hands for a proper mask fit and the second person compresses the bag. If the ventilation is not proper, use of oropharyngeal or NPAs can be done. There are certain patients who are *difficult to ventilate with a BVM*. They can be identified by the mnemonics *MOANS* [mask seal, obesity, age (elderly), no teeth, stiffness stiffness] *BONES* (beard, obesity, no teeth, elderly, snoring, or sleep apnea). These patients can be managed by shaving off the beard with the patient's consent, keeping a denture in edentulous patients, giving reverse Trendelenburg position in the obese, etc. The compression of the self-inflating bag should be slow and not very forceful so as to prevent the air or oxygen to enter the stomach causing distension, vomiting, aspiration, and barotrauma.



FIGS. 9A AND B: (A) Use of bag-valve-mask (BVM) by one person C-E technique; (B) Use of BVM by two persons.

SUPRAGLOTTIC AIRWAY DEVICES

Supraglottic airway device(s) (SAD) (periglottic airway devices and extraglottic airway devices) are designed to provide a means for oxygenation, ventilation, and delivery of anesthetic gases. They are used as an alternative to BVM ventilation and endotracheal intubation. They are used as rescue airways when intubation is difficult or when experienced personnel are not present for intubation. They are also referred to as periglottic airway devices, extraglottic airway devices, or extralaryngeal airway devices. All of them are inserted via the mouth and do not go beyond the laryngeal inlet (**Fig. 10**).

The first SAD was laryngeal mask airway (LMA) developed by Dr Archie Brain in 1981 and put to clinical use in 1988. They are available in various sizes.

Characteristics

The LMA has *three main components, viz., a mask, an airway tube and an inflation line.* The small mask is designed to sit in the hypopharynx with its anterior surface opening lying over the laryngeal inlet. The mask has a rim which can be inflated by a line with a pilot balloon. This rim when inflated creates a seal which allows a positive pressure ventilation of up to 20 cm of H_2O.The adequacy of the seal depends on the proper size of the LMA and correct placement. The airway tube is connected to the posterior surface of the mask and opens into the aperture having two bands which prevent the epiglottis from obstructing the aperture.

Classification of Supraglottic Airway Devices

There are a variety of SADs available and are classified as (**Table 2**):

- *Cook's classification (2011)*: First-generation SAD—simple airway tube with no specific design for safety or performance. Second-generation SAD—have a gastric drain tube, improved pharyngeal seal and bite block.
- *Miller's classification (2014)*: It consists of three generations of SAD depending on sealing mechanism and location of the seal.

FIG. 10: Supraglottic airway devices [laryngeal mask airway (LMA)] different sizes picture showing three main parts of LMA mask tube and inflation line.

Other Supraglottic Airway Devices

Some of the SADs are in use, apart from classical LMA are:

- *Laryngeal mask airway unique*: It is similar to the classical LMA but is meant for single use. It is useful in patients with infections.
- *Proseal LMA*: It is an improvement on the classic LMA and has an esophageal drain tube. It also has a posterior cuff. It forms a high-pressure seal in the pharynx. It can be inserted directly or railroaded on a bougie (**Fig. 11**).
- *Laryngeal mask airway supreme*: It has a drain tube and a large inflatable cuff but no posterior cuff. It is meant for single use. There are fins in the mask bowl to prevent epiglottic obstruction (**Fig. 12**).

TABLE 2: Miller's classification of supraglottic airway devices.

	Location of sealing	
Sealing mechanism	***Perilaryngeal***	***Base of tongue***
First-generation—inflatable cuff	cLMA; pLMA	Combitube
Second-generation—preshaped	i-gel	SLIPA
Third-generation—self energizing	Baska mask	

(cLMA: classic laryngeal mask airway; pLMA: proseal LMA; SLIPA: streamlined liner of the pharynx airway)

FIG. 11: Proseal laryngeal mask airway.

FIG. 12: Laryngeal mask airway supreme.

- *King laryngeal tube (LT)*: It consists of an airway tube and two cuffs, a proximal large balloon cuff and a distal small balloon cuff. The tube is angulated in the middle. Both cuffs are inflated by a single pilot tube and balloon. The proximal cuff provides a seal in the pharynx and the distal cuff seals the esophagus. There are openings between the two cuffs for ventilation. There are six sizes available. There is a modification called LTS-II which has a lumen beyond the esophageal cuff for suctioning. King LT and LTS II are available in single use disposable models also (**Fig. 13**).
- *I-gel*: This is a preshaped cuff-less SAD, made of a gel-like material which adapts to the anatomy of the pharynx after insertion. It also has a channel for suctioning. It is very easy to use and has a fast insertion time (**Fig. 14**).
- *Esophageal tracheal tube (Combitube)*: It consists of two lumens and two cuffs. It is a double lumen-double balloon supraglottic device (**Fig. 15**). It is introduced blindly and can work with either tracheal or esophageal placement. It is easy to learn, easy to use especially in the emergency department. The disadvantages are increased chances of vomiting and aspiration: Oral, tracheal, pharyngeal trauma: difficulty in using with cervical immobilization.
- *Cobra perilaryngeal airway (PLA)*: It is a PLA device with larger pharyngeal cuff when inflated. It has better airway sealing pressure (**Fig. 16**).
- *Intubating LMA (Fastrach)*: It is a rigid anatomically curved airway tube wide enough to pass an 8.0 mm endotracheal tube. It is short enough to ensure passage of the endotracheal tube beyond the vocal cords (**Fig. 17**).

Method of Laryngeal Mask Airway Use

Check the patency of the LMA and the cuff integrity. Lubricate the dorsal surface of the mask of LMA and after deflating the cuff, introduce it in such a manner that the tip goes in the mouth first and the dorsal surface of the mask of the LMA is against the palate. Check for proper ventilation after passing the LMA and fix it (**Fig. 18**).

Advantages of Laryngeal Mask Airway

- It is easier to insert as compared to endotracheal intubation especially by inexperienced personnel.
- It causes less sore throat as compared to endotracheal intubation.
- It gives better oxygen saturation than BVM.
- It causes less hand fatigue as compared to BVM.

Disadvantages of Laryngeal Mask Airway

- There are more chances of gastric distension and it has to be used with caution in persons with full stomach.
- It is not a definitive airway and has to be replaced by endotracheal intubation subsequently.

SUMMARY

Airway management is an essential skill and is fundamental to the practice of emergency medicine. Hypoxia and airway compromise, contribute significantly to prehospital deaths. Hypoxemia prevention needs an unobstructed and protected airway with adequate ventilation that takes precedence over management of all other clinical conditions. The challenges facing an emergency physician are augmented in acute settings and respiratory management demands higher level of competency and composure. There has been a significant progress in effective airway management in emergencies and a lot of efforts are going into training and auditing these core skills. Airway management in emergency department is a challenging procedure. Every emergency physician should be competent to perform it. Airway management is vital procedure and this is not a "one size fit to all" procedure. Emergency physician should be trained and expertise in managing the difficult airway. Patient with respiratory distress often needs airway management. Systematic approach is needed for airway management.

32
CHAPTER

Advanced Airway Management

Venugopalan Poovathumparambil

INTRODUCTION

Airway management is essential skill for all emergency physicians. Timely and effective airway interventions are a critical procedure for optimal resuscitation of medical and trauma patients. Airway management in operation theatre is being done in a highly controlled environment. In a failed airway scenario, there is a possibility to cancel and postpone the procedure. But in emergency department (ED) especially in crashed airway scenario, it will be like "do or die" situation and emergency room is always considered as an uncontrolled environment. Nowadays, emergency clinicians have a wide range of new options for improving airway management skills few examples are various airway techniques and procedures combined with recent advances in rapid sequence intubation (RSI), video laryngoscopy, and further advanced airway techniques.

How to approach airway in emergency room: Initial patient assessment forms the cornerstone of further advanced airway management, and the primary evaluation should focus on the quick identification of those who may need respiratory support. This evaluation includes assessment for the patency of the airway and adequacy of ventilatory effort, potential hypoxia, or presence of illness or injury that could result in further deterioration of the patients' respiratory status.

We will have two categories of patients. First one are those who require urgent airway intervention and another one who are stable and less urgent. In first category are belonging to crash airway where need to interfere as quickly as possible and in second category we need time for planning and systematic approach. *How do you know airway is patent/first step to identify a compromised airway?* 10-second assessment of airway: Just talk with your patient. If someone should able to talk in full sentence means he is maintaining his airway. But there are certain conditions where we must be careful about dynamic airways which will be present as normal, but deteriorate subsequently such as angioedema, neck trauma burns, etc. Indictor of airway patency is level of consciousness, ability to speak in response to any query (upper airway and the level of consciousness are checked), able to clear his or her own secretions.

APPLIED ANATOMY

Mouth and nose are both connected to the airway. Fairly complex structures that serve distinctly different functions and have distinctly different anatomy. Mouth opens into the oropharynx a muscular structure containing large dexterous muscle, the tongue, teeth, and multiple glands. Main purpose is to bring food into the digestive tract and begin to break it down. The nares are specialized structure designed to filter, warm, and humidify air open into the nasopharynx. The structures are essentially mucous membranes stretched over the cartilage. The hard palate divides the oropharynx and nasopharynx and a posterior soft palate, a floppy structure that minimizes reflux of food and fluid into the nasopharynx (**Fig. 1**).

Mandible and Hyoid

One of the most sophisticated structural support systems in the body lurks just anterior to the mandible—the hyoid bone. This is a horse shaped. This is the only bone that does not articulate with another bone in the body. It is attached by a continuous set of ligaments. The internal structures of the neck like tongue (attached to the tongue and, via the hyoepiglottic ligament to

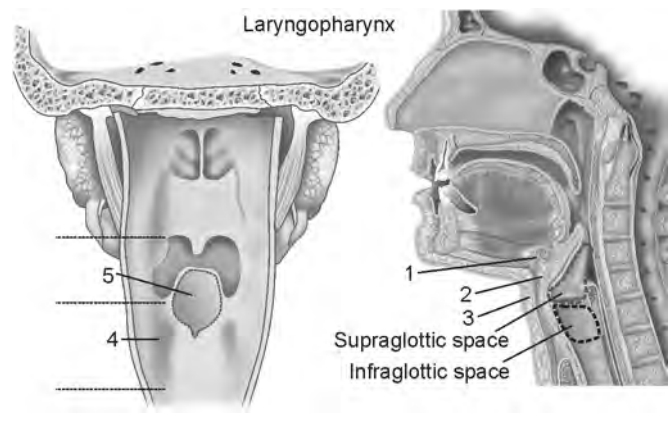

FIG. 1: Anatomy of airway: 1—hyoid bone, 2—thyrohyoid membrane, 3—laryngeal prominence, 4—piriform recess, and 5—laryngeal inlet.

the epiglottis) move wherever the hyoid moves. The hyoid is attached directly the mandible also, and moves with the hyoid.

Hypopharynx

Epiglottis, an anterior, leaf-shaped structure that is essentially attached to the base of the tongue. Lower airway starts below epiglottis and lower airway structure consists of aryepiglottic folds, false cords, and the true vocal cords or glottis. Movement of the thyroid and cricoid cartilage is helpful in speaking, coughing, and airway protection.

The fallen back tongue was considered as the common cause of airway obstruction. "*Loud and noisy breathing* in an unresponsive patient is the sign of airway obstruction. *Partially obstructed airway* by soft tissue or liquid (e.g., blood and emesis) clinically presents as snoring or gurgling noises. *Complete airway obstruction is present as silent chest* but may manifest transiently as retractions of the accessory muscles of respiration (suprasternal, supraclavicular, intercostal, and subcostal) or as cyanosis, until frank respiratory arrest supervenes.

ADVANCED AIRWAY MANAGEMENT

Main aim of advanced airway management (definitive airway) is protection of the airway, sometime useful in temporary or readily reversible condition, such as opioid overdose. Identify whether a ventilatory failure or oxygenation failure using clinical assessment, pulse oximetry with or without capnography, and observation of improvement or deterioration in the patient's clinical condition. In an agitated patient, always ruled out hypoxia first and if the patient is obtunded, think about hypercarbia. Pulse oximeter and capnography are the two very important tools in critical airway management. Someone tolerating OPA means, it indicates that he/she requires definitive airway (**Table 1**).

Definitive Airway

Definitive airway requires a tube placed in the trachea with the cuff inflated below the vocal cords, the tube connected to oxygen-enriched assisted ventilation, and the airway secured in place with an appropriate stabilizing method. Definitive airway can be divided into three types: (1) orotracheal tube, (2) nasotracheal tube, and (3) surgical airway (cricothyroidotomy and tracheostomy). The criteria for establishing a definitive airway in a trauma patient are based on clinical findings and include:

- Inability to maintain a patent airway by other means, with impending or potential airway compromise (e.g., following inhalation injury, facial fractures, or retropharyngeal hematoma)
- Inability to maintain adequate oxygenation by face mask oxygen supplementation, or the presence of apnea
- Altered mental status or combativeness resulting from cerebral hypoxia
- Glasgow Coma Scale score of 8 or less, head injury/with seizures, need protection of lower airway from aspiration of blood or vomitus.

Dynamic Airway

An airway apparently looks like normal but deteriorate quickly and which requires urgent intervention, e.g., angioedema and anaphylaxis, thermal and caustic injuries, bullet injuries of neck, etc.

Four steps to be taken before any intubation:

1. Rapidly assess the patient's need for intubation and the urgency of the situation.
2. Determine the best method of airway management based on assessment of the patient's predicted difficulty and pathophysiology.
3. Decide which pharmacologic agents are indicated, in what order, and in what doses.
4. Prepare a plan in the event that the primary method is unsuccessful, know in advance how to recognize when the planned airway intervention has failed or will inevitably fail, and clearly lay out the alternative (rescue) technique(s).

In emergency room, patients with airway management issues may be divided into those who need an immediate

TABLE 1: Clinical conditions which require advanced airway.

Airway	Mouth and neck infection, tumors, foreign bodies, and bleeds	Causes stridor, hoarseness, dysphonia, dysphagia, dyspnea, and secretions
Breathing	Failure of oxygenation or ventilation	Often amenable to medical or noninvasive therapies. Think NIV and HFNC
Circulation	Sepsis and shock	Intubation and ventilation support tissue oxygen delivery and unloading muscles of respiration
Disability	CNS catastrophe and CNS depression, ongoing seizures, weakness	• Avoid gag—assess ability to swallow and handle secretions (pooling, drooling, and gurgling) for neuromuscular weakness: FVC < 12 mL/kg and NIF < 20 cmH_2O • Vomiting in the obtunded patient is a particular concern
Expected course	• Anticipated decline • Transfer to radiology or another institution	
Feral	• Need for prompt, aggressive sedation to protect patient/others *especially with potential or undiagnosed medical instability*	

(FVC: forced vital capacity; HFNC: high-flow nasal cannula; NIF: negative inspiratory force; NIV: noninvasive ventilation)

definitive intervention versus those who are more stable or less urgent. The first category is generally identified as a *crash airway* and must be managed without delay. The second group may be assessed in a more systematic fashion in an effort to determine the next best step in treatment and to identify factors that could make airway management difficult.

AIRWAY ASSESSMENT

Proper airway assessment is crucial and most import step before starting advanced airway management. Unfortunately, we may fail to carry out this step and very often we may land up in big troubles. Remember time is a big factor in ER airway management scenario and once an airway emergency strikes the clock will start run in reverse direction and if you fail to manage crises it will end up in a disaster. Airway assessment is aiming to identify and anticipate airway difficulties. Four levels of assessment for airway difficulties

1. Difficulty for bag mask ventilation (BMV)
2. Difficulty for endotracheal intubation
3. Difficulty for supraglottic airway (SGA) insertion
4. Difficulty for surgical airway insertion

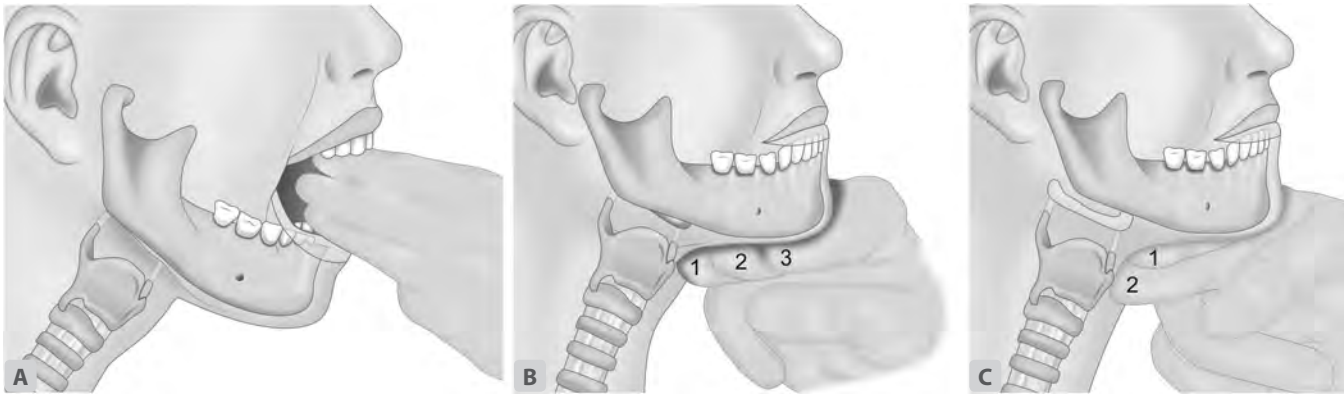
Difficulty for Bag Mask Ventilation (MOANS)

M—mask seal compromise or difficulty. *O—obstruction* (particularly supraglottic obstruction, but can be anywhere in the airway) or *Obesity*—body mass index > 26 (because of redundant upper airway tissue, chest wall weight, and resistance of abdominal mass) or *Obstetric* patient. *A—* advanced *age* (best assessed by physiologic appearance of the patient, but age > 55 years increases risk). *N—no teeth* (edentulous) which independently interferes mask seal. *S—stiffness or resistance to ventilation* (asthma, COPD, pulmonary edema, restrictive lung disease, and term pregnancy) may contribute to increased difficulty with BMV. The difficulty with BMV of the edentulous patient is the basis of the advice often cited for patients with dentures: "teeth out to intubate, teeth in to ventilate." Another approach involves placing the mask inside the patient's lower lip. This may limit air leak in patients without teeth and eliminates the risk of aspiration associated with dental prosthetics or rolled gauze. Take a gamji pad and make a diamond cut in the center. Keep the pad over the face in such a way that the diamond opening at mouth and keep mask over it. This will be useful in edentulous or patients with nasogastric tube in situ.

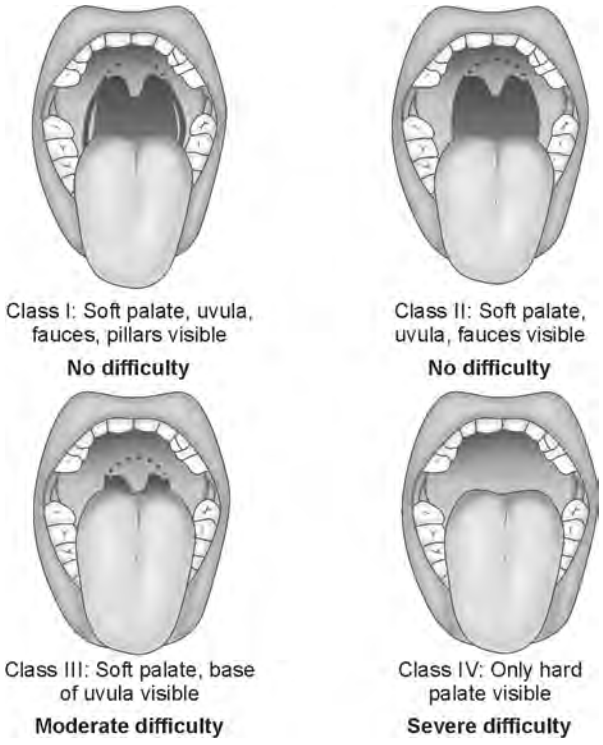
Difficulty in Endotracheal Intubation (Direct Laryngoscopy)

LEMON evaluation is used to assess the difficulty in intubation and direct laryngoscopy.

- *L—Look externally*: A quick external examination of the patient for potential signs of airway problems and their management. First external markers of difficult intubation, should be examined which are based on the specialist clinical impression. For example, the severely combative trauma patient with facial fracture, immobilized in a cervical collar on a spine board, gives immediate impression of anticipated difficult intubation.
- *E—Evaluate 3-3-2 rule*: Examine the airway for structural and anatomic factors that may make intubation difficult. Normally, a mouth opening should accommodate three of the patient's fingers, three fingers distance/measurement from the mentum to the hyoid bone, and a distance of two fingers from the hyoid bone to the thyroid notch. When present, these factors predict sufficient spatial relationships between the mouth, the mandible, temporomandibular joint mobility, and the larynx to allow for successful direct laryngoscopy and eventual endotracheal intubation (**Figs. 2A** to **C**).
  - Interincisor distance less than three fingers means inadequate mouth opening which leads to difficulty in inserting laryngoscope.
  - Thyromental distance less than three fingers mean larynx is anterior and it leads difficulty in visualization of vocal code.
  - Thyrohyoid distance is less than two fingers means high larynx which make vocal code visualization is more difficult.
- *M—Mallampati score*: Assessment of the posterior oropharyngeal structures visualized when the mouth is opened and the tongue is fully protruded (**Fig. 3**). Visibility of the oral pharynx ranges from complete visualization, including the tonsillar pillars (class I), to no visualization at all, with the tongue pressed against the hard palate (class IV). Classes I and II signify adequate oral access, class III signifies moderate difficulty, and class IV signifies a high degree of difficulty.
- *O—Obstruction*: Obstruction of upper airway by foreign bodies, local edema, stridor, or soft tissue masses makes intubation difficult or impossible. Examine the patient for any airway obstruction and assess the patient's voice



FIGS. 2A TO C: 3-3-2 rule assessment: (A) Interincisor distance; (B) Thyromental distance; (C) Thyrohyoid distance.



Class I: Soft palate, uvula, fauces, pillars visible
No difficulty
Class II: Soft palate, uvula, fauces visible
No difficulty
Class III: Soft palate, base of uvula visible
Moderate difficulty
Class IV: Only hard palate visible
Severe difficulty

FIG. 3: Mallampati classification.

to confirm the evaluation. Conditions which make the definitive airway placement difficult are epiglottitis, cancer of head and neck, Ludwig's angina, hematoma of neck, glottis swelling, or glottic polyps. Obese patients generally are more difficult to intubate than their nonobese counterparts, they desaturate quickly and cause increased difficulty with ventilation using BMV or an extraglottic devices (EGD).

- *N—Neck mobility*: Neck positioning is maintained to achieve optimum angles for visualization of the glottis to facilitate definitive airway. Neck movement is restricted in conditions such as cervical spine injuries, rheumatoid arthritis, or degenerative arthritis. Neck mobility is assessed by flexion and extension of the patient's head and neck through a full range of motion. Neck extension is the most important motion, but placing the patient in the full sniffing position provides the optimal laryngeal view by direct laryngoscopy. The "S" in *LEMONS* referring to the patient's *oxygen saturation*.

Difficulty for Supraglottic Airway Insertion

Mnemonic RODS is used to predict difficulty in achieving placement or ventilation. Restricted mouth opening, Obstruction or obesity, Distorted anatomy, and Stiffness (resistance to ventilation). Placement of an EGD, such as a laryngeal mask airway (LMA), Combitube, laryngeal tube airway (LTA) (Kings airway), or similar upper airway device, often can convert a cannot intubate, cannot oxygenate situation to a cannot intubate, can oxygenate situation, which allows time for rescue of a failed airway. EGDs are placed blindly and balloon is inflated which obstructs the oropharynx proximally and esophageal inlet distally, permitting indirect ventilation. Poor seal and ineffective ventilation can result due to distorted upper airway anatomy.

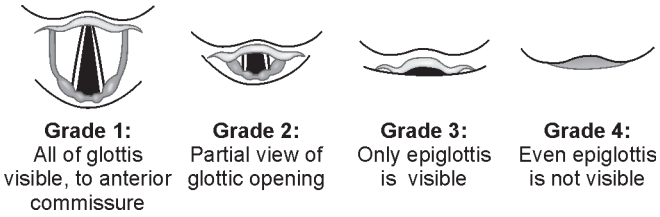


FIG. 4: Cormack and Lehane—laryngoscopic grading for intubation.

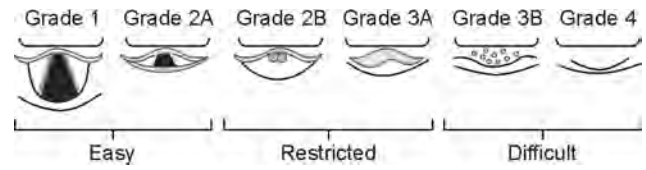

FIG. 5: Modified Cormack and Lehane's classification of laryngeal grade.

Difficulty for Surgical Airway Insertion

Difficult cricothyrotomy can be anticipated whenever there is limited access to the anterior neck or obscured laryngeal landmarks and can be remembered by the mnemonic SMART (Surgery Mass Access/anatomy problem Radiation, Tumor). Causes of difficult cricothyrotomy are history of surgery, hematoma, tumor, abscess, radiation-induced scarring local trauma, obesity, and local edema.

LARYNGOSCOPIC GRADING FOR DIFFICULT INTUBATION

The actual degree to which an intubation is difficult is highly subjective, and quantification is challenging. The CL (Cormack and Lehane) system (**Fig. 4**) is the most widely used system for grading a laryngoscopic view of the glottis, which grades laryngoscopy according to the extent to which laryngeal and glottic structures can be seen. CL devised a scoring system that, although limited by an element of intra- and interobserver variability, provided an objective descriptive measure of the glottic view during laryngoscopy.

The definitions they used are as follows:

- *Grade 1*: Larger part of glottis is visible.
- *Grade 2*: Only the posterior part of glottis is visible.
- *Grade 3*: Only the epiglottis is visible. Glottis is not visible.
- *Grade 4*: Epiglottis is also not visible.

The intubation difficulty will increase from the grade 1 to 4.

Grade 1—extrinsic manipulation of larynx is not required, grade 2—extrinsic manipulation of larynx is required, grade 3—intubation possible with stylet/gum elastic budgie guided, and grade 4—failed intubation.

Perhaps the most useful modification of this basic system is *modified CL's classification* (**Fig. 5**) one that a grade 3 view into a grade 3A, in which the epiglottis can be lifted off the posterior pharyngeal wall, and grade 3B, in which it cannot be lifted.

POSITION FOR INTUBATION

Comfortable intubating position that allows in-line visualization of the airway to the operators is the key for

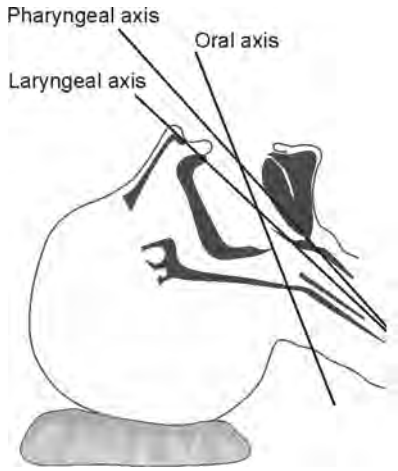

FIG. 6: Aligning laryngeal and pharyngeal axes by placing a pillow under head (not under shoulder in adult).

successful laryngoscopy and placing the definitive airway. This can be achieved by adjusting the height of the patient or the height of the intubator to bring the airway into the laryngoscopist's central field of vision. Jackson advocated full head extension, and Magill recommended the ''sniff'' position, whereby the neck is flexed on the torso and the head is slightly extended on the neck (the flex-extend position). Bannister (an anesthetist) and Macbeth propose the triple-axis alignment. The "sniffing position"—lower cervical flexion and atlanto-occipital extension and is helpful in aligning the oral, pharyngeal, and laryngeal axes of the upper airway and optimizes the laryngoscopic view (**Fig. 6**). Two steps will align these axis's together:

- Keep a pillow under head to align laryngeal and pharyngeal axis
- Extend head to align oral axis to the rest
- Avoid if any contraindication exist

TECHNIQUE OF INTUBATION

- Open the mouth as much as possible.
- Insert the blade and sweep the tongue to the left.
- Advance the tip of the blade down the tongue carefully, lifting, and until the epiglottis is located. The epiglottis is the main anatomic landmark for performing intubation because the glottis can be consistently found just posterior and inferior to it.
- Next step is lifting of the epiglottis. Epiglottis can be displaced indirectly by pressing against the hyoepiglottic ligament at the base of the vallecula if using the curved blades. Epiglottis can be lifted directly with the tip of the straight blade.
- Identify the posterior cartilages and interarytenoid notch. These structures make up the posterior border of the glottis and separate the tracheal inlet from the esophagus. Visualize the vocal cords (**Fig. 7**).
- Pass the tube through the vocal cords and into the trachea.

RAPID SEQUENCE INTUBATION

Rapid sequence intubation is the most widely used technique for emergency intubation of patients without identifiable difficult airway attributes, with recent large registry data

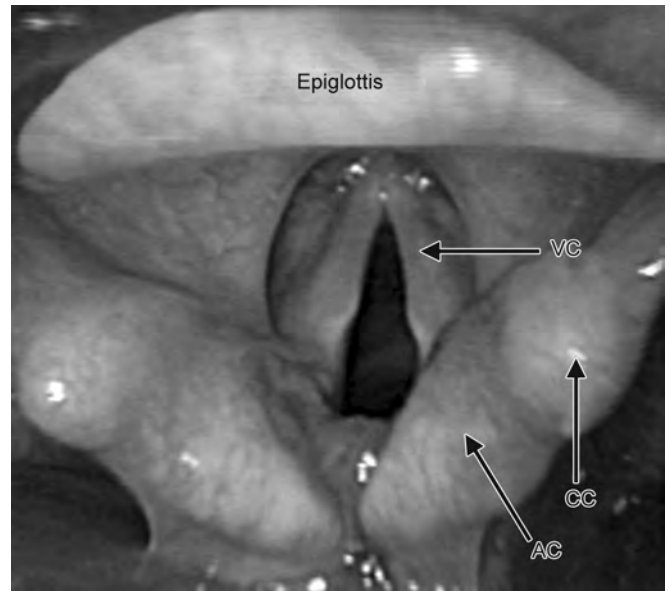

FIG. 7: Laryngoscopic view—anatomy of the laryngeal inlet revealed at direct laryngoscopy. Beneath the epiglottis (E), a view is sought of the whitish vocal cords (VC) in their triangular orientation. The rounded paired posterior (corniculate) cartilages (CC) and arytenoid cartilages (AC) are also shown. ***(For color version, see plate 2)***

showing that it is used in 85% of all ED intubations. This approach provides optimal condition for intubation with minimal risk of aspiration of gastric content. This procedure (RSI) is performed with the help of induction agents (potent sedative) and neuromuscular blocking agents (NMBA) (succinylcholine or rocuronium).RSI is based on the concept that with the help of neuromuscular paralytic agent, conscious spontaneously breathing patient taken to a state of unconsciousness with complete neuromuscular paralysis. Thus positive-pressure ventilation is avoided until the ETT-endotracheal tube is placed correctly in the trachea, with the cuff inflated.

Rapid sequence intubation facilitates successful endotracheal intubation by causing complete relaxation of the patient's musculature, allowing better access to the airway. Finally, RSI permits pharmacologic control of the physiologic responses to laryngoscopy and intubation, mitigating potential adverse effects. These effects include further elevations in intracranial pressure (ICP) in response to the procedure and to the sympathetic discharge resulting from laryngoscopy. The process of RSI is carried out in a very systematic way through 7 Ps. The emergency physician should know every minute aspects of this steps 7 Ps of RSI:

1. Preparation
2. Preoxygenation
3. Pretreatment
4. Paralysis with induction
5. Positioning
6. Placement of tube and confirmation
7. Postintubation management

Preparation

Preparation is the most important step in RSI and very often people will forget or taken for granted in this step. An unprepared RSI may invariably land up in many unavoidable

crisis and airway disasters. *The preparation may in four levels preparation of patient, preparation of drugs and equipment, preparation of the intubator and assistant, and prepare for the difficulties.*

1. *Patient preparation* includes get informed consent, complete airway evaluation including (artificial dentures, loose tooth, etc.) and clinical evaluation including past medical history, allergic history, previous intubation, and anesthetic history, trauma, cervical spine diseases-related to mobility, drug history, and last meal (fasting) are very important. Once patient in the intubation table establish cardiac monitor, pulse oximeter, blood pressure [noninvasive (NIBP)], end-tidal carbon dioxide ($ETCO_2$), etc. Establish two patent IV line. Keep intubation pillow or towel under head (not under the shoulder in adults).
2. *Preparation of equipment and drugs is essential.* ET intubation equipment (**Fig. 8**) and drugs (**Table 2**) are summarized below. Standard tube sizes kept in adult intubation kit are 8/8.5 for male and 7–7.5 for female. But it should keep one size above and below respectively. Drugs should be loaded and labeled. All drugs and equipment should be available at your arm span distances.
3. *Preparation of intubator and assistant*: Wear essential personal protection equipment, communicate the plan to patient bystander, team members and primary consultant, and Anesthetist if needed. Check the checklist. Assign the role for the team members.
4. *Prepare for the difficulties*: Make sure that all back up devices and back support are ready and available. The biggest airway disaster is "cannot intubate, cannot oxygenate" (CICO) scenario.

FIG. 8: Essential equipment for rapid sequence intubation.

TABLE 2: Equipment and drugs for rapid sequence intubations.

- BVM
- Suction
- Airways (oropharyngeal and nasopharyngeal)
- ET tubes of appropriate sizes
- Stylet
- Laryngoscope
- Laryngoscope blades (both curved and straight)
- Magill forceps
- 10-mL syringe
- Stethoscope

Drugs: Pretreatment, induction, and paralysis (PIP)

Pretreatment—LOAD	*Induction*	*Paralysis*
L—Lignocaine	Etomidate	Suxamethonium
O-Opioids—Fentanyl	Propofol	Rocuronium
A—Atropine	Ketamine	Vecuronium
D—Defasciculating agents	Midazolam	Atracurium

(BVM: bag valve mask; ET: endotracheal)

Preoxygenation

Preoxygenation is the crucial step in RSI and it aims to fill the functional reserve of lung [functional residual capacity (FRC)] with 100% oxygen. Through preoxygenation we are removing nitrogen from lung so it is also called denitrogenation. Preoxygenation will help to overcome the apnea period during RSI from paralytic agent to intubation. It also helps to carry out nonbagging technique in RSI (no bag ventilation after the intubating dose of paralytic agent). Risk for dysrhythmia, hemodynamic decompensation, hypoxic brain injury, and death occurs if patients desaturate below 70%.

Administer 100% oxygen for 3 minutes in a normal healthy adult which provides adequate oxygen reservoir and permits 6–8 minutes of safe apnea before oxygen desaturation to <90%.

Desaturation time in *obese patients* can be prolonged by preoxygenating with the patient in a *head-up position* and by *continuing supplemental oxygen* (via nasal cannula at a flow rate of 5–10 L/min) It has been suggested to use LMA for preoxygenation but if the LMA is used as a preoxygenation method, its introduction per se might worsen optimal preoxygenation, as its proper use usually requires deep sedation, which leads to apnea, or at least to severe hypoventilation.

Pretreatment

Pretreatment is the drugs administered 3 minutes before paralytic agents and intubation. Intubation is intensely stimulating and results in a sympathetic discharge, or reflex sympathetic response to laryngoscopy (RSRL). Pretreatment helps to attenuate the sympathetic response of the laryngoscopy and intubation. Fentanyl (3 μg/kg IV) can be administered 3 minutes before RSI can optimize the patient's hemodynamics in patients suffering from a hypertensive emergency. Patients with reactive airways disease can exhibit worsening pulmonary mechanics after intubation as a result of bronchospasm pretreatment for—reactive airway disease—albuterol, 2.5 mg, by nebulizer. If time does not permit albuterol nebulizer, give lidocaine 1.5 mg/kg IV. Cardiovascular disease—fentanyl, 3 μg/kg, to mitigate sympathetic discharge. Elevated ICP—fentanyl, 3 μg/kg, to mitigate sympathetic discharge and attendant rise in ICP. Preload—bolus 500 mL crystalloid solution may be given to reduce postinduction hypotension.

Paralysis with Induction

In this step, a potent sedative agent is administered by rapid intravenous (IV) push in a dose capable of producing unconsciousness rapidly. This is immediately followed by

rapid administration of an intubating dose of a NMBA, either succinylcholine (depolarizing muscle relaxant) at a dose of 1.5 mg/kg IV or rocuronium (nondepolarizing muscle relaxant), 1 mg/kg. It is usual to wait 45 seconds from when the succinylcholine is given and 60 seconds from when rocuronium is given to allow sufficient paralysis to occur. The results from two large meta-analyses have revealed that intubating conditions provided by each drug are equivalent as long as rocuronium is dosed between 1.0 and 1.2 mg/kg IV.

Positioning

Positioning is aiming to align all three axes for better visualization of vocal cords. It is typically described as sniffing position attained by pillow under head and neck extension. Routine use of Selleck's maneuvers is not recommended. It should be considered optional, applied selectively, and released or modified early if the laryngeal view is poor or tube passage is difficult.

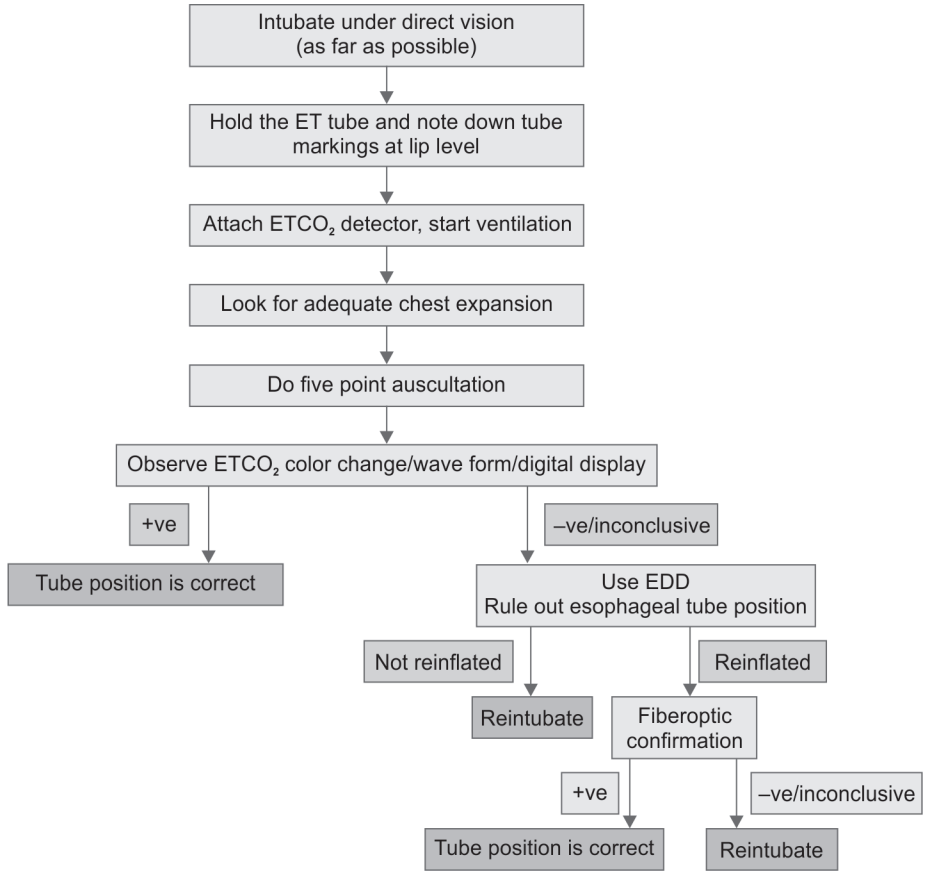
Placement of Tube and Position Confirmation

Patient is relaxed sufficiently approximately 45–60 seconds after administration of the NMBA, and laryngoscopy can be performed. Operator can assess this condition easily by moving the mandible to check absence of muscle tone. At this point ETT can be passed during glottic visualization with the laryngoscope. If the first attempt is unsuccessful but oxygen saturation remains high, it is not necessary to ventilate the patient with a bag and mask between intubation attempts. If the oxygen saturation is approaching 90%, the patient may be ventilated briefly with a bag and mask between attempts to reestablish the oxygen reservoir.

Confirmation of tube placement is equally important as intubation. Various methods are available to confirm tube position. End tidal carbon dioxide is the standard method to confirm tube position. All other methods are with less specificity and sensitivity and chances of errors are more. Gold standard is visualization of tracheal rings using fiberoptic scope. But not recommendable for routine scenario. But in difficult airway scenario, fiberoptic confirmation is gold standard. Ultrasound is useful in tube positioning. But the main challenge is its operator-dependent variability. While doing five point auscultation, it should always start from epigastrium to rule out an esophageal intubation first. An esophageal detector device (EDD) is a device rather used to rule out the esophageal intubation than tracheal tube placement. Suggested systematic approach to confirm tube position is shown in **Flowchart 1**.

Various methods are used to confirm correct position of the endotracheal tube.

- Waveform capnography
- Colorimetric $ETCO_2$ detector
- Auscultation of breath sounds
- Ultrasonography
- Direct visualization of the tube between the cords
- Self-inflating esophageal bulb
- Fogging of the ET tube
- Rise and fall of the chest
- Esophageal detector device
- Pulse oximetry readings



FLOWCHART 1: Approach to confirm tube position after direct laryngoscopy and intubation.

- Improvement in the patients' condition (color and heart rate)
- Fiberoptic scope

X-ray chest is only useful to rule out endotracheal tube position.

Postintubation Management

Confirm tube position by $ETCO_2$ and continues $ETCO_2$ monitoring if available. Take an X-ray chest to rule out endobronchial intubation. Fix ETT appropriately and note the lip mark and document it. Plan and administer postintubation sedation and analgesia. Generally, avoid paralysis with NDNMB such as vecuronium and pancuronium. Make sure that no tube bite, tube block, coughing, and fighting with ventilator. Manage postinduction hemodynamic instability with IV fluids and vasopressors if required. An adequate dose of a benzodiazepine (e.g., midazolam, 0.1–0.2 mg/kg IV) and opioid analgesic (e.g., fentanyl, 3–5 μg/kg IV, or morphine, 0.2–0.3 mg/kg IV) is given to improve patient comfort and decrease sympathetic response to the ETT.

Propofol infusion (5–50 μg/kg/min IV) with supplemental analgesia is an effective method for managing intubated patients who do not have hypotension or ongoing bleeding and is especially helpful for management of neurologic emergencies because its clinical duration of action is very short (<5 min), allowing frequent neurologic examinations. An NMBA is added only if appropriate use of sedation and analgesia fails to control the patient adequately or when ventilation is challenging because of by muscular activity.

Two dangerous emergent issues in the immediate post RSI phase is *hypoxia and hypotension* which should be addressed as quick as possible. *Look for DOPE in all cases of post-RSI hypoxia or hypotension*—D—Displacement (tube)/drugs, O—Obstruction, P—Pneumothorax, E—Equipment failure.

Rapid sequence intubation time line is summarized in **Table 3**.

DELAYED SEQUENCE INTUBATION

Delayed sequence intubation (DSI) is considered as "procedural sedation" using IV. Ketamine 1 mg/kg, in certain cases where preoxygenation with conventional methods such as face mask is difficult due to agitation, delirium, and confusion.

TABLE 3: Time line in rapid sequence intubation.

Time	*Steps*
Minus 10 min	Preparation
Minus 5 min	Preoxygenation
Minus 3 min	Pretreatment
Zero	Paralysis with induction
Plus 30 s	Positioning and cricoid pressure optional
Plus 45 s	Placement of ETT, confirm tube position
Plus 2 min	*Postintubation management*: • Sedation and analgesia as indicated • Initiate mechanical ventilation • NMBA only if needed after adequate sedation and analgesia

(ETT: endotracheal tube; NMBA: neuromuscular blocking agent)

INTUBATION WITHOUT PHARMACOLOGIC AGENTS

Crash Airway

Conditions (like arrested or near-death)—patient may not require pharmacologic agents for intubation, but some time even an arrested patient may retain sufficient muscle tone (which make intubation difficult) administration of a single dose of succinylcholine alone may facilitate laryngoscopy.

Awake Intubation

Awake oral intubation is a technique in which sedative and topical anesthetic agents are administered to permit management of a difficult airway without neuromuscular blockade.

- Topical anesthesia may be achieved by spray, nebulization, or local anesthetic nerve block.
- Aliquots of ketamine at a dose of 0.5 mg/kg IV, titrated to the desired level of sedation and procedural tolerance, are an effective method.
- Dexmedetomidine, alone or in combination with benzodiazepines, can be used for awake airway evaluations. A typical dose is 1.0 mg/kg IV infused over 5–10 minutes. After the patient is sedated, and topical anesthesia has been achieved, gentle direct video laryngoscopy or flexible endoscopic laryngoscopy is performed to determine whether the glottis is visible and intubation possible.

DIFFICULT AIRWAY

A difficult airway is considered in whom anatomical irregularities/deviation predict difficulty in securing the airway. A failed airway is considered in which the chosen technique has failed, and rescue technique is implemented. Obviously, there is much overlap, but it is important to keep the two notions distinct. Difficult airway can be divided into two categories: (1) An anatomically difficult airway, and (2) A physiologically difficult airway. The anatomical difficult airway requires anatomical or logistical manipulation for successful intubation, whereas the physiologic difficult airway requires optimization of overall patient management (correction of low oxygen saturation, blood pressure, or metabolic derangement, such as severe metabolic acidosis).

Difficult airway can be a difficulty in BMV, intubation, insertion SGA, or front of neck access to airway. This can be an anticipated or unexpected airway difficulty. The perception of a difficult airway is relative, and many emergency intubations could be considered difficult. Systematic approach can be adopted for identifying the potentially difficult airway by LEMON, MOANS, RODS, and SMART assessments.

FAILED AIRWAY

A failed airway can be considered when any of the following conditions is met: (1) Oxygen saturation is maintained during or after one or more failed laryngoscopic attempts; or (2) Three failed attempts of orotracheal intubation by an experienced specialist, even when oxygen saturation can be maintained.

- *Cannot intubate, cannot oxygenate:* Airway must be secured immediately (no time to evaluate). Avoid any further rescue

attempt and the airway must be secured immediately to maintain oxygen saturation by BMV or with an EGD.
- *Cannot intubate, can oxygenate:* Various rescue options can be executed (time to evaluate) because the patient is oxygenated.

Airway management failure can be avoided by identifying and anticipating patient with difficult for intubation.

PROTECTED INTUBATION IN HIGHLY INFECTED PATIENT—IN VIEW OF COVID-19

Challenges

- Potential for virus spread
- Inherent complication of intubation
- Inherent pathophysiologic implications of COVID-19
- Intubation, BMV, and suctioning are the procedures with highest aerosolization
- Optimal intubation condition is compromised
- Bag mask ventilation and preoxygenation with high-flow oxygen are dangerous.
- Coughing, sneezing, and tube disconnections are dangerous in terms of viral spread.
- Complex team dynamics
- COVID protocol-related difficulties

Rapid Sequence Intubation Modification

- Appropriate personal protective equipment (PPE) (full PPE for intubator)
- Don under supervision
- Adequate preparation
- Prepare for difficult airway
- Prepare for cardiac arrest
- Plan the procedure and always use checklist
- Most experienced member should intubate.
- Team and role assignment
- "Hot team" will be present inside the intubation room to manage the protected intubation
- "Cold team" will be present outside the room to help in crisis
- Proper communication system between cold and hot team
- Limit the number of persons in the hot team (maximum 3)
- Negative pressure room
- Use intubation hood or box and if not available, use a transparent plastic sheet cover, and do all airway manipulations under the plastic cover
- Preoxygenation with tight mask with two hand ventilation with viral filter and nonrebreather mask (NRB) with oxygen flow of 10–15 L/min
- Preoxygenation with high-flow nasal cannula
- Limited use of noninvasive ventilation (NIV)
- Limited use of nebulization
- Use closed suction only
- Rapid sequence intubation is the choice.
- High dose ketamine (2 mg/kg) is the induction agent of choice.
- High dose rocuronium 1 mg/kg or high dose succinylcholine 2 mg/kg is the paralytic agent.
- Cricoid pressure is desirable.
- Inflate cuff immediately after intubation
- No positive pressure ventilation before intubation and cuff inflation
- Use video laryngoscope for intubation
- Attach viral filter always between breathing circuit and ETT
- Tube positioning with direct visualization in video laryngoscopy and $ETCO_2$ monitoring
- No auscultation to confirm tube positioning
- Always clamp the ETT while changing from BMV to ventilator or vice versa
- Use second generation SGA such as I-GEL in failed intubation scenario
- Plan oxygenation strategy in failed first attempt intubation scenario
- Prepare and do front of neck airway access incase CICO
- Do protected code blue incase cardiac arrest happened
- Ventilator setting should be lung protective (tidal volume 6 mL/kg. RR 16–18/mt, inspiratory flow rate 60–80 L/min, PPlat <30 cm of H_2O and start positive end-expiratory pressure (PEEP) at 5 cm of H_2O and titrate up to get optimum arterial partial pressure of oxygen (PaO_2) at an acceptable fraction of inspired oxygen (FiO_2).
- Do appropriate postintubation care including sedation and paralysis, avoid tube disconnections, coughing, and bucking
- Doff under supervision and follow proper BMW (biological waste management) protocol
- Take shower in case any breach in PPE is detected.

CAPNOGRAPHY

Capnography is a mandatory tool in airway management in ED and ambulances. It is essential to confirm tube placement after intubation, monitoring of intubated patients in ED and also during medical transport. Capnometry is the continuous measurement of CO_2 in a sample of gas and represented as graphic form (time on X-axis and expired partial pressure of CO_2 on the Y-axis). The $ETCO_2$ is the maximal partial pressure or concentration of CO_2 in the respiratory gases at the end of an exhaled breath. A capnometry monitor displays the $ETCO_2$ value alone, whereas a capnography monitor displays the $ETCO_2$ value plus a continuous capnography waveform.

Capnography wave has got four phases—normal capnography wave morphology (**Fig. 9**)

1. *Phase I* (inspiratory phase) represents inspiratory phase, so no CO_2 is detected. The end of phase I represents the beginning of expiration, but because the initial gases expired originate from unventilated dead space, the capnography trace remains at zero.
2. *Phase II* (expiratory upstroke) represents expiration of both dead space gas and alveolar gas from the respiratory bronchioles and alveoli.
3. *Phase III* (alveolar plateau) represents phase of expiration of alveolar gases. At the end of phase III, the maximal value of CO_2 measured is equivalent to the $ETCO_2$. Note that if the alveoli all contained exactly the same partial pressure of CO_2, phase III would be completely horizontal.
4. *Phase IV (expiratory downstroke)* represents the beginning of the next breath, with the CO_2 content returning rapidly

to zero. Healthy patients with normal respiratory function will produce a capnography trace with this form. Lung pathologies will change the appearance of the capnograph due to a number of different factors—bronchoconstriction and obstruction to airflow, destruction of alveoli, an increase in the range of alveolar time constants (alveoli that empty at different rates), and an increase in V/Q spread (variation in CO_2 content of each alveolus). As a result, the slope of phase III is often markedly increased in respiratory disease that empty at different rates), and an increase in V/Q spread (variation in CO_2 content of each alveolus). As a result, the slope of phase III is often markedly increased in respiratory disease.

Morphology of Capnography

A healthy patient with normal lungs when ventilated via a patent tracheal tube or tracheostomy, the continuous waveform produces a typical *"square wave"* capnography trace and provides visual breath-by-breath assessment of a patient's airway and ventilation. Morphology of capnography traces is shown in **Figures 10A** and **B**.

- *Capnography waveform with up-sloping plateau phase*: It signifies bronchospasm, airway is partially blocked or that the endotracheal tube has migrated beyond the carina and into a main bronchus.
- *Capnography waveform with a peaked, triangular appearance*: This suggests that there is a significant leak around the tracheal tube or tracheostomy.
- *Flat capnography trace*: This suggests one of the following:
  - The esophagus has been mistakenly intubated instead of the trachea.
  - The tracheal tube or tracheostomy has become displaced.
  - The breathing circuit has become disconnected.
  - The airway has become obstructed: with secretions, or tracheal tube bitten by patient and occluded.
- *A sudden drop in $ETCO_2$, but with a square wave capnography trace still seen*, suggests a sudden drop in lung perfusion, either caused by an obstruction to blood flow through the lungs (caused by thrombus, air or fat) or by a reduction in cardiac output. When $ETCO_2$ falls because of reduced pulmonary perfusion, the arterial CO_2 will rise due to the inability of the lungs to excrete CO_2. The clinician may need to give consideration to increasing alveolar ventilation in this circumstance.
- *A steady increase in the $ETCO_2$ value, again with a square wave trace*, suggests hypoventilation, but may rarely represent malignant hyperpyrexia if associated with rise in temperature (malignant hyperthermia).

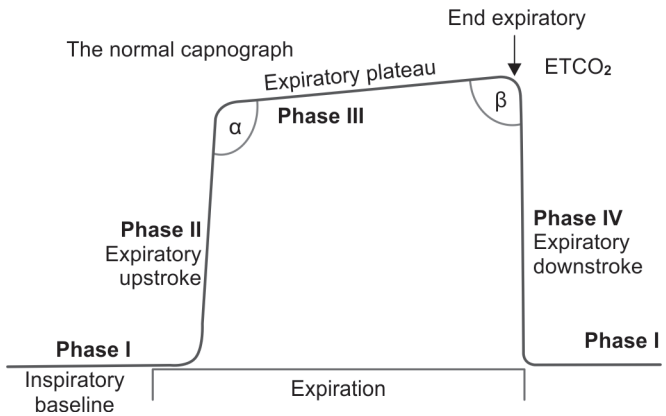


FIG. 9: Morphology of normal capnography wave.

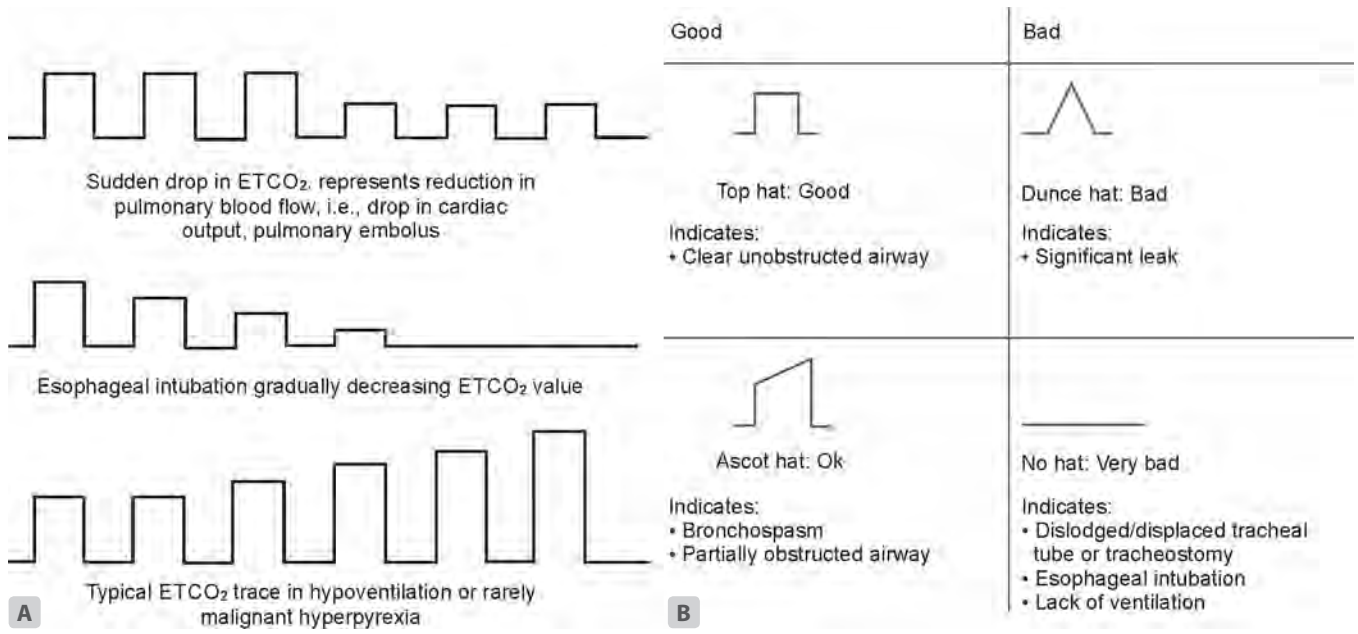
SUMMARY

All emergency physicians must be aware about advanced airway management skill. During resuscitation of medical and trauma patients, timely and effective airway interventions are a critical procedure. In ED which is always considered as



FIGS. 10A AND B: Morphology of capnography (A) critical $ETCO_2$ wave; (B) "hats and caps" in $ETCO_2$ trace.

an uncontrolled environment, especially in crashed airway scenario, it will be like "do or die" situation. Nowadays, emergency clinicians have a wide range of new options for improving airway management skills few examples are various airway techniques and procedures combined with recent advances in RSI, video laryngoscopy, and further advanced airway techniques.

33 CHAPTER

Cardiopulmonary Resuscitation

Mabel Vasnaik

INTRODUCTION

Cardiopulmonary resuscitation (CPR) is a skill every physician should master, particularly physicians in an emergency department. In the event of a cardiorespiratory arrest, a systematic approach to resuscitation and early restoration of spontaneous circulation greatly improves the prognosis of the patient. Cardiac arrest is the cessation of cardiac mechanical activity. It is a clinical diagnosis, confirmed by unresponsiveness, absence of a detectable central pulse, and apnea (agonal respiration). Three types of rhythms can be seen during a cardiac arrest.

1. Ventricular fibrillation (VF) or ventricular tachycardia without a pulse (pulseless VT)
2. Asystole
3. Pulseless electrical activity (PEA)

A cardiorespiratory arrest can be either an in hospital or an out of hospital arrest. Patients who are in the hospital can arrest if they are critically ill with serious cardiac, respiratory, and metabolic conditions. The algorithmic approach to resuscitation increases the chance of return of spontaneous circulation (ROSC) in these patients. A large number of cardiorespiratory arrests are out of hospital arrests and occur either at home, in the workplace, on the road, in an open space or in an ambulance en route to a hospital. Most out of hospital cardiac arrests are sudden and unexpected and most often due to a cardiac or respiratory illness.

The approach to such patients is BLS or basic life support. Checking unresponsiveness along with an initial assessment and management of the circulation, airway and breathing are the components of BLS (*CAB's of resuscitation*). It includes the diagnosis of cardiac arrest, calling for help and actions to restore spontaneous circulation by chest wall compressions, ventilation, and defibrillation if an automated external defibrillator (AED) is available. BLS has to be started at the scene of arrest and continued till the patient reaches a hospital or an ambulance. Once the patient reaches a hospital or if the ambulance is well-equipped with drugs, advanced airway equipment, and a defibrillator, ACLS or advanced cardiac life support is performed.

Basic life support and ACLS are two ends of the resuscitation spectrum. ACLS is an extension of BLS and includes BLS plus advanced techniques such as endotracheal intubation, intravenous (IV) drugs, defibrillation, etc. Well-performed BLS and ACLS are essential in order to achieve early ROSC and give the patient the best chance of survival.

STEPS OF RESUSCITATION

Step I: Assessment of Responsiveness

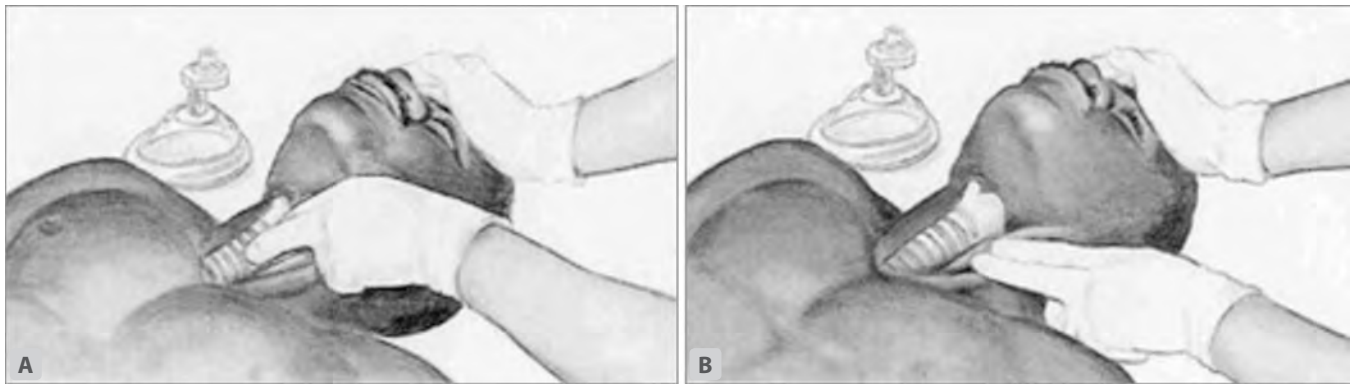
After assessing scene safety, assess responsiveness by gently shaking and calling. If not responsive call for help and an AED/defibrillator. After calling for help, position the patient on a firm, flat surface. Check for breathing by looking for chest rise and also for a carotid pulse simultaneously. If the patient is not breathing or only gasping and there is a pulse, give the patient rescue breaths at the rate of 10–12 breaths/min. If there is no breathing or only gasping and no carotid pulse then start CPR immediately (**Figs. 1A** and **B**).

Step II: Cardiopulmonary Resuscitation

- Give the patient 30 chest compressions at a rate of 100–120 compressions a minute (**Fig. 2**). The chest should be compressed to at least 5 cm depth. The chest should completely recoil after each compression and there should be minimum interruptions in chest compressions. After chest compressions open the airway with a head tilt, chin lift maneuver (**Fig. 3**).
- One hand is placed on the forehead to tilt (extend) the head. Two fingers of the rescuer's other hand lift the mandible outward by lifting the chin.
- If a cervical spine injury is suspected, do only the jaw-thrust maneuver (**Fig. 4**). Use two or three fingers of each hand to lift the jaw, while the remaining fingers guide the jaw upward and outward.

The above two maneuvers ensure airway patency.

- Give two breaths to make the chest rise.
- Use a pocket mask or any other barrier device if available to give the breaths. In an ambulance or hospital breaths are delivered with an artificial mechanical breathing unit (AMBU) bag and a mask connected to oxygen.



FIGS. 1A AND B: Determining pulselessness. (A) Locate the larynx while maintaining the head-tilt position (top). (B) Slide your fingers into the groove between the trachea and the muscles at the side of the neck where the carotid pulse can be felt (bottom).

FIG. 2: External chest compression. Locate the correct hand position on the lower half of the sternum; proper position of the rescuer, with shoulders directly over the victim's sternum and elbows locked. Note that the body weight of the rescuer falling forward provides the force to depress the sternum. The sternum should be depressed approximately 1.5–2 inches.

Courtesy: Sinoy Jose.

FIG. 3: Head tilt and chin lift maneuver.

FIG. 4: Jaw thrust maneuver.

Courtesy: Dr Amit Nabar.

- In case, you do not have a mask or any other barrier device, then do mouth-to-mouth resuscitation.
- Each breath should be delivered over 1 second and sufficient time should be given for exhalation between the breaths. Chest compressions should be resumed in <10 seconds.
- Keep alternating 30 chest compressions with 2 breaths.
- Five sets of 30 compressions and 2 breaths should take approximately 2 minutes.
- At the end of two minutes switch compressors in order to avoid compressor fatigue.

Step III: Defibrillation

The following rhythms are observed during a cardiopulmonary arrest.

- *Ventricular fibrillation/pulseless VT:* These are the most common rhythms seen in victims of cardiac arrest the incidence being up to 80% of adult cardiac arrests.
- *Asystole:* There will be a flat line on the electrocardiogram (ECG) monitor.
- *Pulseless electrical activity:* There will be electrical complexes seen on the ECG monitor (other than VF or VT) in the absence of a palpable carotid pulse and other signs of life.

Defibrillation is the only effective treatment for VF/pulseless VT. The sooner the patient is defibrillated the better are the chances of the shock being effective. If the shock is

delivered in the first minute of cardiac arrest, the chances of the shock being successful are up to 80%. For every minute delay in defibrillation, the chances of the shock being effective reduce by 8–10%. Hence if a shock is delivered after around 12 minutes after a cardiac arrest, the chances of the shock being effective is nearly nil. However, if the patient is receiving CPR then the time for responsiveness of the heart to a shock is increased. In the event of asystole or pulseless electrical activity (PEA), CPR should be continued while efforts are on to identify the cause of cardiac arrest. Defibrillation is not indicated in these situations as it stuns the myocardium and reduces the chances of recovery. The two types of defibrillators in use are the AED and the manual defibrillator.

Automated External Defibrillator

Since it is very important to shock a patient immediately after the onset of VF and pulseless VT a defibrillator should be readily available at all times and in all places. Unfortunately, very few people have a cardiac arrest in a hospital as most cardiac arrests occur at home, in the neighborhood or in one's workplace. When these arrests occur bystander, CPR has to be started and this is almost always done by nonmedical personnel. Hence the AED was designed so that it could be used by lay people during CPR. The AED is a computerized device which is able to recognize whether the cardiac rhythm is shockable or nonshockable. It uses voice and visual prompts to particularly guide lay providers to defibrillate a patient safely. Method of operating an AED is as follows:

- When a patient is diagnosed to be having a cardiac arrest, CPR is begun and an AED is immediately asked for.
- The AED has to be switched on. As soon as it is switched on the voice prompts begin.
- The pads have to be applied on to the bare chest and the AED starts analyzing the heart rhythm. During the analysis, the patient should not be touched and hence CPR has to be momentarily stopped.
- If the rhythm is shockable, the button that is used to shock the patient is highlighted and the voice prompts the rescuer to press that button. The shock is then delivered. After delivery of the shock, CPR has to be continued for a further five cycles or 2 minutes after which the AED will reanalyze the heart rhythm. The cycle thus continues.
- Once the AED paddles have been applied, they should not be removed throughout the resuscitation. Every two minutes the AED paddles continue to analyze the rhythm.
- The AED paddles are disposable, hands free paddles that stick on to the surface of the chest. They act as electrodes as well as deliver a shock to the patient.

Manual Defibrillator

Manual defibrillators are available in an ambulance or hospital setting. Method of defibrillation is as follows:

- In an unresponsive patient, the first step is to call for help as well as a defibrillator.
- As soon as the defibrillator arrives, it is switched on, put on paddle mode and paddles are applied on to the chest. One paddle is applied below, the right clavicle and the second paddle in the left axilla and a quick look at the rhythm is obtained.
- If the rhythm is a VF or a pulseless VT, the defibrillator is charged to 200 Joules and a shock is delivered to the patient. Before delivering the shock, it is important to make sure that the person delivering the shock and everyone else performing the resuscitation are not in contact with the patient or the bed.
- As soon as the shock is delivered, CPR is continued.
- Every 2 minutes or after every five cycles of 30 chest compressions and 2 breaths, the rhythm is reanalyzed and a shock is delivered if it is still a shockable rhythm.
- The strength of the first shock and every subsequent shock is 200 Joules.
- There is no upper limit to the number of shocks that can be delivered. The patient needs to be defibrillated as long as a shockable rhythm continues.
- Before shocking the patient, sufficient electro gel needs to be applied on to the paddles in order to overcome the resistance of the chest wall.
- The paddles need to be pressed onto the chest wall with a force of 25 pounds/sq inch in order to overcome the impedance of the chest wall.

Step IV: Intravenous Access and Drugs

Cannulate a peripheral vein, preferably a vein of the upper limb, with a 16 gauge IV cannula, and administer drugs through it. Elevating the arm and flushing the cannula with a bolus of 20 mL of normal saline helps the entry of the drug into the central circulation. If an IV access cannot be obtained drugs can be given through an intraosseous (IO) route. Drugs used in CPR are as follows:

- *Adrenaline*:
  - Adrenaline is indicated in all types of cardiac arrests.
  - *Dose*: 1 mg IV every 3–5 minutes as long as CPR is continued.
- *Antiarrhythmic drugs*: Antiarrhythmic drugs are indicated during CPR in patients with a cardiac arrest due to a VF or pulseless VT when defibrillation and adrenaline have failed to restore a normal perfusing rhythm.
  - *Amiodarone*: The first dose is 300 mg diluted in 20 mL of 5% dextrose IV bolus. The second dose is 150 mg which is given after 3–5 minutes for persistent VF/VT.
  - *Lignocaine*: In case amiodarone is not available, lignocaine may be administered. The first dose is 1–1.5 mg/kg IV bolus. The second and subsequent doses are 0.5–0.75 mg/kg at 5–10-minute intervals to a maximum dose of 3 mg/kg.
  - *Magnesium sulfate*: This drug is used in the presence of torsades de pointes. The loading dose is 1–2 g IV diluted in 10 mL of 5% dextrose or normal saline given over 5–20 minutes. Routine administration of magnesium sulfate in cardiac arrest patients is not recommended.

Step V: Advanced Airway

The airway should be secured by using either an endotracheal tube or a supraglottic advanced airway device. See Chapter 32 for detail about advanced airways. Proper endotracheal tube placement should be confirmed. End-tidal capnometry can be used if available. After securing an advanced airway ventilation and chest compressions are done independently of each other. The patient is ventilated around 10 times a minute and continuous chest compressions are given at 100–120 times a minute.

Checking for Reversible Causes

While performing CPR one should simultaneously check for the cause of the cardiac arrest many of which are reversible. The common reversible causes leading to a cardiac arrest are summarized in the pneumonic 5 H's and 5 T's. The 5 H's are hypoxia, hypovolemia, hypo- or hyperkalemia, hypothermia, and hydrogen ion excess or acidosis. The 5 T's are tension pneumothorax, cardiac tamponade, cardiac or pulmonary thrombus, and toxins. Ultrasound can be used without interrupting CPR to identify some of the above causes. It is important to quickly identify and treat the underlying cause during CPR itself in order to obtain ROSC.

Importance of Team Effort

Successful CPR requires good team effort. The members of the team should all be well versed with the steps of CPR. There should be good coordination and communication within the members of the team.

POSTCARDIAC ARREST CARE

Once perfusing rhythm is restored, postcardiac arrest care is very important to sustain the spontaneous circulation and to prevent a rearrests. Post-ROSC care is summarized in **Table 1**.

- Adequate oxygenation (supplemental oxygen, endotracheal intubation, and assisted ventilation)
- Adequate circulation (IV fluids and infusion with one of the vasopressors given below):
  - IV epinephrine (0.1–0.5 μg/kg/min)
  - IV dopamine (5–10 μg/kg/min)
  - IV norepinephrine (0.1–0.5 μg/kg/min)
- 12-lead ECG to find out if there is a myocardial infarction.
- To protect the brain in patients who are not conscious, targeted temperature management should be done. The patients' temperature should be maintained between 32°C and 36°C for at least 24 hours. This is most often done by infusing ice-cold fluids postresuscitation. Other surface cooling measures can also be used.
- Treat the underlying cause
- Relevant investigations should be done (arterial blood gas, complete blood count, electrolytes, renal functions, blood sugar, and chest X-ray).
- Monitoring O_2 saturation, ECG, central venous pressure (CVP), blood pressure (BP), and urine output
- Measures to support other organ systems
- Reassessment of the patients' history and physical examination
- All resuscitated patients should be transferred to an intensive care unit for further monitoring and treatment.

TABLE 1: Post-ROSC checklist.

System	*Intervention*
Airway	• Intubation • Ventilation • Tidal Volume @ 6–8 mL/kg • Placement of nasogastric/orogastric tube • Chest X-ray
Breathing	• Adjust PEEP FiO_2 to achieve saturation >94% • Adjust respiratory rate to achieve $EtCO_2$ 30–40 mm Hg
Circulation	• 12-lead ECG activate cardiac catheterization laboratory • Cardiology consultation • Place central and arterial line • Goal SBP > 90 mm Hg (MAP—65 mm Hg) • Use of fluid noradrenaline adrenaline infusion • Point of care ultrasound for cardiac lung and IVC view • Send laboratory investigation ABG serum lactate • Place foleys catheter (Goal UO 1 mL/kg/h) • Rule out PE by CT chest angiography
Disability	• Begin cooling • Targeted temperature management—32–36°C • Consider CT heat

(ABG: arterial blood gases; MAP: mean arterial pressure; PEEP: positive end expiratory pressure; ROSC: return of spontaneous circulation; SBP: systolic blood pressure)

CARDIOPULMONARY RESUSCITATION IN CHILDREN-HOW IS IT DIFFERENT?

Classification in Children

1–28 days of life: Neonate, we will not be discussing CPR in a neonate in this chapter. *28 days–1 year Infant***:** *1 year to onset of puberty-child (*onset of puberty is taken as appearance of axillary hair in a male and breast development in a female). CPR is done in the same manner as adults in infants and children with a few exceptions which are given below.

- *Step 1*: *Calling for help after assessing responsiveness (common for infant and child)*:
  - *Witnessed arrest*: If the rescuer is present when the child has collapsed then he calls for help after assessing unresponsiveness and then only starts CPR.
  - *Unwitnessed arrest*: If the rescuer enters a room and finds that a child has collapsed and is unresponsive, he first gives 2 minutes of CPR. After 2 minutes of CPR he calls for help.
- *Step 2*: *Pulse check*:
  - *Infant*: The brachial artery in the arm is palpated to look for a pulse.
  - *Child*: The carotid or femoral artery is palpated to look for a pulse.
- *Step 3*: *Chest compressions*:
  - *Hand placement*:
    - *Infant*: Hand placement varies depending whether it is single rescuer or two-rescuer CPR. In single rescuer, CPR chest compression is done one finger's width below the intermammary line using the middle and ring fingers (**Fig. 5**). Sternal compression is performed by the "two-thumb-encircling hands" technique in two-rescuer CPR (second rescuer taking care of the airway) (**Fig. 6**).
    - *Child*: Compressions should be performed with the heel of one hand over the lower half of the sternum. If it is a bigger child two hands can be used as in adults.

FIG. 5: Chest compressions in infants. Single rescuer CPR—two finger sternal compressions.

FIG. 6: Chest compressions in infants. Two-rescuer CPR—the "two-thumb-encircling hands" chest compression technique.

Courtesy: Sinoy Jose.

  - *Compression depth*:
    - *Infant*: At least one-third of the AP diameter of the chest (1.5 inches or 4 cm)
    - *Child*: At least one-third of the AP diameter of the chest (2 inches or 5 cm)

In an unresponsive infant or child with adequate breaths but a pulse rate <60 beats per min starts chest compressions with ventilations.

- *Ventilation*
- *Breathing techniques*: In infants, mouth-to-mouth and nose technique are preferred. However, if one cannot cover the infant nose and mouth with your mouth then the mouth-to-mouth technique can be used.
- *Rescue breathing*: Give 12–20 breaths/min in both infants and children who have a pulse but are not breathing.
- *Compression ventilation ratio*:
  - *Infant*: When there is a single rescuer, it is 30 compressions to 2 breaths. When there are two rescuers, it is 15 compressions and 2 breaths.
  - *Child*: The ratio is 30 compressions and 2 breaths whether, it is single rescuer or two rescuers.
- *Defibrillation*
- *Use of AED*: A pediatric capable AED should be used if available. These are designed to be used both in adults and children and automatically deliver a reduced dose of shock when the pediatric pads are used.
- *Infants*: In infants, a manual defibrillator is preferred to an AED as lower energy joules can be set.
- In case a manual defibrillator is not available then an AED with a pediatric dose attenuator should be used. If not available, then an AED without a pediatric dose attenuator can be used. Child pads should be used. In case, there are no child pads then adult pads can be used but they should be placed on the anterior and posterior surface of the chest so that they do not touch each other.
- *Children <8 years of age*: Use an AED as soon as it is available. An AED with a pediatric dose attenuator is preferred. Use child pads if available. If not available then adult pads can be used on the anterior and posterior surface of the chest.
- *Children 8 years of age of older*: Use and AED as soon as it is available. Use adult pads. Pediatric pads should not be used because they might give too low a dose of shock.
- *Shock dose*: If the AED that is being used cannot deliver the pediatric dose, then the adult dose may be delivered.
- *Use of a manual defibrillator*: If a manual defibrillator is being used, the child pads have to be applied.
- The initial dose of the shock delivered is 2 Joules/kg. The subsequent doses should be 4 Joules/kg or higher. It should not exceed 10 Joules/kg or the standard adult dose.

Drug Dosages in Children during CPR

- *Injection adrenaline*: IV/IO dose: 0.01 mg/kg (0.1 mL/kg of 1:10,000 concentration). Administer every 3–5 minutes during arrest. Note that the maximum dose that can be administered is 1 mg.
- *Intraosseous infusion* is used in a child when an IV access is not available. The flat anteromedial surface of the tibia, approximately 1–3 cm below the tibial tuberosity is the preferred site for infants and children < 6 years of age, since the marrow cavity in that location is very large and the potential for injury to tissues is minimal.

SPECIAL SITUATIONS

The following precautions need to be taken in the following situations:

- *Trauma*: Unnecessary movement of the head and neck should be avoided when providing CPR to patients with trauma. The airway should be opened using the jaw-thrust technique without extension of the head. While securing a definitive airway, one person should stabilize the head in a neutral position. Manual spinal restriction is preferable to the use of immobilization devices. Spinal immobilization devices can be used during transport.
- *Pregnancy*: When doing chest compressions in a pregnant woman, a wedge should be inserted under the right hip so that there is a left sided tilt. This prevents aortocaval compression and CPR is thus made effective.
- *Cardiopulmonary resuscitation in a highly infectious patient (e.g., patient who is infected with COVID-19)*: When approaching a patient who is suffering from a highly infectious condition, it is important that the

healthcare providers take adequate precautions to protect themselves and their colleagues from exposure. This is very relevant when faced with a pandemic situation. *Certain precautionary measures to prevent exposure*:

- Before approaching the patient and beginning the resuscitation, all healthcare personnel should don personal protective equipment that protects both against contact with airborne as well as droplet particles.
- Minimum number of healthcare personnel should be involved in the resuscitation.
- All healthcare providers in the vicinity should be informed about the infected state of the patient.
- Resuscitation can be attempted in a separate area reserved for the same, if possible. It would be beneficial if such an area was provided with negative suction facilities.
- Manual chest compressions can be replaced with mechanical CPR devices, if available as this will reduce rescuer fatigue.
- Early intubation as bag mask ventilation is a highly aerosol producing procedure.
- Passive oxygenation with nonrebreathing face mask can be used as an alternative to bag mask ventilation.
- Connect a high-efficiency particulate air (HEPA) filter when ventilating the patient.
- A person who is skilled in intubation should intubate the patient as failed intubation increases the chances of aerosol generation.
- Video laryngoscopy if available can be used.
- Chest compressions should be paused during intubation.
- Feasibility of resuscitation should be taken into account and prolonged resuscitation should not be attempted in patients who have a very poor prognosis.

DEFIBRILLATION

A defibrillator is a device that administers a controlled electrical shock to patients to terminate a cardiac arrhythmia. The technique of administering the electrical shock is usually referred to as defibrillation, if it is used to terminate VF or cardioversion if it is given for unstable patients with arrhythmias such as atrial fibrillation, atrial flutter, supra-VT, or VT with a pulse. A direct current defibrillator consists of a variable transformer allowing the operator to select a variable voltage potential, an AC to DC converter that includes a capacitor to store the energy, a charge switch that allows the capacitor to charge, and discharge switches to complete the circuit from the capacitor to the electrodes.

Importance of Early Defibrillation

The most frequent initial rhythm in sudden cardiac arrest in adults is VF. The only effective treatment for VF is electrical defibrillation. The probability of successful defibrillation diminishes rapidly over time. Hence defibrillation should be performed as soon as a VF is detected. The probability of successful defibrillation and subsequent survival to hospital discharge is directly related to the time interval between the onset of VF and delivery of the first shock. VF tends to convert to asystole within a few minutes. CPR should be performed while waiting for the defibrillator as it appears to prolong VF and contributes to preservation of heart and brain function.

Energy, Current, and Voltage

A defibrillation shock passes a large flow of electrons through the heart over a brief period. This flow of electrons is called current, which is measured in amperes. The pressure pushing this flow of electrons is referred to as the electrical potential, and potential is measured in volts. There is always a resistance to this flow of electrons, which is called impedance, measured in ohms. In short, electrons flow with a certain pressure for a certain period of time, (usually milliseconds) through a substance that has resistance. Although the operator selects the shock energy in joules, it is the current flow in amperes that actually defibrillates. With a constant amount of energy stored in the capacitor, the delivered current depends on the impedance (resistance) present between the defibrillator electrodes.

Transthoracic Impedance

Defibrillation is accomplished by passage of sufficient electric current (amperes) through the heart. The energy chosen (joules) and the transthoracic impedance (ohms), or resistance to current flow, determine the current flow. Factors that determine transthoracic impedance include energy selected, electrode size, paddle-skin coupling material, number and time interval of previous shocks, phase of ventilation, distance between electrodes (size of the chest), and paddle electrode pressure. The average adult human impedance is approximately 70–80 ohms. When transthoracic impedance is too high, a low energy shock will not generate enough current to achieve defibrillation. To reduce transthoracic impedance, the defibrillator operator should always press firmly on handheld electrode paddles and use a gel or cream or saline-soaked gauze pads between handheld electrode paddles and the chest. Self-adhesive monitor defibrillator electrode pads do not require additional pressure. Use of bare hand-held paddles without a coupling material between electrodes and the chest wall creates high transthoracic impedance. Male patients with a hirsute chest have poor electrode to chest contact plus air trapping. This results in high impedance with occasional arcing. Although extremely rare, in an oxygen rich environment such a critical care unit this arcing has been known to produce fires if an accelerant is present.

Electrode Position

The electrodes should be placed in positions to maximize current flow through the myocardium. The standard placement is one electrode just to the right of the upper sternal border below the clavicle. The second electrode should be placed to the left of the nipple with the center of the electrode in the midaxillary line (**Fig. 7**). An acceptable alternative is to place the apex paddle anterior, over the left precordium and the other paddle-labeled sternum posterior to the heart in the right infrascapular location. Care should be taken to see that the electrodes are well separated and that paste or gel is not smeared on the chest between the paddles, because the current may follow a superficial pathway along the chest wall, missing the heart. When performing cardioversion or defibrillation in patients with permanent pacemakers or implantable

FIG. 7: Chest pads placement for defibrillation and cardioversion. *Courtesy*: Sinoy Jose.

cardioverter defibrillators (ICDs), electrodes should not be placed near the device generator, because defibrillation can cause malfunction. A pacemaker or ICD also may block some current to the myocardium during defibrillation, delivering suboptimal energy to the heart. Finally, because some of the defibrillation current flows down the pacemaker lead, the pacing threshold should always be evaluated aftershocks are given to patients with permanent pacemakers. ICD function also should be evaluated.

Electrode Size

In general, the larger the electrode, the less the impedance, but too large an electrode can result in inadequate contact with the chest or a large portion of the current traversing extracardiac pathways and missing the heart. For adults most defibrillation electrodes range from 8.5 to 12 cm in diameter and these are effective. Infants and children require smaller electrodes. However, high transthoracic impedance in children is found when small pediatric paddles are used. Thus larger adult paddles should be used as soon as the paddles will fit completely on the child's chest. This transition occurs at approximately 10 kg, the average weight of a 1-year-old child.

Principle of Working

Massive amounts of electrical energy are delivered by defibrillator shocks over a few milliseconds. This electrical energy passes between the positive and negative defibrillator paddles placed on the chest wall and passes through the fibrillating heart. The current flow totally depolarizes the entire myocardium and produces a complete electrical silence. This allows spontaneously repolarizing pace making cells within the heart to recover. The regular cycles of repolarization and depolarization of these pacemaker cells allow coordinated contractile activity to resume if the cells are not damaged. Although the defibrillator operator selects the shock energy in joules it is the current flow in amperes through the heart that actually defibrillates the patient. Hence defibrillation is achieved by generating an amplitude of current flow which is sustained for a time interval. *Shock energies*: The recommended energy for shocks is 200 Joules.

Indications for Defibrillation

The only indication for defibrillation is a VF and a pulseless VT during a cardiac arrest. Successful defibrillation depends on the electrical and metabolic state of the myocardium, the amount of myocardial damage that has occurred during the arrest, the prior functional state of the heart and the cause of the VF. Prolonged VF exhausts the energy stores of ATP in the myocardium, particularly from the cardiac pacemaker cells. Hence the longer the VF persists, the energy stores will be depleted and there will be a lot of myocardial deterioration. Therefore, the myocardium will not respond to defibrillation and shocks will not be effective. Hence it is very important to shock the patient as soon as possible after a VF before depletion of ATP and myocardial damage occurs.

Procedure for Defibrillation

- The patient should be placed in a safe environment, away from pooled water or a metal surface under either the patient or the rescuer.
- Electrode gel or paste should be applied to the hand-held electrodes or readymade electrode pads should be used.
- The defibrillator should be turned on.
- An energy level of 200 Joules should be selected to shock a VF or pulseless VT.
- The capacitor should be charged.
- The electrodes should be properly placed on the chest, one electrode below the right clavicle and the other over the apex. Firm pressure should be applied over hand-held paddle electrodes. There should be no smearing of the coupling material between the paddles, as the current may preferentially follow this low resistance pathway along the chest wall, missing the heart. Any transdermal medication patches should be removed.
- No personnel should be directly or indirectly in contact with the patient. If ventilation via a bag mask device or endotracheal tube is being performed, the rescuer should step back and momentarily release the bag. It is unnecessary to disconnect a bag from an endotracheal tube if the tube is well secured.
- The electric shock should be delivered by depressing both discharge buttons simultaneously.
- *Disarming the defibrillator*: Once the defibrillator has been charged, if one does not wish to deliver the shock as the rhythm is not shockable, the disarm button on the defibrillator needs to be pressed in order to remove the charge.
- *False asystole*: An asystole should not be defibrillated. However, occasionally a VF can present as a false asystole due to technical errors such as no power, leads unconnected, gain set to low, or incorrect lead selection.

Monophasic and Biphasic Defibrillators

Defibrillators deliver energy or current in waveforms. The two broad categories of waveform are monophasic and biphasic.

1. *Monophasic defibrillators*: Monophasic defibrillators deliver energy in monophasic waveforms. Monophasic waveforms deliver current in primarily one direction. Monophasic defibrillators require high levels of energy to be delivered, namely 360 Joules for the first shock as well as for every subsequent shock.

2. *Biphasic waveform defibrillators*: Biphasic waveform defibrillators developed recently and approved for clinical use. Monophasic waveforms deliver current in one direction. Biphasic waveforms in contrast, deliver current that flows in a positive direction for a specified duration. The current then reverses and flows in a negative direction for the remaining milliseconds of the electrical discharge. Biphasic waveforms have proved superior to monophasic waveforms for defibrillation by implantable defibrillators. Current research confirms that biphasic shock energies ≤200 Joules are safe and effective. Nonescalating biphasic energies appear to have success rates for VF termination equivalent to or better than monophasic shocks that increase in energy for each shock.

The postresuscitation arrhythmias seen are much less with the biphasic defibrillators and hence these defibrillators have replaced the monophasic ones.

Charging the Battery of the Defibrillator

Every defibrillator has a battery and the shock is delivered from this battery. Hence it is important to make sure that the battery is always well charged for the shock to be properly delivered. The power cord of the defibrillator should be connected to the main power supply with the defibrillator in the switched off mode. This ensures that the battery of the device is being charged. The defibrillator should be checked every day to make sure that it is in a proper working condition and that the battery is charged.

Pediatric

In children, separate pediatric paddles have to be applied which are smaller in size. The pediatric paddles are applied in the same place as in adults. The first shock delivered in case of a VF or a pulseless VT is 2 Joules/kg body weight and the second and subsequent shocks are 4 Joules/kg body weight.

Special Situations

- In case a person is sweating profusely or has been rescued from water, the anterior surface of the chest needs to be wiped before applying the paddles as the current will pass from one paddle to another and not through the heart as water is a good conductor of electricity.
- A medicine patch needs to be removed from the chest if present before the shock is delivered for fear of a burn occurring.
- In case of an implantable pacemaker or ICD being in place, the paddles need to be placed at least 2.5 inches away from the device. If placed closer, the ICD may block some current to the myocardium during defibrillation causing delivery of suboptimal energy to the heart.
- In addition to the special situations mentioned above, in case of a patient with a hairy chest, the hair should first be shaved before the paddles are applied, or else the pads will not be able to stick firmly to the chest wall and rhythm analysis will not be possible.
- *Pediatric patients*: AED's have a separate pediatric mode as well as smaller pediatrics pads to be applied on children. The preset joules in the pediatrics mode are less than that in an adult patient. The pediatric pads in children are applied in the same position as in adults. Since they are disposable adhesive pads they can also be applied on the anterior surface of the chest and posteriorly over the back.

CARDIOVERSION

Cardioversion is the delivery of a synchronized shock to a patient who has an unstable tachyarrhythmia. The shock is synchronized with the QRS complex of the ECG. This is achieved by pressing the sync button present on the defibrillator. Synchronization avoids delivery of the shock during the relative refractory period of the cardiac cycle, when a shock itself can push the myocardium into a VF.

Principle of Working

Reentry rhythms are caused by an abnormal rhythm circuit which allows a wave of depolarization to travel in a circuit, recirculating the same path over and over again. Delivery of a shock can stop these rhythms because a shock interrupts the circulating pattern. *Cardioversion is indicated for unstable tachyarrhythmias* such as supra-VT, atrial flutter and fibrillation, and VT with a pulse.

Cardioversion requires much lower energy levels to be delivered than defibrillation as the cardiac rhythm is an organized rhythm and not a disorganized rhythm as occurs in a VF. *Quantum of synchronized joules for the different arrhythmias are*: Supraventricular tachycardia—50–100 Joules: *Atrial fibrillation*—120–200 Joules: *Atrial flutter*—50–100 Joules*: VT with a pulse*—100 Joules

Steps of Cardioversion

- Once a tachyarrhythmia has been diagnosed and the patient has been found to be unstable the defibrillator is switched on and ECG leads are attached to the patient.
- Consent is obtained from the patient or his attenders for the procedure.
- The crash cart with resuscitation drugs and airway equipment is kept at the bedside in case of an untoward event requiring resuscitation.
- The patient is given an adequate dose of a sedating agent as well as analgesia as the shock can be very painful.
- The sync button of the defibrillator is switched on, the paddles are applied to the patient after applying electrogel.
- The required amount of joules is selected, the device is charged, it is made sure that neither the operator nor anyone else is touching the patient, and the bed and the shock is delivered.
- In case the rhythm has not reverted, another shock is delivered with increased number of joules as indicated for the rhythm.
- After the shock is delivered, sync button is switched off.
- The heart rate and the BP are recorded.

Atrial Fibrillation

The recommended initial energy for cardioversion of atrial fibrillation is 100–200 Joules. Atrial flutter and paroxysmal supraventricular tachycardia (PSVT) generally require less energy. An initial energy of 50–100 Joules is often sufficient with stepwise increases in energy if initial shocks fail.

Ventricular Tachycardia

The amount of energy required for cardioversion of VT depends on the morphological characteristics and rate of the arrhythmia. Monomorphic VT (regular form and rate) with or without a pulse responds well to cardioversion shocks at initial energies of 100 Joules. Polymorphic VT (irregular morphology and rate) responds similarly to VF, the initial shock energy should be 200 Joules. The shocks can be increased stepwise, if the first shock fails to cardiovert. The energy delivered should be synchronized with the QRS complex to reduce the possibility of inducing VF, which can occur when a shock hits the relative refractory portion of the cardiac cycle. Synchronization to prevent this complication is recommended for hemodynamically stable wide complex tachycardia requiring cardioversion, supra-VT, atrial fibrillation, and atrial flutter. VF requires unsynchronized defibrillation mode. It is important to note that synchronization in VT may be difficult and misleading because of the wide complex and variable forms of ventricular arrhythmia. The VT patient who is pulseless, unconscious, hypotensive, or in severe pulmonary edema should receive unsynchronized shocks to avoid the delay associated with attempts to synchronize. The healthcare provider should be prepared to deliver another unsynchronized shock within seconds, if VF or pulseless VT remains or recurs. The defibrillator is used both for defibrillation as well as for cardioversion. One should make sure that the sync button is removed after each cardioversion so that in case the patient goes into a pulseless rhythm it is possible to defibrillate the patient. It is not possible to defibrillate a patient when in the sync mode.

RECENT ADVANCES

Current-based defibrillation and other cardiac arrhythmias can be terminated by electric shock when sufficient current passes through the myocardium. A promising alternative approach to defibrillation is the use of electric current amperes instead of energy joules. This approach would prevent attempts to deliver inappropriately low energy levels to a patient with high impedance. Current-based therapy would also prevent high energy shocks to patients with low impedance which result in excessive current flow, myocardial damage, and failure to defibrillate.

Implantable cardioverter defibrillators—certain high-risk patients with cardiac arrhythmias are implanted with a device that can pace, detect a cardiac arrhythmia and automatically perform defibrillation or cardioversion. These devices are called implantable cardioverters/defibrillators. They protect the patient from undergoing a cardiac arrest by intercepting and pacing or cardioverting an arrhythmia. Also in case the patient has a cardiac arrest, it can recognize a shockable rhythm and defibrillate the patient.

RECENT UPDATES ON CARDIOPULMONARY RESUSCITATION

The American Heart Association (AHA) guidelines for adult, pediatric, and neonatal, resuscitation is revised in year 2020. These guidelines are helpful for the resuscitation providers and instructors during cardiac arrest resuscitation and also result in changes in resuscitation training and practice. The changes in the 2020 AHA Guidelines for CPR summarize below.

- Easy to remember resuscitation scenarios, algorithms, and visual aids guidance for BLS and advanced cardiovascular life support (ACLS) are developed.
- Re-emphasis is given on the importance of early initiation of CPR by lay rescuers
- Early epinephrine administration has been reaffirmed with emphasis like previous guidelines.
- Use of real-time audio-visual feedback is suggested as a means to maintain CPR quality.
- To improve CPR quality, continuous measure of arterial blood pressure and end-tidal carbon dioxide ($ETCO_2$) during ACLS resuscitation is emphasized.
- Routine use of double sequential defibrillation is not recommended as per recent evidences.
- For medication administration during ACLS resuscitation, IV access is the preferred route but IO access is acceptable if IV access is not available.
- After ROSC, patient care requires close attention to oxygenation, blood pressure control, evaluation for percutaneous coronary intervention, targeted temperature management, and multimodal neuroprognostication.
- Post cardiac arrest recovery is long and continues process after the initial hospitalization, patients should have formal assessment and support for their physical, cognitive, and psychosocial needs.
- Debriefing after resuscitation for lay rescuers, EMS providers, and hospital-based healthcare workers is beneficial to support their mental health and well-being.
- Management of cardiac arrest in pregnancy focuses on maternal resuscitation and improves the chances of successful resuscitation of the mother with preparation for early perimortem cesarean delivery if necessary to save the infant.

The changes in algorithms and other performance aids are:

- A sixth link, *recovery,* is added to the "resuscitation"—Chains of Survival (**Fig. 8**).

Early recognition and prevention of causes of cardiac arrest
Activation of Emergency Response System
High quality CPR and Defibrillation
Advanced Resuscitation
Post Cardiac Arrest Care
Recovery

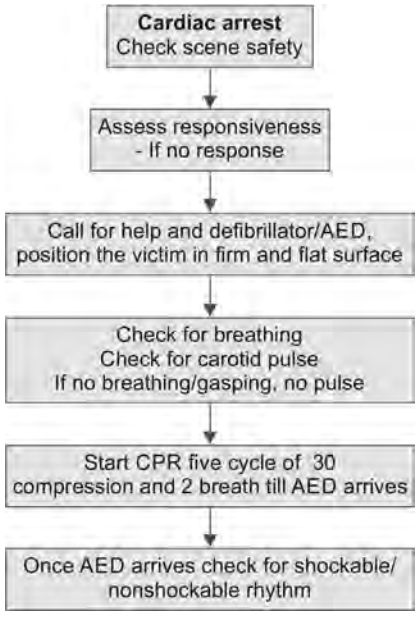
(CPR: cardiopulmonary resuscitation)

FIG. 8: Resuscitation: Updated chain of survival.

- The emphasis is given on the role of early epinephrine administration for patients with nonshockable rhythms in the universal "Adult Cardiac Arrest Algorithm" (modified now).
- Two new algorithms for "opioid-associated emergency" have been added for lay rescuers and trained rescuers
- The Post-cardiac Arrest Care Algorithm was updated to emphasize the need to prevent hyperoxia, hypoxemia, and hypotension.
- In post-cardiac arrest care section, new diagram is added to guide and inform neuroprognostication.
- A new algorithm has been added to address "Cardiac Arrest in Pregnancy."

SUMMARY

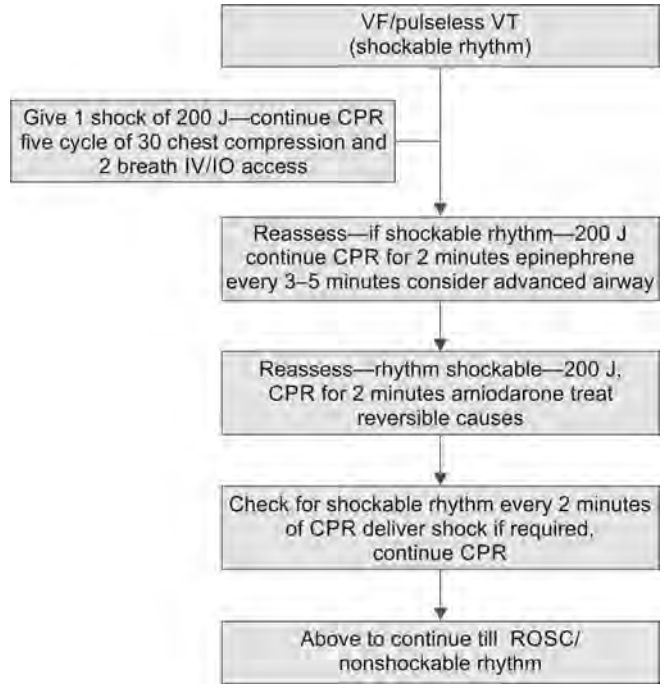
Cardiac arrest is most often the consequence of serious respiratory and circulatory conditions causing the patient to decompensate. Early recognition of a cardiac arrest and early good quality CPR improve the chances of ROSC. BLS and ACLS are two ends of the same spectrum. The most common rhythm seen during an adult cardiac arrest is a VF. The treatment for VF and pulseless VT is immediate defibrillation. Cardioversion is used for unstable tachyarrhythmias. It is important to press the sync button during cardioversion and to remove it once the shock has been delivered. The defibrillator is a very important device and should be checked on a regular basis to make sure that it is functioning properly. The algorithmic approach to resuscitation (**Flowcharts 1** to **3**) increases the chance of ROSC in cardiac arrest patients. CPR summarized in algorithm for cardiac arrest, VF/pulseless VT, and asystole/PEA.



Cardiac arrest
Check scene safety
Assess responsiveness
- If no response
Call for help and defibrillator/AED,
position the victim in firm and flat surface
Check for breathing
Check for carotid pulse
If no breathing/gasping, no pulse
Start CPR five cycle of 30
compression and 2 breath till AED arrives
Once AED arrives check for shockable/
nonshockable rhythm

(AED: automated external defibrillator; CPR: cardiopulmonary resuscitation)

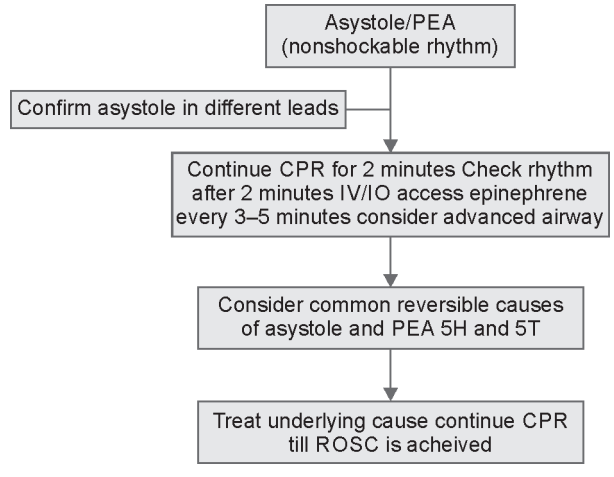
FLOWCHART 1: Cardiac arrest.



VF/pulseless VT
(shockable rhythm)
Give 1 shock of 200 J—continue CPR
five cycle of 30 chest compression and
2 breath IV/IO access
Reassess—if shockable rhythm—200 J
continue CPR for 2 minutes epinephrene
every 3–5 minutes consider advanced airway
Reassess—rhythm shockable—200 J,
CPR for 2 minutes amiodarone treat
reversible causes
Check for shockable rhythm every 2 minutes
of CPR deliver shock if required,
continue CPR
Above to continue till ROSC/
nonshockable rhythm

(CPR: cardiopulmonary resuscitation; IV: intravenous; IO: intraosseous; ROSC: return of spontaneous circulation; VF: ventricular fibrillation; VT: ventricular tachycardia)

FLOWCHART 2: Shockable rhythm (VF/VT).



Asystole/PEA
(nonshockable rhythm)
Confirm asystole in different leads
Continue CPR for 2 minutes Check rhythm
after 2 minutes IV/IO access epinephrene
every 3–5 minutes consider advanced airway
Consider common reversible causes
of asystole and PEA 5H and 5T
Treat underlying cause continue CPR
till ROSC is acheived

(CPR: cardiopulmonary resuscitation; IV: intravenous; IO: intraosseous; PEA: pulseless electrical activity; ROSC: return of spontaneous circulation; VF: ventricular fibrillation; VT: ventricular tachycardia)

FLOWCHART 3: Nonshockable rhythm (asystole/PEA).

Cardiopulmonary Resuscitation in Special Situation

34 CHAPTER

Jesús Daniel López Tapia, Andrea Pechir Cerrillo

INTRODUCTION

The proper cardiopulmonary resuscitation (CPR) is based on guidelines which outline the proper technique of CPR and the indications on how and when to use it. There are special circumstances which make room for changing the steps and techniques previously established for CPR. The management of this special situation can be divided in three groups: (1) Special causes, (2) Special patients, and (3) Special locations. By mentioning special causes, this refers to those etiologies which are potentially reversible and can cause a cardiac arrest. It is important to recognize these causes due to the high success rates once they are reverted. We can divide them in two groups which are mentioned in **Table 1**.

Special patients are those who have chronic comorbidities or physiological conditions such as pregnancy or advanced age which forces the physician to consider different factors in the decision-making toward management and treatment of these patients. By special locations, we mean those specific places where the universal guidelines must be modified due to environmental factors that may make difficult the usual techniques of CPR.

HYPOXIA

Hypoxia is the reduction of oxygen in the blood usually due to pathological changes in the oxygen-carbon dioxide exchange between the lungs and the air. During these cases, it is essential to use oxygen supplementation while performing CPR. It is recommended the use of capnography to monitor an effective assisted ventilation hoping to maintain values between 10–20 mm Hg when the CPR technique is adequate. Role of oxygen therapy is discussed in detail in Chapter 36.

TABLE 1: Special causes of cardiac arrest: The 4 H's and 4 T's.

4 H's	*4 T's*
Hypoxia	Cardiac tamponade
Hypo-/hyperpotassemia (and other electrolyte abnormalities)	Tension pneumothorax
Hypo-/hyperthermia	Thrombosis (Coronary, pulmonary)
Hypovolemia	Toxins (intoxications and poisoning)

ELECTROLYTE IMBALANCES

Abnormalities in electrolytes may be the cause of cardiac arrhythmias and cardiac arrest. It is recommended to manage each electrolyte abnormality in an individual manner as shown in **Table 2** and continue to follow the CPR protocol. Management of electrolyte imbalance is discussed in detail in Chapter 46.

HYPOTHERMIA

A body temperature of <35°C (95°F) is defined as hypothermia. When the body is going through hypothermia, the oxygen consumption levels diminish which gives vital organs such as brain and heart priority on oxygen consumption. This could potentially lead to a complete neurological recovery after a prolonged cardiac arrest (for details of accidental hypothermia and cold injuries Chapter 239).

Management on hypothermic patients consists on removing the patient from cold location as well as remove clothing to prevent any more heat loss and use heated or normal blankets to restore heat as well as administer IV liquids at approximately 40°C (104°F). Any gastric, peritoneal, or vesical lavage should use liquids of this temperature. Increases in body temperature should be gradual of 1–1.5°C/h (33.8–34.7°F/h). Administration of oxygen at 40°C (104°F) is also recommended after intubation. It is important to monitor serum electrolytes due to frequent electrolyte imbalances when reheating patients.

When practicing CPR on hypothermic patients, remember the thorax may be more rigid than that of a normal temperature patient which may require greater pressure when compressing and ventilating to guarantee a successful CPR technique. Patients exhibiting cardiac instability should be transferred to an extracorporeal life support center without any delays.

TABLE 2: Intervention in electrolyte imbalance.

Electrolyte imbalance	*Management*
Hyperpotassemia	• It is the most common cardiac arrest cause and the most serious one • When serum potassium is >6.5 mmol/L, it is considered potentially mortal • Acidosis enhances hyperpotassemia due to potassium leaking into extracellular space • *Management*: Administer one rapid bolus of calcium chloride 10%, 10 mL IV; sodium bicarbonate 50 mEq, 1M and short-acting insulin 10 U + 50 g glucose
Hypopotassemia	• Less common, usually occurring in hospitalized patients • It is considered severe when values reach < 2.5 mmol/L • The management is based on administration of IV potassium
Hypocalcemia	• A serum calcium of <8.5 mg/dL or 2.1 mmol/L is considered hypocalcemia • Causes usually are sepsis, large corporal surface burns, acute pancreatitis, and intoxication due to calcium antagonists • Management with IV calcium chloride 10% administration, 10–40 mL and magnesium sulfate 10% 2 g is recommended
Hypermagnesemia	• Serum magnesium > 1.1 mmol/L is considered hypermagnesemia • Management consists on ClCa 10%, 10 mL administration
Hypomagnesemia	• Serum magnesium < 0.6 mmol/L. Usually is accompanied by hypopotassemia • Management consists of 2 g of magnesium sulfate 50% administration

HYPOVOLEMIA

Hypovolemia may be caused by hemorrhages or severe vasodilation as is the case in sepsis and anaphylaxis. The CPR should follow the same guidelines as a normovolemic cardiac arrest while correcting the hypovolemic cause. Discussed in detail in Chapter 48.

CARDIAC TAMPONADE

When there is pre-existing trauma, cardiac tamponade is responsible for 10% of cardiac arrests. When the trauma is penetrating thorax or epigastrium, the thoracotomy or ultrasound-guided pericardiocentesis are the immediate actions to follow. Cardiac tamponade and pericardiocentesis are discussed in Chapter 71.

TENSION PNEUMOTHORAX

Tension pneumothorax is suspected when at auscultation the respiratory sounds are unequal in each lung. Treatment is immediate and is a decompression throughout thoracentesis with a needle or a unilateral or bilateral thoracotomy. Pneumothorax and steps in insertion of chest tube are discussed in Chapter 88.

THROMBOSIS (CORONARY AND PULMONARY)

Patients with a cardiac arrest in whom we suspect it has a cardiac origin, the most frequent cause is an acute coronary thrombosis or an acute myocardial infarction, should start CPR right away while in hospital transfer. When patient reaches hospital, they should be transferred directly to a catheterization laboratory or hemodynamic laboratory to proceed with a percutaneous coronary intervention. For details of acute coronary syndrome, see Chapter 65. Pulmonary thromboembolism is suspected when the patient experiences dyspnea, thoracic pain, and syncope. The treatment of choice is fibrinolytic therapy even though an embolectomy may also be appropriate if indicated. After fibrinolytic therapy administration CPR should continue for around 60–90 minutes. Detail about pulmonary embolism is discussed in Chapter 76.

TOXINS (POISONING AND INTOXICATIONS)

Intoxications may be accidental or self-induced. When a patient has a cardiac arrest while intoxicated there should be a decontamination of the substance, promote its elimination and use specific antidotes. Usually, in these cases the reason for cardiac arrest is the obstruction of the airway due to bronchopulmonary aspiration of gastric content.

Gastrointestinal decontamination with activated charcoal is highly effective within the first hour of the ingestion. When there is an overdose of antidepressants especially tricyclic antidepressants, IV sodium bicarbonate must be administered. When overdose on local anesthetics, a lipidic emulsion infusion is the treatment of choice. General management of poisoned patient is described in Chapter 199.

Opioid overdose causes respiratory depression which may be corrected with an initial naloxone dose of 0.4–2 mg via intravascular, intramuscular, subcutaneous, or intraosseous every 2–3 minutes until patients breathing is adequate or protective airway reflexes are present.

SPECIAL PATIENTS

By special patient, we refer to those that due to physiological reasons such as pregnancy or advanced age or to comorbidities such as asthma, cardiac insufficiency with ventricular assistance device, neurological diseases, or obesity specific guidelines, must be followed during CPR.

Polytraumatic Patient

Victims of cardiac arrest during or after traffic or work accidents have a high mortality and neurological disability sequelae.

Global survival rate increases when CPR techniques are started within the first 3 minutes of cardiac arrest.

Pregnant Patient

Cardiac arrest management in pregnancy will require a manual left uterine displacement while performing CPR technique. The uterus overpasses the umbilicus around the 20th gestational week and can then compress the inferior vena cava and aorta preventing the venous return and cardiac output leading to a cardiac arrest. The displacement may be unimanual or bimanual. While performing chest compressions, the hands must be placed slightly higher over the sternum especially in third trimester patients. Early intubation may be considered with a 0.5–1 mm tube to facilitate pulmonary ventilation due to increased intra-abdominal pressure.

The main causes of cardiac arrest during pregnancy are hemorrhages, amniotic fluid embolism, eclampsia, and preeclampsia. Fetal survival rate is greatly dependent on maternal survival. Initial CPR should be focused on the pregnant patient. The evacuation of gravid uterus by cesarean section alleviates aortocaval compression which makes it a part of the resuscitation technique after second trimester. Resuscitation in pregnant is described in detail in Chapter 159. Some studies show a spontaneous return of circulation after delivery via C-section in pregnant patients with cardiac arrest.

Asthmatic Patients

When a cardiac arrest is due to an asthma exacerbation, it regularly means the patient has been having a considerate amount of time under hypoxia due to severe bronchospasms. The management for this patient is to maintain oxygen saturation between 94% and 98%, administer inhaled beta-2 agonists such as 5 mg of inhaled or IV salbutamol, nebulized anticholinergics such as 0.5 mg of ipratropium bromide every 4–6 hours, nebulized magnesium sulfate, IV corticosteroids, bronchodilators and 5 mg/kg of weight of aminophylline. An early tracheal intubation is preferred keeping 8–10 respirations per minute while performing CPR maneuvers to minimize air trapping. Dynamic hyperinflation due to air trapping may be causing transthoracic impedance which could lead to a nonsuccessful first electric discharge and a need for increasing energy in the defibrillation process.

Special Locations

Special locations are those that due to their geographic or environmental location may lead to situations which demand an adaptation to CPR techniques. Some examples of these locations are cardiac surgeries or interventions, catheterization laboratories, dialysis units, dental surgery, commercial airplanes and helicopters, high altitudes, avalanche and drowning victims, electricity lesions, and massive incidents.

Cardiopulmonary Resuscitation in Cardiac Interventions

In the catheterization laboratories and operating rooms, there should be defibrillators present and in high-risk patients, the patches may be placed before the procedure takes place. The use of thoracic compression machines is encouraged to reduce the health personnel exposure to radiation in the need of CPR while in angiography. When the cardiac rhythm is shockable for example in the ventricular fibrillation or pulseless ventricular tachycardia, it is recommended to perform three defibrillation shocks before starting thoracic compressions. Cardiac arrest during a major cardiac surgery is relatively common especially during the postoperative phase.

Cardiopulmonary Resuscitation in Airplanes

When there is a cardiac arrest victim in a commercial airplane flight, it is encouraged to follow the basic life support algorithm. The immediate deviation of the plane to the nearest airport will be a priority.

Cardiopulmonary Resuscitation in Athletes

When there is a sudden loss of consciousness during physical activity, the most probable origin is cardiac, and a rapid recognition of cardiac arrest is essential to start basic life support and an early shockable defibrillation.

Cardiopulmonary Resuscitation in Drowning Victims

The early rescue is essential. The patient must be removed from the water quickly. Oxygenation and good ventilation are the management pyramids. If patient presents hypothermia, it must be managed as mentioned earlier in this chapter. See Chapter 242 for details about drowning.

Cardiopulmonary Resuscitation in Great Altitudes and Avalanche Victims

Cardiopulmonary resuscitation in great altitudes or for avalanche victims does not differ from standard CPR, but it is important to consider that when there is a great altitude, the person who is performing the thoracic compressions will be exhausted far earlier than performing the same activity at sea level and this could lead to less effective compressions. Patients who were victims of avalanche usually have associated trauma and hypothermia, there should be a careful management of spinal column and seek an effective immobilization. Extracorporeal vital support is indicated when patient was buried under snow for >60 minutes, corporeal temperature at extraction was <30°C (86°F) and serum potassium is ≤8 mmol/L. See Chapter 243 for details about high altitute emergencies.

SUMMARY

There are various circumstances that require an adaptation to the standard vital life support techniques in order to deliver an optimal medical care service in any place to everybody. The knowledge and dominance of vital life support are essential to guarantee the best care.

35
CHAPTER

Postcardiac Arrest Syndrome

Devendra Richhariya, Bhawana Sharma

INTRODUCTION

Complete recovery from cardiac arrest is considered with successful return of spontaneous circulation (ROSC). Postcardiac arrest syndrome is the complex pathophysiological processes that occur following whole body ischemia during cardiac arrest and the subsequent reperfusion response during cardiopulmonary resuscitation (CPR). Severity of the postcardiac arrest syndrome depends on the cause of the cardiac arrest, and the many patients will require multiple organ support. Quality of the neurological recovery and overall outcome is depending on the treatment they receive during this postresuscitation period.

Once ROSC is achieved and patient is stabilized, the patient is transferred to the most appropriate high-care area [e.g., emergency room, cardiac catheterization laboratory, or intensive care unit (ICU)] for the postresuscitation phase care, continued diagnosis, monitoring, and treatment. The key interventions are required to optimize outcome for these patients (**Flowchart 1**). Depending on the cause of arrest, system and quality of care of these comatose patients admitted to ICUs after cardiac arrest, as many as 40–50% survive to be discharged from hospital, majority have a good neurological outcome although many have subtle cognitive impairment.

POSTCARDIAC ARREST SYNDROME—PATHOPHYSIOLOGY

The postcardiac arrest syndrome consists of:

- Postcardiac arrest brain injury
- Postcardiac arrest myocardial dysfunction
- Systemic ischemia/reperfusion response
- Persistent precipitating pathology

Duration and cause of cardiac arrest determine the severity of this syndrome. If the cardiac arrest is brief, it may not occur at all. Postcardiac arrest brain injury may present as coma, seizures, myoclonus, and varying degrees of neurocognitive dysfunction and brain death. Brain injury is the major cause of death in out-of-hospital cardiac arrest (OHCA). In the first 3 days, most deaths are due to cardiovascular failure and brain injury responsible for most of the later deaths. *Risk factors for the postcardiac arrest brain injury* are microcirculatory failure, impaired autoregulation, hypotension, hypercarbia, hypoxemia, hyperoxemia, pyrexia, hypoglycemia, hyperglycemia, and seizures. As discussed earlier, there is significant myocardial dysfunction after cardiac arrest but start recovering after 2–3 days but full recovery takes longer time. On the other hand, immune and coagulation pathways activated after whole body ischemia/reperfusion of cardiac arrest contributing to multiple organ failure and increasing the risk of infection. Intravascular volume depletion, vasodilation, endothelial injury, and abnormalities of the microcirculation are feature of the postcardiac arrest syndrome which mimics sepsis. Important steps in management of postcardiac arrest syndrome are described below.

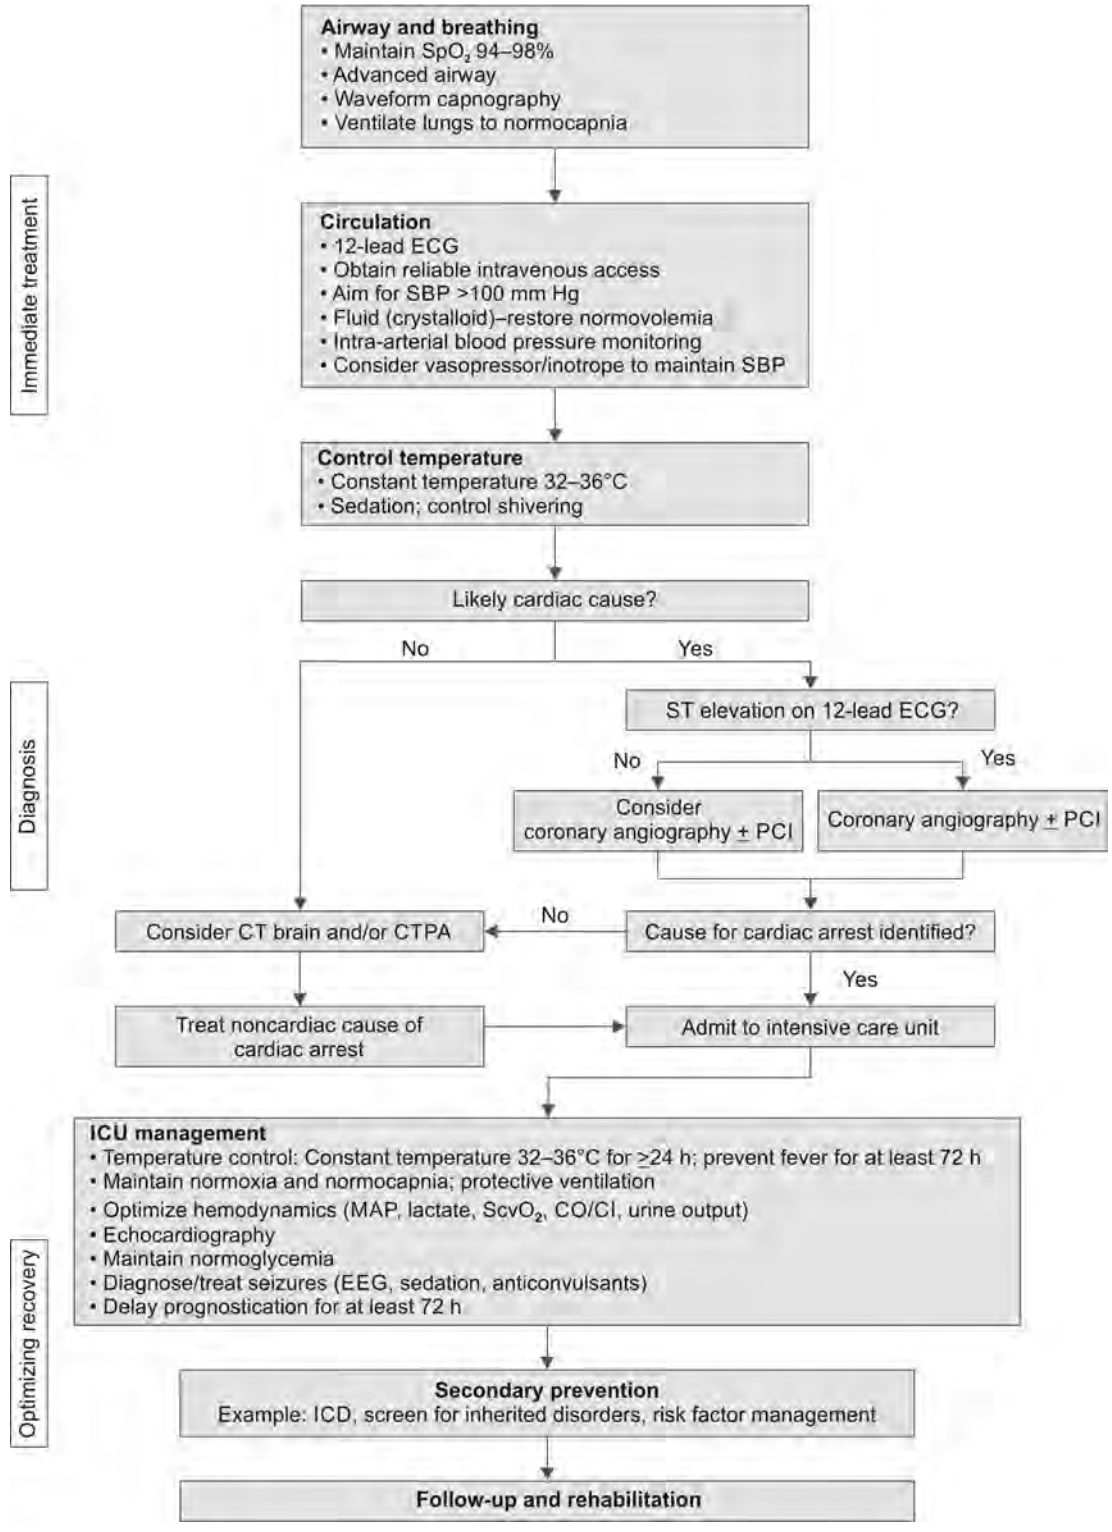
AIRWAY AND BREATHING

Control of Oxygenation

Those patients who recovered from brief period of cardiac arrest responding immediately to appropriate treatment (immediate return of normal cerebral function) can be managed with oxygen via a face mask. These patients do not require tracheal intubation and ventilation. If hypoxemia and hypercarbia are not treated timely, lead to further cardiac arrest and contribute to secondary brain injury. In the OHCA and after ROSC, it is difficult to obtain reliable arterial blood oxygen saturation values using pulse oximetry. If arterial blood oxygen saturation cannot be monitored reliably, possibility of myocardial dysfunction, increased neurological injury after cardiac arrest. Blood gas analysis and/or pulse oximetry should be monitored reliably as soon as possible to maintain the arterial blood oxygen saturation in the range of 94–98%. Avoid hypoxia, which is harmful and ensure reliable measurement of arterial oxygen saturation before reducing the inspired oxygen concentration.

Control of Ventilation

In any patient with obtunded cerebral function, consider tracheal intubation, sedation, and controlled ventilation. Endotracheal tube should be positioned correctly. Do not allow hyperventilation to occur as it causes cerebral ischemia. Cerebral vasoconstriction and a decreased cerebral blood



Immediate treatment
Airway and breathing
• Maintain SpO2 94–98%
• Advanced airway
• Waveform capnography
• Ventilate lungs to normocapnia
Circulation
• 12-lead ECG
• Obtain reliable intravenous access
• Aim for SBP >100 mm Hg
• Fluid (crystalloid)–restore normovolemia
• Intra-arterial blood pressure monitoring
• Consider vasopressor/inotrope to maintain SBP
Control temperature
• Constant temperature 32–36°C
• Sedation; control shivering
Diagnosis
Likely cardiac cause?
No
Yes
ST elevation on 12-lead ECG?
No
Yes
Consider coronary angiography ± PCI
Coronary angiography ± PCI
Consider CT brain and/or CTPA
No
Cause for cardiac arrest identified?
Yes
Treat noncardiac cause of cardiac arrest
Admit to intensive care unit
Optimizing recovery
ICU management
• Temperature control: Constant temperature 32–36°C for ≥24 h; prevent fever for at least 72 h
• Maintain normoxia and normocapnia; protective ventilation
• Optimize hemodynamics (MAP, lactate, ScvO2, CO/CI, urine output)
• Echocardiography
• Maintain normoglycemia
• Diagnose/treat seizures (EEG, sedation, anticonvulsants)
• Delay prognostication for at least 72 h
Secondary prevention
Example: ICD, screen for inherited disorders, risk factor management
Follow-up and rehabilitation

(ECG: electrocardiogram; ICD: implantable cardioverter defibrillator; MAP: mean arterial pressure; PCI: percutaneous coronary intervention; $ScvO_2$: central venous oxygen saturation)

FLOWCHART 1: Key interventions in postcardiac arrest syndrome.

flow occur if hypocarbia persists. Apply protective lung ventilation—tidal volume 6–8 mL kg^{-1} ideal body weight and positive end-expiratory pressure 4–8 cm H_2O. Use adequate doses of sedative preferably as per sedation protocol, which will reduce oxygen consumption. If using targeted temperature management (TTM) bolus doses of a neuromuscular blocking drug may be required. Infusions of neuromuscular blocking drugs not advisable as this interfere with clinical examination and may mask seizures. To detect seizures in these patients, especially when neuromuscular blockade is used, continuous electroencephalography (EEG) is recommended. Obtain a chest radiograph to check the position of the tracheal tube, gastric tube and central venous lines, assess for pulmonary edema, and detect complications from CPR such as a pneumothorax

associated with rib fracture. Gastric tube should be inserted to decompress the stomach; gastric distension caused by mouth-to-mouth or bag-mask ventilation will splint the diaphragm and impair ventilation.

CIRCULATION

Hemodynamic Management

Postresuscitation myocardial dysfunction causes hemodynamic instability, which manifests as hypotension, low cardiac index, and arrhythmias. Perform early echocardiography in all patients in order to detect and quantify the degree of myocardial dysfunction. Postresuscitation myocardial dysfunction needs inotropic support. Noradrenaline, with or without dobutamine, and fluid therapy is usually the most effective treatment. Blood pressure, heart rate, urine output, rate of plasma lactate clearance, and central venous oxygen saturation should be monitored during the treatment. In the ICU setting, an arterial line for continuous blood pressure monitoring is essential. In hemodynamically unstable patients' serial echocardiography may also be used. Cardiac output monitoring may help to guide treatment in hemodynamically unstable patients. Some studies advocate use of an intra-aortic balloon pump (IABP) in patients with cardiogenic shock. Specific systolic blood pressure (>90 mm Hg) and mean arterial blood pressure (>65 mm Hg) should be targeted, to achieve an adequate urine output (1 mL kg^{-1} h^{-1}). Normal or decreasing plasma lactate values is desirable. During mild-induced hypothermia, oxygen requirements are reduced and the normal physiological response is bradycardia. As long as blood pressure, lactate and urine output are sufficient, a bradycardia of ≤40 $minutes^{-1}$ may be left untreated as studies suggest bradycardia associated with good outcome. Postcardiac arrest period is associated with hyperkalemia. Further in due course, hypokalemia occurs due to endogenous catecholamine release and correction of metabolic and respiratory acidosis promotes intracellular transportation of potassium. Hypokalemia should be corrected promptly as it may predispose to ventricular arrhythmias.

Coronary Reperfusion

Out-of-hospital cardiac arrest frequently caused by acute coronary syndrome (ACS), the invasive management, early coronary angiography followed by immediate percutaneous coronary intervention (PCI) is recommended by many studies, particularly those having prolonged resuscitation and nonspecific ECG changes, though it is controversial also because of the lack of high-quality evidence and significant burden on use of resources (transfer of patients to PCI centers).

Acute coronary lesion is more likely (>80%) in patients with ST segment elevation (STE) or left bundle branch block (LBBB) on the post-ROSC electrocardiogram (ECG). Immediate angiography and PCI when indicated should be performed in resuscitated OHCA patients whose initial ECG shows ST-elevation, even if they remain comatose and ventilated. Observational studies also indicate that by implementing combination of TTM and PCI optimal outcomes after OHCA can be achieved. Thus this strategy can be included as a standardized postcardiac arrest protocol to improve neurologically intact survival. In contrast to the usual presentation of ACS, those presenting with non-STE, there are conflicting data from observational studies on the potential benefit of emergent cardiac catheterization strategy. Factors which influence the decision to undertake the intervention in the acute phase or to delay it are patient age, duration of CPR, hemodynamic instability, presenting cardiac rhythm, and neurological status upon hospital arrival. Implantable cardioverter defibrillators (ICDs)—in ischemic patients (primary coronary event induced ventricular arrhythmias) with significant left ventricular dysfunction, insertion of an ICD can be considered.

Brain and chest CT scan can be performed at hospital admission, before or after coronary angiography for early identification of a respiratory or neurological cause. Perform coronary angiography first if there is clinical or ECG evidence of myocardial ischemia or in absence of signs or symptoms suggesting a neurological or respiratory cause (e.g., headache, seizures, or neurological deficits for neurological causes, shortness of breath or documented hypoxemia).

DISABILITY-OPTIMIZING NEUROLOGIC RECOVERY

Cerebral Perfusion

Studies suggested that there are various changes regarding cerebral perfusion following ROSC, there is a short period of multiple areas of cerebral no-reflow followed by transient global cerebral hyperemia (1 for 5–30 min) and then followed by cerebral hypoperfusion (up to 24 h till cerebral metabolic rate gradually recovers). Which means that cerebral perfusion varies with cerebral perfusion pressure, autoregulation of cerebral blood flow is impaired for some time after cardiac arrest.

Sedation

Although there are no high-level data to support a defined period of ventilation, sedation, and neuromuscular blockade after cardiac arrest but it is common practice to sedate and ventilate patients for at least 24 hours after ROSC. A combination of opioids and hypnotics is usually used to adequately sedate the patient during treatment with TTM, and the duration of sedation and ventilation is influenced by this treatment. Adequate sedation helpful in reducing the oxygen consumption. Use short-acting drugs (e.g. propofol, alfentanil, and remifentanil) helpful in reliable and earlier neurological assessment and prognostication.

Control of Seizures

In approximately one-third of patients who remain comatose after ROSC seizures are common after cardiac arrest. Most common seizures are myoclonus (15–25%) followed by focal or generalized tonic-clonic seizures or a combination of seizure types. To detect epileptic activity in patients with clinical seizure manifestations, intermittent EEG should be used. Patients with a diagnosed status epilepticus (SE) need effective treatment so consider continuous EEG monitoring. Seizures may adversely affect the outcome, exacerbate brain injury by increasing the cerebral metabolic rate: antiepileptic drugs such as sodium valproate, levetiracetam, phenytoin,

benzodiazepines, propofol, or a barbiturate are used to treat the seizures. Postanoxic myoclonus can be treated effectively with clonazepam, sodium valproate, and levetiracetam which are antimyoclonic drugs. In postcardiac arrest patient's, routine seizure prophylaxis is not recommended because of adverse effects and the poor response to antiepileptic drugs among patients with clinically and electrographic diagnosed seizures. Treatment of seizures with sedatives decreases the reliability of a clinical examination so prolonged observation may be necessary in these patients. Seizure activity (myoclonus SE) is related to a poor prognosis.

Glucose Control

High blood glucose, severe hypoglycemia, or increased blood glucose variability is associated with increased mortality and unfavorable neurological outcome after cardiac arrest. Following ROSC maintain the blood glucose at ≤10 mmol L^{-1} (≤180 mg/dL) and avoid hypoglycemia. Do not implement strict glucose control in adult patients with ROSC after cardiac arrest because it increases the risk of hypoglycemia.

Treatment of Hyperpyrexia

A period of hyperthermia (hyperpyrexia) is common in the first 48 hours after cardiac arrest. Although the effect of elevated temperature on outcome is not proven, it seems reasonable to treat hyperthermia occurring after cardiac arrest with antipyretics and to consider active cooling in unconscious patients.

TARGETED TEMPERATURE MANAGEMENT

Studies suggest that after achieving ROSC (period of global cerebral hypoxia-ischemia), mild-induced hypothermia is used as a neuroprotective and outcome improving measures. Mild-induced hypothermia suppresses the many pathological process leading to delayed cell death, including apoptosis (programmed cell death). Hypothermia reduces the release of excitatory amino acids, free radicals and decreases the cerebral metabolic rate for oxygen ($CMRO_2$) by about 6% for each 1°C reduction in core temperature. Hypothermia reduces the inflammatory response associated with the postcardiac arrest syndrome. The previous term therapeutic hypothermia is replaced by new term TTM. Several treatment recommendations on TTM by "The Advanced Life Support Task Force of the International Liaison Committee on Resuscitation" (ILCOR) are discussed below.

Targeted temperature management is indicated for adults after OHCA with an initial shockable/nonshockable rhythm or any other initial rhythm that remains unresponsive after ROSC. Temperature is maintained between 32°C and 36°C with temperature control monitoring system. Minimum duration of TTM should be at least 24 hours. Following the TTM trial, many intensive care clinicians elected to use 36°C as the target temperature for postcardiac arrest temperature control. This has several advantages of selecting temperature of 36°C compared with a target temperature of 33°C. Vasopressor support is reduced to minimum with lower lactate levels. The rewarming phase is shorter and chances of rebound hyperthermia after rewarming are less.

How to Control Temperature

The TTM application is divided into three phases: (1) Induction, (2) Maintenance, and (3) Rewarming. For initiation and maintaining the TTM, external and/or internal cooling techniques can be used. An infusion of 30 mL kg^{-1} of 4°C saline is given if a lower target temperature (e.g., 33°C) is chosen, approximately 1.0–1.5°C decrease in core temperature is probably safe in a well-monitored environment. This method should not be used for prehospital cooling because of increased risk of pulmonary edema and rearrest during transport to hospital. *Methods of inducing and/or maintaining TTM include*:

- The first inexpensive method is by simple ice packs and/or wet towels; for nursing staff, this method is time consuming, also temperature fluctuations will be more, and controlled rewarming is not possible.
- Cooling blankets or pads
- Water or air circulating blankets
- Water circulating gel-coated pads
- Transnasal evaporative cooling—large multicenter randomized controlled trial is needed.
- Intravascular heat exchanger, placed usually in the femoral or subclavian veins
- Extracorporeal circulation [e.g., cardiopulmonary bypass, extracorporeal membrane oxygenation (ECMO)]

Initially soon after ROSC because the temperature normally decreases within this first hour in most cases, it is easy to cool patients. Allow a slow passive rewarm if a target temperature of 36°C is chosen. If a target temperature of 33°C is chosen, magnesium sulfate, neuromuscular blockade and sedation, is used to prevent shivering. In the maintenance phase, a cooling method with effective temperature, monitoring system should be chosen to avoid temperature fluctuations. A thermistor is placed in the bladder and/or esophagus for monitoring the temperature. Slow rewarming is recommended with rate of 0.25–0.5°C of rewarming per hour. During rewarming electrolyte imbalance, intravascular volume, and metabolic rate can change rapidly. Adverse neurological outcome is reported due to rebound hyperthermia. Thus, choosing a strategy of 36°C will reduce this risk.

Complications of Hypothermia

Well-known physiologic effects and complications of hypothermia should be managed carefully:

- Shivering will increase metabolic and heat production, the occurrence of shivering is a sign of a normal physiological response, indication of good neurological outcome; in patient with ROSC after cardiac arrest. A sedation protocol is required (discussed earlier in this chapter).
- Mild-induced hypothermia causes arrhythmias (usually bradycardia), this may be beneficial, it reduces diastolic dysfunction and its occurrence has been associated with good neurological outcome.
- Mild-induced hypothermia causes a diuresis and electrolyte abnormalities such as hypophosphatemia, hypokalemia, hypomagnesemia, and hypocalcemia.
- Hyperglycemia can occur due to hypothermia (decreases insulin sensitivity and insulin secretion), which will need insulin therapy.

- Increased infection rates due to hypothermia (impaired the immune system)
- During hypothermia, increase in serum amylase concentration is reported.
- At core temperature closer to 37.0°C, clearance of sedative and neuromuscular blockers drugs is near normal while clearance is reduced by up to 30% at a core temperature of 34°C.

Contraindications to Hypothermia

Generally recognized contraindications to TTM at 33°C, but which are not applied universally, include—severe systemic infection and preexisting medical coagulopathy (fibrinolytic therapy is not a contraindication to mild-induced hypothermia).

PROGNOSTICATION

Hypoxic-ischemic brain injury is common cause of mortality after resuscitation following OHCA. When predicting poor prognosis about patients who are comatose after resuscitation from cardiac arrest, tests should have 100% specificity or zero false positive rate (FPR). Most prognostication studies done only on few patients that it is very difficult to be completely confident in the results. Prognostication of the comatose postcardiac arrest patient should involve multiple types of tests of brain injury, and should be done after 72 hours from cardiac arrest, by this time any neurological recovery and full clearance of sedatives can occur. The tests are as follows:

- *Clinical examination*—GCS score, pupillary response to light, corneal reflex, and presence of seizures
- *Neurophysiological studies*—somatosensory evoked potentials (SSEPs) and EEG
- *Biochemical markers*—neuron-specific enolase (NSE) is the most commonly used.
- *Imaging studies*—brain computed tomography (CT) and magnetic resonance imaging (MRI)

Clinical Examination

Bilateral absence of pupillary light reflex at 72 hours from ROSC predicts poor outcome with close to 0% FPR. Similar performance has been documented for bilaterally absent corneal reflex. An absent or extensor motor response to pain at 72 hours from ROSC is with high FPR (about 27%). Myoclonus is sudden, brief, involuntary jerks caused by muscular contractions and prolonged period of continuous and generalized myoclonic jerks (>30 min) is commonly described as status myoclonus. A status myoclonus starting within 48 hours from ROSC is considered as a poor outcome (FPR 0%). Thorough clinical evaluation is recommended after stopping all sedation in patient with postarrest status myoclonus; in those patients, EEG evaluation should be done with recording of EEG signs of awareness and reactivity and coexistent epileptiform activity. Clinical examination is inexpensive and easy to use, for predicting the poor outcome therefore their results may potentially influence clinical management.

Electrophysiology

Apart from its prognostic significance, recording of EEG, either continuous or intermittent, in comatose survivors of cardiac arrest both during therapeutic hypothermia and after rewarming is helpful to assess the consciousness level, which may be masked by prolonged sedation, neuromuscular dysfunction, or myoclonus, and to detect and treat nonconvulsive seizures, which occur in about 25% of comatose survivors of cardiac arrest.

- *Short-latency somatosensory evoked potentials*: Bilateral absence of the N_20 SSEP wave predicts death or vegetative state with high reliability (FPR 0–2%). Appropriate skills and experience are required for SSEP recording, avoid electrical interference from muscle artifacts or from the ICU environment while SSEP recording. Bilateral absence of N20 SSEP has been used as a criterion for deciding on withdrawal of life-sustaining treatment (WLST) in most prognostication studies.
- *Electroencephalography*: Absence of EEG reactivity—absence of EEG background reactivity predicts poor outcome with a FPR of 0–2%.
- *Status epilepticus*: In TTM-treated patients, the presence of SE is almost invariably—but not always—followed by poor outcome (FPR 0–6%), especially in presence of an unreactive or discontinuous EEG background.
- *Burst-suppression*: Burst-suppression defined as >50% of the EEG record consisting of periods of EEG voltage <10 μV, with alternating bursts. During the first 24–48 hours, after ROSC burst-suppression may be compatible with neurological recovery, while at ≥72 hours from ROSC a persisting burst-suppression pattern is consistently associated with poor outcome.

Biochemical Markers

Neuron-specific enolase and S-100B are protein biomarkers that are released following injury to neurons and glial cells, respectively. Their blood values after cardiac arrest are likely to correlate with the extent of anoxic-ischemic neurological injury and, therefore, with the severity of neurological outcome. Advantages of biomarkers over both EEG and clinical examination include quantitative results and likely independence from the effects of sedatives. Their main limitation as prognosticators is that it is difficult to find with a high degree of certainty a consistent threshold for identifying patients destined to a poor outcome.

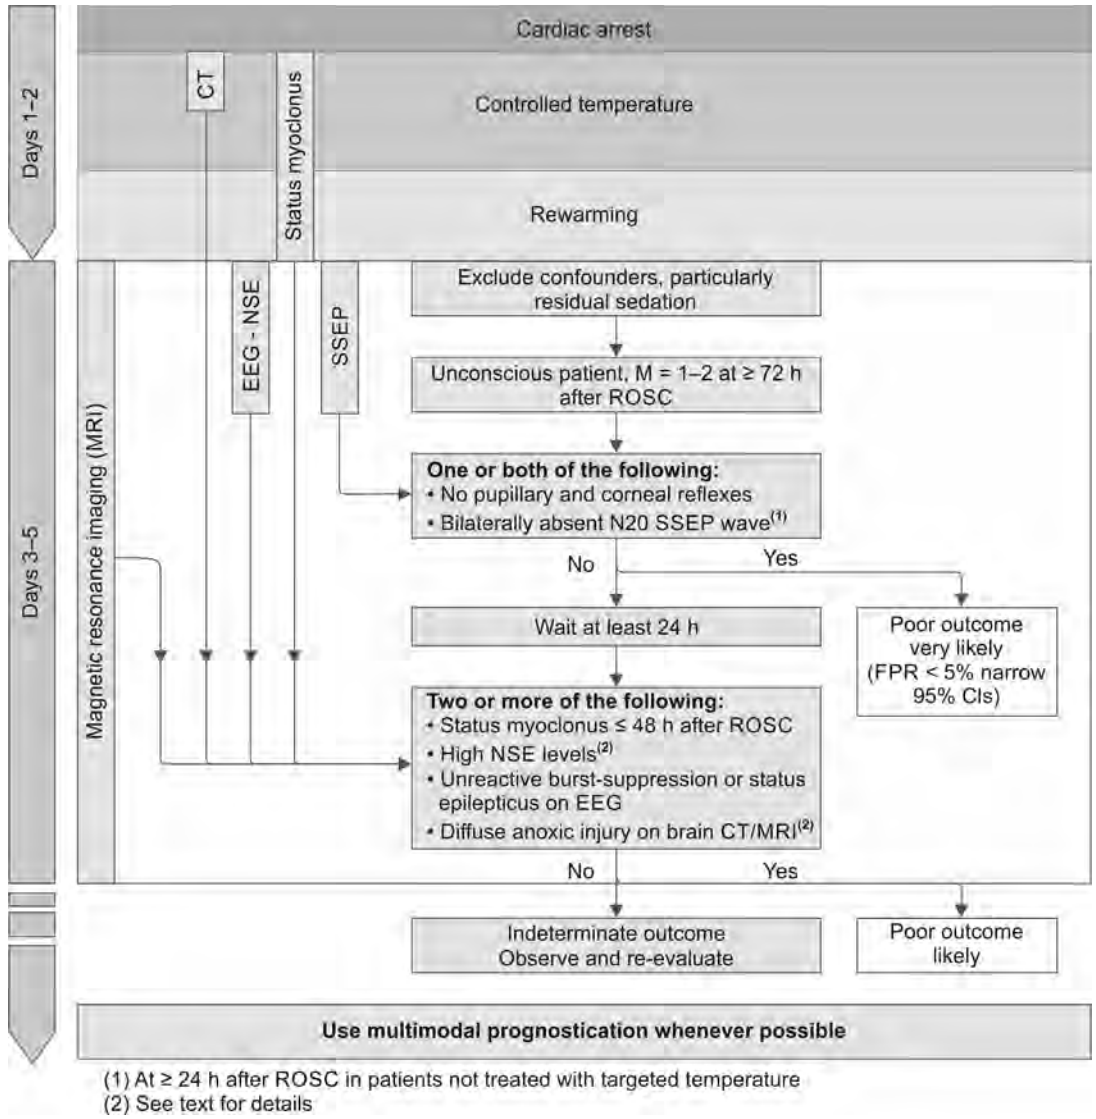
Imaging

The main brain CT finding of global anoxic-ischemic cerebral insult following cardiac arrest is cerebral edema, which appears as a reduction in the depth of cerebral sulci (sulcal effacement) and an attenuation of the gray matter/white matter (GM/WM) interface, due to a decreased density of the GM, which has been quantitatively measured as the ratio (GWR) between the GM and the WM densities. The GWR threshold for prediction of poor outcome with 0% FPR in prognostication studies ranged between 1.10 and 1.22. Brain MRI is more sensitive than CT for detecting global anoxic-ischemic brain injury caused by cardiac arrest; however, its use can be problematic in the most clinically unstable patients. MRI can reveal extensive changes when results of other predictors such as SSEP are normal. All studies on prognostication after cardiac arrest using imaging have a small sample size requested at the discretion of the treating physician, which may have caused a selection bias and overestimated their performance.

Suggested Prognostication Strategy

For prognostication of the comatose patient after cardiac arrest, a careful clinical neurological examination remains the cornerstone. A thorough clinical examination should be performed daily to detect signs of neurological recovery (any purposeful movement) or monitor brain stem reflexes. Within 72 hours from arrest in most of the patients, the process of brain recovery following global postanoxic injury is completed. Major confounders must be excluded, e.g., sedation and neuromuscular blockade, hypothermia, severe hypotension, hypoglycemia, and metabolic, and respiratory derangements before making any conclusion. Short-acting sedative is preferred over long-acting sedative or neuromuscular blocking drugs to avoid interference with clinical examination. Consider using antidotes to reverse the effects of these drugs when residual sedation/paralysis is suspected. The prognostication strategy algorithm (**Flowchart 2**) can be used to all patients who remain comatose with an absent or extensor motor response to pain at ≥72 hours from ROSC.

- Evaluate the most reliable predictors first, with highest specificity and precision (FPR < 5% with 95% CIs < 5% in patients treated with controlled temperature), they include bilaterally absent pupillary reflexes and bilaterally absent SSEP N20 wave predict poor outcome.
- If none of the signs above is present to predict a poor outcome, a next group of predictors can be evaluated (less accurate). These predictors include the presence of early status myoclonus (within 48 hours from ROSC), high values of serum NSE at 48–72 hours after ROSC, an unreactive malignant EEG pattern (burst-suppression and SE) after rewarming, the presence of a marked reduction of the GWR or sulcal effacement on brain CT within 24 hours after ROSC or the presence of diffuse ischemic changes on brain MRI at 2–5 days after ROSC.
- Expert suggest waiting at least 24 hours after the first prognostication assessment and combining at least two of these predictors for prognostication. When dealing with an uncertain outcome, clinicians should consider prolonged observation.



Cardiac arrest
Days 1–2
CT
Status myoclonus
Controlled temperature
Rewarming
Days 3–5
Magnetic resonance imaging (MRI)
EEG - NSE
SSEP
Exclude confounders, particularly residual sedation
Unconscious patient, M = 1–2 at ≥ 72 h after ROSC
One or both of the following:
• No pupillary and corneal reflexes
• Bilaterally absent N20 SSEP wave(1)
No
Yes
Wait at least 24 h
Poor outcome very likely (FPR < 5% narrow 95% CIs)
Two or more of the following:
• Status myoclonus ≤ 48 h after ROSC
• High NSE levels(2)
• Unreactive burst-suppression or status epilepticus on EEG
• Diffuse anoxic injury on brain CT/MRI(2)
No
Yes
Indeterminate outcome Observe and re-evaluate
Poor outcome likely
Use multimodal prognostication whenever possible
(1) At ≥ 24 h after ROSC in patients not treated with targeted temperature
(2) See text for details

(CT: computed tomography; EEG: electroencephalography; NSE: neuron-specific enolase; ROSC: return of spontaneous circulation; SSEP: somatosensory evoked potential)

FLOWCHART 2: Prognostic algorithm for postcardiac arrest syndrome.

REHABILITATION

Cognitive and emotional problems and fatigue are common in the majority of cardiac arrest survivors. Cognitive impairments remain for longer period of time in half of survivors. Memory followed by attention problem and executive of functioning (planning and organization) is the main problem in cardiac arrest survivors. Cerebral performance categories (CPC) or the Mini-Mental State Examination (MMSE) is used to detect mild cognitive impairment. Emotional problems, including depression, anxiety, and post-traumatic stress can affect a patient's daily functioning, return to work and quality of life.

ORGAN DONATION

In those comatose patients in whom a decision is made to withdraw life-sustaining therapy, who fulfill criteria for death using neurological criteria organ donation should be considered after circulatory death occurs. Organ retrieval is classified as controlled or uncontrolled. Controlled donation performed after planned withdrawal of treatment after nonsurvivable injuries. Uncontrolled donation performed from patients with unsuccessful CPR.

36 CHAPTER

Oxygen Therapy and Oxygen Delivery System

Bhawana Sharma, Devendra Richhariya

INTRODUCTION

Oxygen though ubiquitously present is actually a drug, it can be lifesaving but can also be lethal in some cases. Oxygen is essential to cellular metabolism; unfortunately, it is difficult to assess cellular function. Certain organs are very dependent on oxygen such as brain and heart thus it is possible that even minor degrees of hypoxia can produce varying effects on coronary or cerebral circulation. Studies have shown a PaO_2 of 30 mm Hg is generally adequate to maintain cellular metabolism.

INDICATIONS

Oxygen therapy is generally first and commonly initiated therapy in hypoxic state in emergency department as oxygen saturation level is directly correlating with the clinical presentation (**Table 1**) Commonly, there are four types of hypoxia (**Table 2**), describe in clinical practice on the basis of their different pathophysiology in which oxygen therapy is indicated:

- Hypoxemic and hypercapnic respiratory failure
- Acute myocardial infarction
- Postoperative and perioperative states
- Acute asthma and exacerbation of chronic obstructive pulmonary disease (COPD)
- Conditions of tissue hypoxia with normal PaO_2 (normoxic hypoxia):
  - Anemic condition—supplemental oxygen may be used as a temporary measure.
  - Carboxyhemoglobin—in these cases, PaO_2 may be characteristically normal, PaCO level has to be measured. If PaCO level is >40% indicates brain involvement, hence hyperbaric therapy if available is indicated.

TABLE 1: Correlation of PaO_2/SpO_2 and clinical outcome.

PaO_2 values—SpO_2 values	*Clinical significance*
97 mm Hg—100%	Normal young person
80 mm Hg—95%	Normal young person during sleep
70 mm Hg—93%	Lower limit of normal
60 mm Hg—90%	Respiratory failure
50 mm Hg—85%	Significant respiratory failure, patient needs admission
40 mm Hg—75%	Significant respiratory failure, normal venous blood values
30 mm Hg—60%	Unconscious

TABLE 2: Types of hypoxia.

Types	*Mechanism*	*Causes*
Hypoxic hypoxia	Low PaO_2 caused by low oxygen supply	• High altitude • Ventilatory failure—postarrest, NM disease • *Shunt*: Anatomical—R to L shunt Physiologica—pneumonia, pneumothorax, and acute respiratory distress syndrome (ARDS)
Anemic hypoxia	Arterial oxygen tension is normal but less availability due low or physiological abnormal hemoglobin	Massive hemoptysis, carbon monoxide poisoning, and methemoglobinemia
Stagnant hypoxia	Inadequate circulation causing insufficient oxygen tension	Left ventricular failure, pulmonary embolism, and hypovolemia
Cytotoxic hypoxia	Normal transport of oxygen but inadequate cellular metabolism	Cyanide toxicity and arsenic toxicity

- Sickle cell crisis—it is documented that deoxygenated states can cause sickling of cells, hence oxygen would be useful. However, oxygen toxicity should also be avoided in these conditions.
- Respiratory distress
- Shock
- Hypotension
- To prevent postsurgical infections.

CLASSIFICATION OF OXYGEN DELIVERY SYSTEM

It is very important to have in depth knowledge of oxygen delivery system so that proper device is selected according to patient need and clinical problem. Oxygen delivery devices can be classified on the basis of their design. There are three basic designs available—*(1) Low-flow system, (2) Reservoir, and (3) High-flow system while the fourth available design is enclosure* ***Table 3***. So, the physician should be able choose the appropriate oxygen delivery system on the basis of two important questions, (1) how much oxygen can be delivered by system and (2) whether fraction of inspired oxygen (FiO_2) delivered remain fixed or can be altered according to patient requirement. On the basis of FiO_2 delivered the system can be further divided in to low (<35%), moderate (35–65%), high (>70%) oxygen concentration delivery devices.

Fraction of inspired oxygen delivered depends on *patient factors* (inspiratory flow rate, tidal volume, respiratory rate, and presence of a respiratory pause) and *device factors* (volume of the mask, tightness of fit, oxygen concentration, and air vent size). Characteristic of various low- and high-flow oxygen devices are summarized in **Table 4**.

Components of Oxygen Devices

- *Oxygen source and flow control*: Generally, oxygen is supplied through cylinders, concentrators, or central oxygen supply of the hospital. There is a valve device to control flow, rate often indicated by a flow meter.
- *Connecting tubes*: The bore of the tube is important as narrower the bore, the lesser the amount of oxygen delivered.
- *Reservoir*: Reservoir is important as it ensures the oxygen supply for the next breathing effort, however, too large a reservoir has the problem of CO_2 rebreathing. In a nasal cannula, nasopharynx is the reservoir, the mask is the reservoir in a face mask, and tent is the reservoir in an oxygen tent.

TABLE 3: Classification oxygen delivery system.

Low-flow oxygen therapy system	*High-flow oxygen therapy system*	*Enclosures*
• Nasal cannula • Nasal catheters • Transtracheal catheters • Reservoir cannula • Simple mask • Partial rebreathing mask • Nonrebreathing mask • Nonrebreathing circuit (closed)	• Air entrainment (Venturi) mask (AEM) • Air entrainment nebulizer • Blending system • High-flow nasal cannula system • (HFOT)	Oxyhood isolette tent

- *Expiratory device*: It is important to let out the expired air out in the environment, so that the air is not rebreathed. A face mask has holes in ask to let out the air. A continuous positive airway pressure (CPAP) system has holes in the expiratory limb.
- *Humidification*: It is important in especially in high-flow systems, may cause excess dryness and irritation. In that case, external humidifier or heat and moisture exchanger can be used. Other systems use natural humidification of nasopharynx.

LOW-FLOW SYSTEM

Nasal cannula and face mask are considered as low-flow oxygen delivery devices.

Nasal Cannula

These are easy to use, disposable, low cost, and well tolerated by patient but main drawbacks are they can be easily dislodged, unstable; patient becomes uncomfortable with high-flow oxygen. Nasal cannula can be best used in patient with low FiO_2 requirement, home care with long-term oxygen therapy (LTOT) and while eating. The oxygen flow rate and FiO_2 can be delivered through nasal cannula is (1 L/min—24% 2 L/min—28%, 3 L/min—32%, 4 L/min—36%, 5 L/min—40%, and 6 L/min—44%) (**Fig. 1**).

Face Mask

There are two types of face mask are used, simple face mask and reservoir face mask. Simple face mask is also easy to use disposable and inexpensive, it has to be removed while eating. Simple face mask can be best used in emergency when moderate FiO_2 is required (**Fig. 2**).

Reservoir Face Mask

It is a high oxygen, low-flow, variable performance device. The reservoir empties during inspiration, ambient air is entrained from vents. The mask with a reservoir bag must remain inflated during both inspiration and expiration. The patient inhales oxygen preferentially from the reservoir. The rate of oxygen delivered depends on mask fit, capacity of reservoir bag, oxygen flow rates, and patients inspiratory flow rate. There are two types of reservoir mask—(1) Partial rebreathing; and (2) nonrebreathing.

- *Partial rebreathing mask*: Simple mask with a reservoir bag. Oxygen flow should always be supplied to maintain the reservoir to at least one-third to one-half on inspiration. The reservoir receives fresh gas exhaled gas approximately equal to the volume of the patient's anatomic dead space. Minimum flow rate required is 10 L/min to avoid collapse of bags during inspiration and the system provides FiO_2 of 40–70%.
- *Nonrebreathing mask*: Do not permit mixing of exhaled gases with fresh gas supplied. The remaining exhaled air exits through vents. The presence of one-way valve ensures a fresh oxygen supply with minimal dilution from the entrainment of room air. It provides a higher FiO_2 than partial rebreathing mask provided the mask fits correctly. Minimum flow rate required is 10 L/min, delivered FiO_2 of this system is 60–80% at flow rates of 12–15 L/min (**Fig. 3**).

TABLE 4: Oxygen delivery devices and their characteristics.

Methods	*Amount of O_2 flow/ FiO_2*	*Precaution*	*Advantages*	*Disadvantages*
Low-flow oxygen therapy				
Nasal cannula	• Low flow-(1–6 L/min) • FiO_2 24–44%	• To check whether both prongs are in patients' nostrils • In patient with chronic lung disease to deliver 2–3 L/min	• Patient able to talk and eat • Can be used in home setting • Well tolerated • Inexpensive	• May cause irritation to nasal mucosa • May cause epistaxis
Simple face mask	• Low flow (5–10 L/min) • FiO_2 35–50%	• Frequently check placement of mask • Check for claustrophobia • CO_2 retention may occur unless flow rate <2 L/min or minute ventilation is high	• Can provide increased oxygen demand for a limited period of time	• Tight seal required • Difficult to keep mask over mouth and nose • Oxygen wasting • Uncomfortable for patient while speaking or eating • Problematic with RT in situ
Partial rebreather mask	• Minimum 10 L/Min • FiO_2 40–70%	• Reservoir bag should be two-thirds filled during inspiration • Reservoir bag should be free of kinks	Patient can inhale room air through openings in mask if oxygen supply briefly interrupted	Tight seal required (eating and talking are difficult)
Nonrebreathing mask	• Minimum 10 L/min (prevent bag collapse on inspiration) • FiO_2 60–80%	• Maintain flow rate so that reservoir bag collapses only slightly during inspiration • Check valves are functioning properly	• Delivers highest possible oxygen concentration • Suitable for spontaneously breathing patient with severe hypoxemia	• Not useful for long-term therapy • Malfunction can cause CO_2 retention • Feeling of suffocation • Expensive
High-flow oxygen therapy (HFOT)				
Air Entrainment Mask (AEM) Venturi system	• Variable flow can be set • FiO_2 24–50% • Fixed system	FiO_2 varies with back pressure Different colored vent are used for achieving different FiO_2	Easy to apply disposable low-cost system Precise FiO_2 can be achieved	Only be used in adult FiO_2 >40% not sure FiO_2 varies with back pressure
High-flow oxygen cannula system	• Flow rate up to 50 L/min or more FiO_2 35–90%	• FiO_2 is ensured but system dependent	Wide range of FiO_2, relative/ absolute humidity can be used in adult children and infants	FiO_2 is depend on system input and patient breathing pattern Infection risk

FIG. 1: Nasal cannula.

FIG. 2: Simple face mask.

HIGH-FLOW SYSTEM

Air Entrainment (Venturi) System

Oxygen concentration is determined by the Venturi principle—oxygen passing through a small orifice entrains air to a predictable dilution. The Venturi principle depends on the Bernoulli's effect, when fluid flows through a narrow constriction, it accelerates, gaining kinetic energy from the surrounding potential energy, thus a negative pressure surrounding is created this entrains the surrounding fluid through the constriction (**Figs. 4A** and **B**). The FiO_2 is adjusted by changing the Venturi "valve" and setting the appropriate oxygen flow rate. The larger orifice results in the system behaving like a simple mask. However, a fixed delivery system is possible at a lower FiO_2, higher the FiO_2 required, lower the oxygen flow rate (**Fig. 5**). The correct flow rate/FiO_2 of oxygen is varying with specific color of mask and written on the mask blue—2–4 L/min oxygen 24% FiO_2, white—4–6 L/min oxygen 28% FiO_2, yellow—8–10 L/min oxygen 35% FiO_2, red—10–12 L/min oxygen 40% FiO_2, and green—12–15 L/min oxygen 60% FiO_2.

SELECTION OF OXYGEN DELIVERY SYSTEM

It is very important to choose appropriate oxygen delivery system in emergency department to achieve targeted FiO_2 and correction of hypoxia which is the final goal of the oxygen therapy. There are many factors which help in choosing the appropriate oxygen delivery system and patient initial assessment is one of them. Generally, 3 Ps (*purpose, patient, and performance*) are considered helpful in selection of the appropriate oxygen delivery system.

We all know the purpose or goal of the oxygen therapy is to raise the FiO_2 adequately so that arterial hypoxia can be corrected resulting features of hypoxia and cardiopulmonary work load is reduced.

Patient-related factors very important while selecting the oxygen delivery system is patient age group (adult, children, and infant), severity and causes of hypoxia, level of alertness and consciousness of patient, mouth/nose breathing patient, presence or absence of tracheal airway, and stability of minute ventilation.

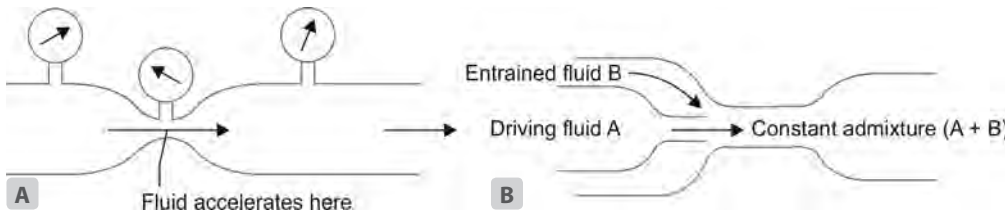
Performance of delivery system should also be considered, e.g., FiO_2 delivery to patient and stability of FiO_2 with changing demand of the patient. Critically ill patient needs more and stable FiO_2. **Table 5** guides the physician in selecting the oxygen delivery system on the basis of level and stability of FiO_2 required by patient.

INITIATION OF OXYGEN THERAPY IN EMERGENCY DEPARTMENT

- *Patient severely hypoxemic, critically ill*—start at 15 L/min via reservoir face mask, once stabilized, can be tapered to maintain saturation between 94 and 98%.If at risk of type 2 respiratory failure to maintain SpO_2 between 88 and 92%.
- *Patient seriously ill moderately hypoxemic*: Start O_2 via face mask at 6 L/min, if no improvement in condition, increase to up to 15 L/min via reservoir bag. SpO_2 to be maintained between 94 and 98%.
- *Chronic obstructive pulmonary disease like condition, at risk of type 2 respiratory failure*: Venture mask (at 4 L/min) preferred, to maintain SpO_2 between 88 and 92%. Should repeat arterial blood gas (ABG) after 30–60 minutes to see the PaO_2 and $paCO_2$ levels.

FIG. 3: Nonrebreathing mask.

FIG. 5: Venturi device. ***(For color version, see plate 2)***



FIGS. 4A AND B: Bernoulli's principle effect air entrainment (Venturi) system.

TABLE 5: Selection of oxygen delivery system based on required FiO_2 level.

	Desired FiO_2 stability	
	Fixed	***Variable***
If low, FiO_2 (<35%) is desired	• Air entrainment mask (AEM) • Air entrainment nebulizer • Blending system • Incubators (infants) • Isolette	• Nasal cannula • Nasal catheter • Transtracheal catheter
If moderate, FiO_2 (35–60%) is desired	• Air entrainment nebulizer • Blending system • Oxyhood (infants)	• Simple mask • Air entrainment nebulizer • Tent (child)
If high, FiO_2 (>60%) is desired	• Blending system • Oxyhood (infants) • High-flow nasal cannula	• Partial rebreather • Nonrebreather

LONG-TERM OXYGEN THERAPY

Oxygen prescribed a low flow rate at least 16 hours a day including night. LTOT improves sleep, survival, and cognition. Oxygen sources include oxygen cylinder and oxygen concentrators. Oxygen delivered through nasal cannulae, transtracheal catheters, etc. If LTOT is prescribed during an acute exacerbation, ABG should be repeated in 30–90 days after discharge.

Indications—(1) Patient with $SaO_2 < 88\%$, $PaO_2 < 55$ mm Hg, (2) Patient with SaO_2 between 88 and 90%, PaO_2 between 55 and 60 mm Hg with—polycythemia and cor pulmonale.

Weaning—patients with chronic lung disease may require oxygen for longer periods of time

Weaning to be attempted once vitals such as respiratory rate, pulse rate, saturation of oxygen, and blood pressures are settled. The oxygen requirement should be assessed by reducing the FiO_2 and evaluating every 30 minutes using an ABG. However, pulse oximeter is preferred as is less invasive.

OXYGEN TOXICITY

Toxicity of oxygen is caused by free radical injury due to superoxide, hydroxyl, and oxygen singlet. At higher pressures, the protective natural scavenging mechanism of the body is lost. The toxicity is related to the FiO_2 of the air inspired. Generally, anything above 60% for >6 hours may be injurious. Studies have shown, if clinically allowed, can be tried for air brakes. Generally, normobaric therapy affects lungs, while hyperbaric therapy affects CNS, eyes in addition to lungs.

- *Symptoms and signs*: Nasal stuffiness, fatiguability, substernal chest pain**,** nasal stuffiness, and sore throat, headache**,** nausea, and vomiting, radiological signs of atelectasis (adhesive atelectasis)—mimicking ARDS and hypoventilation.
- *Evaluation of oxygen toxicity needs examination of* pattern and breathing rate**,** pink color in nail beds, conjunctiva, and lips, whether disorientation or difficulty in cognition present, regular ABG for PaO_2, and hemoglobin concentration.
- *Complications*: Absorption atelectasis**,** hypoventilation, bronchopulmonary dysplasia**,** retrolental fibroplasia, drying of mucous membranes (if humidifier not used), and fire-related hazards.

HIGH-FLOW NASAL CANNULA OXYGEN THERAPY

Oxygen support therapy should be given to the patients with acute hypoxic respiratory insufficiency in order to provide oxygenation of the tissues until the underlying pathology improves. Maximum flow rate of 15 L/min is produced by low-flow and high-flow conventional oxygen support systems and FiO_2 changes depending on the patient's peak inspiratory flow rate, respiratory pattern, the mask that is used, or the characteristics of the cannula. The inspiratory flow rate requirement of patients with respiratory insufficiency varies between 30 and 120 L/min. The inability to provide adequate airflow leads to discomfort in tachypneic patients. High-flow nasal oxygen (HFNO) cannulas are able to delivered warmed and humidified air matching the body temperature with the regulated flow rates of 5–60 L/min, and oxygen delivery varies between 21 and 100%.

Studies show that physiological parameters are improved with HFNO treatment when compared to conventional oxygen systems. Although there are studies indicating successful applications in different patient groups, there are also studies indicating that it does not create any difference in clinical parameters, but patient comfort is better in HFNO when compared with standard oxygen therapy and noninvasive mechanical ventilation (NIMV).

Physiological Effect of High-flow Nasal Oxygen Cannula Therapy

The physiological positive effects of HFNO therapy are summarized in **Box 1**. It was reported that by providing positive airway pressure, HFNO increases the end-expiratory lung volumes and functional residual capacity and decreases the inspiratory resistance. This leads to positive nasopharyngeal pressure and the elimination of CO_2 in the nasopharyngeal dead space. Thus, the metabolic load for gas exchange is reduced and it recovers oxygenation.

Set-up of the High-flow Oxygen Cannula Device

The HFNO device consists of an air/oxygen mixer, an active heater, a humidifier, a unidirectional inspiratory circuit hose, and a soft nasal cannula that is slightly larger than the standard nasal cannula. In the air/oxygen mixer, FiO_2 can be increased

BOX 1: Positive physiological effects of high-flow nasal oxygen.

- Generation of constant FiO_2
- Generation of a positive end-expiratory pressure
- Decrease in anatomical dead space
- Improved mucociliary clearance
- Decreased work of breathing

from 21% (room air) to 100% (pure oxygen) depending on the flow (up to a maximum of 60 L/min). The oxygen is hydrated with water vapor by the active humidifier, and the oxygen can be heated to 37°C prior to delivery to the patient through the unidirectional inspiratory circuit hose (**Fig. 6**).

Indications of High-flow Nasal Cannula Oxygen Therapy

Positive physiological effects produced by HFNO indicates that high-flow oxygen therapy (HFOT) is useful in the treatment of respiratory failure, which can be caused by many different conditions, such as hypoxemic respiratory failure, exacerbation of COPD, postextubation, preintubation oxygenation, sleep apnea, and acute heart failure (**Box 2**). High-flow nasal cannula (HFNC) has been gaining attention as an alternative respiratory support for critically ill patients after few large randomized clinical trials. Initial data of published trials are mostly available for neonates. In seriously ill adults, however, evidence for use of HFONT is not even because the studies included conditions of varying etiology, like hypoxemic respiratory failure, exacerbation of COPD, postextubation, preintubation oxygenation, sleep apnea, acute heart failure, and conditions entailing do-not-intubate orders.

Concern Regarding Use of High-flow Nasal Cannula Oxygen Therapy

Studies suggest that HFNC use decreases breathing frequency and work of breathing and reduction for the need of respiratory support escalation though the main concern regarding the use of HFNC has been that overuse of this modality may lead to unnecessary and potentially precarious delays in intubation. Further studies are required to resolve some important issues such as definitive indications for HFNC and criteria for timing the starting and stopping of HFNC and for escalating treatment. HFNC is emerging as an innovative and effective modality for early treatment of adults with respiratory failure with diverse underlying diseases despite some issues.

MEDICAL OXYGEN CYLINDERS: TYPES CAPACITY AND ESTIMATION OF RUNNING TIME

The amount of oxygen in the air is sufficient for a healthy person in normal conditions. However, patient with abnormal respiratory or cardiac conditions may require extra oxygen support. There are two types of medical devices that provide oxygen gas in accordance with health. These are oxygen cylinders and oxygen concentrators. Oxygen cylinders can be refilled, but oxygen concentrators do not require refilling because oxygen concentrators produce the oxygen gas to be given to the patient. Medical oxygen cylinders are available in different capacities. Oxygen cylinders have varieties according to the materials they are produced from, and their weights and usage purposes vary. Accessories used together vary depending

BOX 2: Recommended indications for high-flow oxygen therapy.

- Acute respiratory distress syndrome and acute hypoxemic respiratory failure
- Hypoxemia induced by severe heart failure
- Postextubation respiratory compromise
- Airway instrumentation (as adjunct during manipulation of the airway, e.g., bronchoscopy, intubation in patients with both low and high risk, i.e., hypoxemia and morbid obesity)
- Immune compromise
- End-of-life care

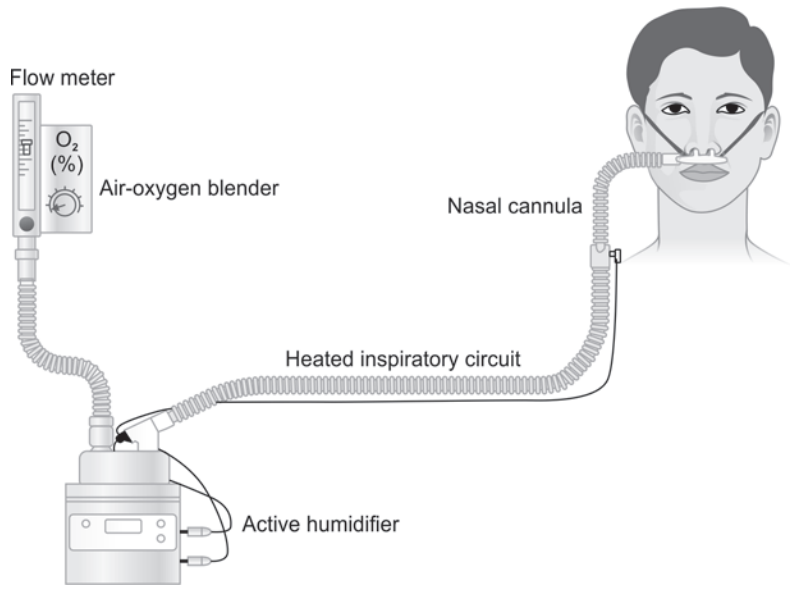


FIG. 6: Setup of the high-flow nasal cannula oxygen therapy—*Air/oxygen blender can generate up to 60//min flow. The gas is heated and humidified through active heated humidifier and delivered via single limb heated inspiratory circuit.*

on where and for what purpose the tube will be used. Oxygen cylinders can be used alone or with other oxygen delivering machine such as noninvasive ventilation and mechanical ventilation. Oxygen tubes are resistant to high pressure. The density of the oxygen gas in the oxygen cylinder is about 98% and 90–95% in oxygen concentrators.

What are the types of oxygen cylinders?

Medical oxygen cylinders are produced in different sizes and capacities (**Table 6**). This capacity is expressed in liters. The size of the oxygen tube increases as its capacity increases. There are steel and aluminum types according to the material from which the tube is made. Aluminum ones are lighter. Oxygen cylinders up to 10 liters capacities are portable, regardless of whether they are aluminum or steel. Cylinders with a capacity of >10 liters are almost impossible to carry by one person. Portable oxygen cylinders are generally used in ambulances, hospital emergency units, and homes. Since aluminum ones are lighter, they are also easier to carry and are preferred especially during patient transfer. There is a central gas system in hospitals, medical oxygen gas can be delivered to every point of need such as patient rooms, intensive care units, and operating rooms and emergency rooms. The gas used in the central system is stored either in large oxygen tanks or in many large oxygen cylinders depending on the capacity of the hospital. Oxygen cylinders contain high pressure gas and not possible to apply directly to the patient in this form. The pressure is reduced and made suitable for use and medical tube manometers are used to measure the pressures. Aluminum manometers with pin index (pin entry) are used because they are generally lighter in aluminum tubes. These are lighter than standard type manometers. If it is desired to use standard manometers in aluminum tubes, the connection part must be changed. Some consumables and adjuncts are required when using the oxygen cylinder. These are materials such as an oxygen mask, oxygen cannula, oxygen catheter, or water container (**Fig. 7**). It should be stored in adequate numbers in the ward. The mask attached to the oxygen tube is applied to the face covering the mouth and nose. Nasal oxygen cannulas and catheters are used by placing them in the nostrils. The water container is attached to humidify the oxygen gas coming out of the tube which is connected to the manometer. For refilling the oxygen cylinder, there are certified facilities and certain standards must be complied with in order to obtain quality certificate.

How long does oxygen cylinders use?

The duration of use of oxygen cylinders depends on the oxygen tube, volume, and flow setting. Running time of any oxygen cylinder can be calculated by formula given in **Table 7**.

TABLE 6: Oxygen cylinder size and capacity.

Size	*Capacity (L)*	*Pressure (psi)*	*Tare weight (kg)*	*Valve type*
B	200	1,900	2.27	Pin index
D	400	1,900	3.4	Pin index
E	660	1,900	5.4	Pin index
F	1,360	1,900	14.5	Bull nose
G	3,400	1,900	34.5	Bull nose
H	6,900	2,200	53.2	Bull nose
M	3,450	2,200	29.0	Bull nose

SUMMARY

Oxygen is a drug, hence, except for emergencies, should be prescribed. Oxygen is the treatment of hypoxemia and not breathlessness. The target saturation should always be prescribed—in case of type 1 respiratory failure between 94 and 98% and in type 2 respiratory failure between 88 and 92%. Various devices are available or delivery of oxygen, indication of use, patient comfort, target saturation, and efficient usage of oxygen to be considered while deciding the device. Oxygen has its own sets of complications, hence weaning should be attempted while patient has stable vitals.

CHAPTER

Hyperbaric Oxygen Therapy

Amit Gupta

INTRODUCTION

Oxygen therapy is always considered as a drug and can be easily given under normal pressure but requires compression if we want to give it at >1 atmospheric pressure. Details of oxygen therapy are already described earlier. Hyperbaric oxygen therapy (HBOT) is the therapy when 100% oxygen is used for therapeutic indications at higher than the normal atmospheric pressure. This therapy is given in specialized chambers of various sizes. The chamber can accommodate one patient (called monoplace) or multiple patient chamber (multiplace). HBOT has been available for the last many decades and used for many indications. HBOT is considered a safe therapy with mild and reversible adverse effect. Systemic administration of 100% oxygen to lungs at >1 atmospheric absolute (ATA-typically 2–3 ATA) to increase the amount of oxygen dissolved in the blood to fight infection or minimize injury. The duration of each session lasts 30 min–2 hours and a person may need 5–40 treatments until clinical improvement is seen.

HISTORY

Historically, the first documented hyperbaric chamber was designed by British physician and clergyman, Nathaniel Henshaw in 1662, using bellows and unidirectional valves to change atmospheric pressure in a sealed chamber called *domicilium* almost a century before oxygen was invented. This was followed in 1690 by Edmond Halley who designed a diving bell with various modifications over time to extend underwater time to a little over 4 hours. A number of other hyperbaric chambers were designed all over the globe across three centuries with limited clinical success in various illnesses until in 1955–56, Churchill-Davidson evaluated the trials on HBOT at St. Thomas Hospital, London to augment the effects of radiation therapy in cancer patients which begin the era of its scientific use in clinical medicine. There has been a history of using HBOT from antiaging treatment to chronic neurological conditions with weak research background. This therapy is available since decades and used in various diseases with little or no evidence so HBOT also termed as *"therapy in search of diseases"*. Presently, the primary scientific body for clinical practice of hyperbaric medicine is Undersea and Hyperbaric Medical Society (UHMS), a nonprofit organization which was founded in 1967 and the European Committee for Hyperbaric Medicine (ECHM) which systematically review all scientific literature related to HBOT and formulate absolute indications for its use.

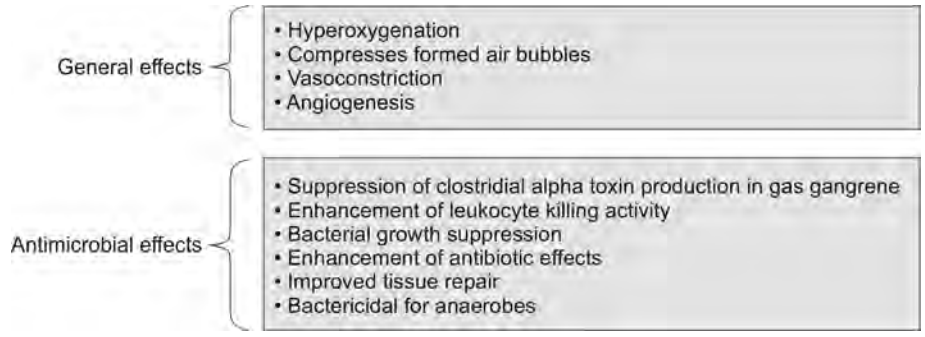
PHYSIOLOGY

Under normal condition, we live at 1 atmospheric pressure (ATA) or in medical term 760 mm Hg, (14.7 psi,760 torr, or 33 feet of undersea water). At the depth of 33 feet (10 m) diver is exposed to 2 ATA (1 ATA from the atmosphere above the water and 1 ATA 33 feet/10 m below the sea water). HBOT effect based on *Henry's law* which states that the amount of gas dissolved in a liquid is in proportion to the pressure of gas above the liquid and *Boyle's law* which states that volume and pressure are inversely proportional to each other, i.e., a gas will compress proportionately to the amount of pressure exerted on it.

Hyperbaric oxygen therapy is application of atmospheric pressure > 1 ATA. HBOT increases partial pressure of oxygen and hence its availability at cellular level. Tissues at rest extract 5–6 mL of oxygen per deciliter of blood, assuming normal perfusion. Administering 100% oxygen at normobaric pressure increases the amount of oxygen dissolved in the blood to 1.5 mL/dL; at 3 atmospheres, the dissolved-oxygen content is approximately 6 mL/dL, which is more than enough to meet resting cellular requirements without any contribution from hemoglobin. It is interesting to know that 100% oxygen at 3 ATA can supply enough dissolved oxygen to support life without hemoglobin.

RATIONALE OF USE OF HYPERBARIC OXYGEN THERAPY/MECHANISM OF ACTION

The main principle of using the HBOT is to improve tissue oxygenation. So, the primary indications are disease with *regional or global hypoxia*. Second indications are anaerobic infections which develop in hypoxic areas and lack of host response to infection. So, HBOT provides relief of ischemia and improves host response to *infection.* HBOT also provides stimulus for angiogenesis in hypoxic area (**Fig. 1**).



General effects
• Hyperoxygenation
• Compresses formed air bubbles
• Vasoconstriction
• Angiogenesis
Antimicrobial effects
• Suppression of clostridial alpha toxin production in gas gangrene
• Enhancement of leukocyte killing activity
• Bacterial growth suppression
• Enhancement of antibiotic effects
• Improved tissue repair
• Bactericidal for anaerobes

FIG. 1: Rationale of use of hyperbaric oxygen therapy.

EQUIPMENT AND PROCEDURE

Hyperbaric chambers are used to administer the HBOT. There are two types of hyperbaric oxygen chambers—(1) monoplace chamber and (2) multiplace chamber are used.

1. *Monoplace chamber*: It can accommodate one patient in supine position (**Fig. 2**), monitoring is done from outside, compressed with 100% oxygen, patient breathes without any mask, main advantages are its less cost and space requirement.
2. *Multiplace chamber*: Multicompartment treatment chamber where many patients (**Fig. 3**) can sit or accommodate multiple patients' beds with attendants, patient breathes oxygen through facemask endotracheal tube or face hood, monitoring is done inside the chamber which is compressed with air, this is suitable for critically ill patients requiring ventilation and continuous monitoring. Pressure and duration of therapy depends on situation, generally 2–6 ATA for 2–6 hours.

Care in Chamber—Practical Aspect

Fire safety measures need to be maintained by keeping electrical circuit outside the chamber, and through insulated cables. Use of defibrillation is controversial because of fire but decompression of the chamber is required before using defibrillation. Intravenous infusion can be given by flexible bags not by glass bottles. Battery-operated syringe infusion pump can be used. Tracheal tube cuff, face mask seal should be monitored closely. Positive pressure ventilation and volume cycle ventilators can be used.

Treatment Guidelines

Manage ABC, vascular access, 100% oxygen, and monitoring vitals. Treatment of primary causes immediate removal from source, early aggressive debridement, and antimicrobials in cases of infective etiology. Determine the need for HBOT, early transfer to facility with availability of HBOT chamber after weighing risks and benefits, if not available. Comprehensive physical examination to rule out any contraindications. Baseline examination before treatment including ABG for hypoxemia and chest roentgenogram to rule out pneumothorax. Fill all balloon devices with fluid in place of air to prevent rupture due to air expansion. Decongest, if sinus complaint and myringotomy in cases of otitis media.

- *Pressure*: HBOT usually starts at 2–2.5 ATA for infections, 2.8 ATA for decompression sickness
- *Duration*: 90–120 minutes

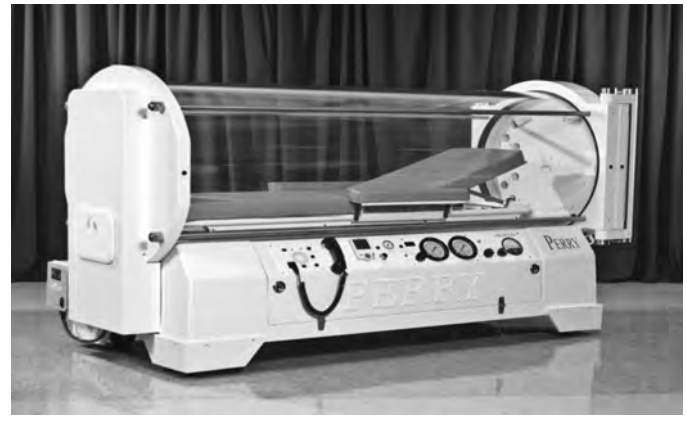


FIG. 2: Monoplace chamber for hyperbaric oxygen therapy.

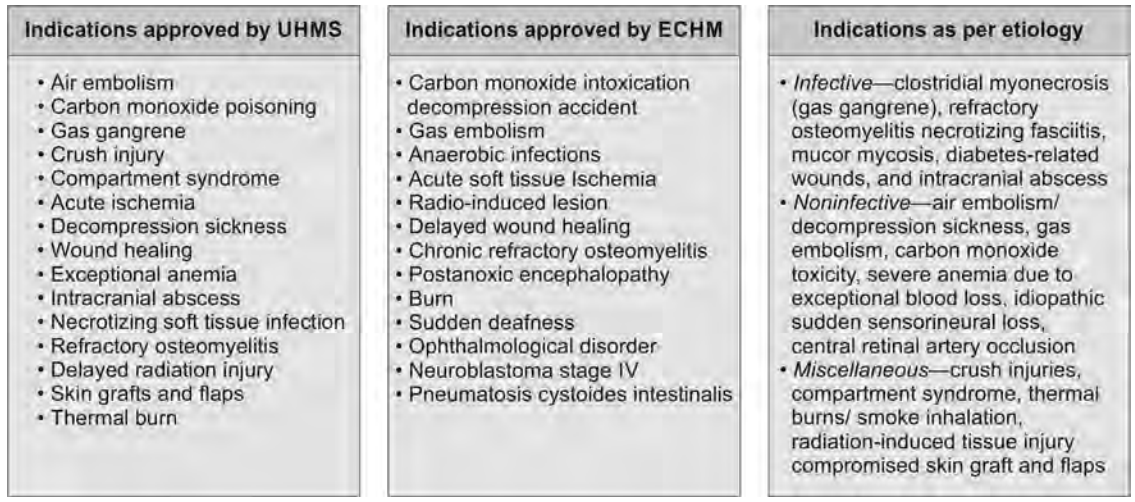
FIG. 3: Multiplace chamber for hyperbaric oxygen therapy.

- *Frequency*: One or two times daily depending on severity
- *Treatments*: Until clinical improvement
- *Review*: After 30–60 sessions, but only 1–2 in decompression sickness and gas embolism

INDICATIONS

Medical societies such as Undersea and Hyperbaric Medical Society (UHMS) and European Committee for Hyperbaric Medicine (ECHM) were established to address the shortcoming on HBOT and to reach on common consensus over indications of HBOT (**Fig. 4**).



Indications approved by UHMS
• Air embolism
• Carbon monoxide poisoning
• Gas gangrene
• Crush injury
• Compartment syndrome
• Acute ischemia
• Decompression sickness
• Wound healing
• Exceptional anemia
• Intracranial abscess
• Necrotizing soft tissue infection
• Refractory osteomyelitis
• Delayed radiation injury
• Skin grafts and flaps
• Thermal burn
Indications approved by ECHM
• Carbon monoxide intoxication decompression accident
• Gas embolism
• Anaerobic infections
• Acute soft tissue Ischemia
• Radio-induced lesion
• Delayed wound healing
• Chronic refractory osteomyelitis
• Postanoxic encephalopathy
• Burn
• Sudden deafness
• Ophthalmological disorder
• Neuroblastoma stage IV
• Pneumatosis cystoides intestinalis
Indications as per etiology
• Infective—clostridial myonecrosis (gas gangrene), refractory osteomyelitis necrotizing fasciitis, mucor mycosis, diabetes-related wounds, and intracranial abscess
• Noninfective—air embolism/ decompression sickness, gas embolism, carbon monoxide toxicity, severe anemia due to exceptional blood loss, idiopathic sudden sensorineural loss, central retinal artery occlusion
• Miscellaneous—crush injuries, compartment syndrome, thermal burns/ smoke inhalation, radiation-induced tissue injury compromised skin graft and flaps

FIG. 4: Indications of hyperbaric oxygen therapy (HBOT).

CONTRAINDICATIONS

- *Absolute*: *Untreated pneumothorax*—can convert to tension pneumothorax, *use of cisplatin*—delayed wound healing, and *bleomycin*—significant lung injury or doxorubicin can lead to cardiac toxicity.
- *Relative*: *Cardiac instability*—do not use monoplace chamber but multiplace chamber with close monitoring, if benefits outweigh risks, *history of thoracic surgery, upper respiratory infections, seizure disorder, high fever, stapes implant, and chronic sinusitis.*

CLINICAL APPLICATION

- *Decompression sickness* occurs when atmospheric pressure decreases too rapidly as in scuba diving or rapid ascent while flying in unpressurised aircraft. Symptoms of this condition include joint pain (bends), headache, dizziness, fatigue, tingling or numbness, and sometimes, a skin rash. These symptoms are caused by blocked blood supply, damage from direct mechanical effects, or later biochemical actions from suspected bubbles evolving from inert gas dissolved in blood or tissues. The treatment of choice is recompression. Emergency treatment includes high-flow oxygen, positioning in left lateral position with head tilted down, and maintaining blood pressure. HBOT acts by decreasing the size of bubbles of nitrogen with increase in pressure as well as oxygen gradient thereby causing efflux of nitrogen from bubble into bloodstream.
- *Carbon monoxide (CO) poisoning* occurs accidentally due to inhalation of CO especially with the use of gas geysers in closed spaces. The binding affinity of CO to hemoglobin is around 200 times that of oxygen and it shifts oxygen dissociation curve to left thereby decreasing oxygen supply to the tissues. It also binds cytochrome oxidase and myoglobin. Symptoms of CO poisoning are nonspecific and include flu-like symptoms such as headache, nausea, dizziness, and visual changes. Serious manifestations include loss of consciousness, seizures, electrocardiogram (ECG) changes, and acidosis. The treatment is based on theory that oxygen competitively replaces CO from hemoglobin thereby reversing symptoms. However, at room air, this takes around 300 minutes. With 100% oxygen, this time is reduced to about 90 minutes and HBOT reduces it further to about 30 minutes only. HBOT in addition reduces cytochrome oxidase and also prevents delayed neurological sequel. HBOT is more effective if the treatment is initiated sooner. A total of 1–5 sessions may be needed depending on clinical situation at 2.5 ATA for 60–90 minutes.
- *Crush injuries and compartment syndrome* lead to acute peripheral ischemia and edema and have poor outcome even after surgical intervention due to reperfusion response. Symptoms include severe pain, swelling, weakness, pain with passive stretch, and tense compartment as compartment pressure exceeds capillary perfusion pressure. HBOT is beneficial in both impending stage when surgery is not indicated and after fasciotomy to decrease morbidity. HBOT causes hyperoxygenation, reduction in blood flow allowing capillaries to reabsorb extrafluid thereby decreasing edema, decreased neutrophilic adherence, and reducing reperfusion injury as it generates scavengers to destroy oxygen radicals. It should be started as soon as feasible, preferably within 4–6 hours of injury. Postsurgery, HBOT should continue at 2.5 ATA for 60–90 minutes two to three times daily until visible improvement.
- *Necrotizing soft tissue infections* are rapidly progressive, life-threatening, deep-seated infections involving fascia and subcutaneous tissues with mortality in range of 20–40%. The organisms involved include *Staphylococcus aureus, Escherichia coli, Bacteroides fragilis*, and various species *of Streptococci, Enterococci*, and *Clostridium*. These infections are named based on their clinical presentation and include necrotizing fasciitis, clostridial and nonclostridial myonecrosis, and Fournier gangrene. The primary treatment includes aggressive, early surgical debridement, often repeated, with broad spectrum antibiotic therapy. HBOT plays an adjunctive role but with significant reduction in mortality, avoiding amputations in selected cases and reduced number of debridement compared to surgical treatment alone. HBOT starts at 2.5 ATA for 60–90 minutes one to two times daily until maximum clinical improvement.

- *Gas gangrene,* also known as clostridial myonecrosis, is a rapid, progressive, and invasive clostridial infection of previously healthy muscle. The most common species implicated is *Clostridium perfringens*, a gram positive, spore forming, and anaerobic bacteria mainly in traumatic or postsurgical cases. Symptoms include pain out of proportion to size of infected area, low-grade fever, disproportionate tachycardia, anxiety, blebs, and bulla formation with crepitus felt during clinical examination mainly due to action of exotoxin production most notably alpha toxin which degrades cell membranes and produces a liquefactive necrosis, and in combination with other toxins, has a powerful myocardial depressant effect. The rationale for HBOT lies in the fact that hyperbaric oxygen at 3 ATA completely suppresses alpha toxin production and prevents any further damage. In addition, it has an antianaerobic organism effect which suppresses the growth of clostridia. However, the benefits of HBOT are best seen in combination with antibiotics and aggressive debridement.
- *Chronic refractory osteomyelitis* is an infection of the bone along with inflammation-induced bony destruction over months or even years and characterized by presence of organisms, low-grade inflammation, and even necrotic bone and fistulous tracts, which have not responded to conventional interventions including antibiotics and surgery. HBOT in these cases helps by having a direct suppressive effect on anaerobic organisms, augmenting the efficacy of antibiotics, osteogenesis by promoting fibroblast activity, and enhancing osteoclast activity. However, management of this condition requires a multidisciplinary approach including aggressive debridement, good local wound care, offloading (if on pressure point), appropriate antibiotics, nutritional support, and control of serum glucose in addition to HBOT.
- *Exceptional anemia* in patients who are unable to receive blood products due to medical or religious reasons can be candidates for HBOT. Tissues at rest extract 5–6 mL of oxygen per deciliter of blood, assuming normal perfusion. Administering 100% oxygen at normobaric pressure increases the amount of oxygen dissolved in the blood to 1.5 mL/dL; at 3 atmospheres, the dissolved-oxygen content is approximately 6 mL/dL, which is more than enough to meet resting cellular requirements without any contribution from hemoglobin. It is based on oxygen debt which is the difference between volume of oxygen consumed during and after the insult and baseline volume during same time interval. Since the central nervous system (CNS) and cardiovascular systems are the two most oxygen-sensitive systems in the body, patients with oxygen debt >33 L/m^2 do not survive, whereas patients with debt <9 usually recover. HBOT in these cases at 2–3 ATA is needed till patient can receive blood products, has no end-stage organ failure or no calculated oxygen debt.
- *Idiopathic sudden sensorineural hearing loss (SSHL)* is the predominant though relatively rare cause of SSHL which presents as unilateral tinnitus, vertigo or blocked ear in addition to hearing loss. The main etiology is related to inner ear hypoxia as cochlea requires a high oxygen supply and hence the role of HBOT in treating this condition. HBOT at 1.5–2.5 ATA for 90 min/day for 2–3 weeks is recommended for significant improvement in this condition.

POTENTIAL HARM, SAFETY, AND PRECAUTIONS

Hyperbaric oxygen therapy is considered safe. Adverse effects are generally mild and reversible. To avoid serious life-threatening adverse effect, it is important to take strict precaution, like proper installation and maintenance of facility with adequate staffing and their specific training. Sometime low risk of fire and explosion in monoplace chamber is present which is difficult to deal with presence of a patient. Claustrophobia is frequent problem seen in monoplace chamber and for successful therapy sedation is required. Sedation should be used cautiously

Barotrauma

Barotrauma is generally used when there is a tissue trauma due to differential pressure of the gas. The most common areas of the body affected are ear sinuses and the lungs. Most commonly reported adverse effect is middle ear barotrauma and patient complains of ear pain and discomfort which can be minimized by topical or systemic vasoconstrictors and myringotomy in special cases. Pulmonary barotrauma is a problem particularly during decompression phase of HBOT. Pulmonary barotrauma can be avoided by careful selection of patient (contraindicated in emphysema) and whenever it is suspected, therapy should be stopped immediately. Pneumothorax should be treated with chest tube insertion.

Oxygen Toxicity

As stated earlier, oxygen is considered as a drug and at high dose it generates free radicles which cause oxidation of chemical components of the tissue. Most common organs affected by oxygen toxicity are *lung*—pulmonary barotrauma during decompression phase, pulmonary toxicity can be reduced by intermittent inhalation of normal oxygen, *central nervous system*—seizure, muscular twitching, *eyes*—reversible myopia and cataract, prolonged oxygen therapy, and pressure affect the shape of the lens and refractory index, but these changes are reversible, one therapy is over. HBOT-induced cataract is usually not reversible.

SUMMARY

Hyperbaric oxygen therapy started as decompression illness therapy about 100 years ago, but since the last 50 years their role in various other illnesses is also proposed. HBOT is a therapy when 100% oxygen is administered intermittently at a pressure higher than the normal sea level pressure in the specified chamber. Scientific societies on hyperbaric medicine approved specific indications for use of HBOT. HBOT has certain specific indications in both infectious and noninfectious diseases that are often additive/adjunct to routine treatment and has been shown to be beneficial in most of the approved indications despite paucity of randomized controlled trials for its use. However, aggressive debridement, good local wound care, appropriate antimicrobial therapy, maximizing nutritional intake, and controlling serum glucose levels are the cornerstones to ensure the success of HBOT in approved indications.

CHAPTER

Noninvasive Ventilation

Kishalay Datta

INTRODUCTION

In early nineties, increasing experience with positive-pressure ventilation led to development of a ventilatory strategy, where ventilation could be delivered through a well-fitted mask in patients of obstructive sleep apnea (OSA). Increasing success of noninvasive ventilation (NIV) in cases of OSA led to its adoption in ventilatory management of patients with chronic obstructive pulmonary disease (COPD). Finally, in the next ensuing 20 years, noninvasive positive-pressure ventilation (NIPPV) delivered via a mask widely became adopted as the first-line ventilatory management in many medical centers over the whole world.

Noninvasive ventilation/NIPPV refers to the administration of ventilatory support through the patient's upper airways using oronasal/nasal/similar masks without using an invasive artificial airway (endotracheal or tracheostomy tube). NIV has now become an integral tool in the management of both acute and chronic respiratory failure, in both hospital and home settings. NIV is being used as a replacement for invasive ventilation in many cases due to its advantages and flexibility.

The basic *concept of NIPPV* is the application of positive pressure during the respiratory cycle (inspiration and expiration). The simplest application of that is a continuous positive pressure throughout the respiratory cycle, which is named continuous positive airway pressure (CPAP). The next application is administration of two different levels of pressure, one for inspiratory phase and one for the expiratory phase, otherwise known as bilevel positive airway pressure (BiPAP). NIPPV operates with application of positive pressure to upper airway (via masks) either by using a conventional ventilator or specialized equipment such as BIPAP/CPAP machines. NIPPV can also be given by volume cycled or pressure cycled ventilators. CPAP/BIPAP/pressure support ventilation (PSV)/ other modes can all be used in NIV, as per ventilatory needs of the patient.

Evaluation and management of acute respiratory failure are a routine for emergency physician. It is important for emergency physician to be well aware about NIV/NIPPV, patient selection, modes of delivery, application of appropriate positive pressure, and appropriate monitoring methods. Patient on NIV should be monitored closely and signs and every hourly symptoms of patient should be evaluated to determine success or failure of therapy.

MODES OF NONINVASIVE VENTILATION

There are two *modes of NIV*—(1) CPAP and (2) BiPAP. In CPAP, same pressure is applied/set during inspiratory and expiratory phase of respiratory cycle. CPAP is comparable to positive end-expiratory pressure (PEEP) used in invasive mechanical ventilation. CPAP is most useful in hypoxic respiratory failure. In BiPAP, different pressure is applied/set in inspiratory and expiratory phase of respiratory cycle, these pressures known as inspiratory positive airway pressure (IPAP) and expiratory positive airway pressure (EPAP). EPAP is the pressure which is comparable to the pressure of CPAP. BIPAP is useful in both hypercapnic as well as hypoxic respiratory failure. High-flow nasal cannula (HFNC) is a recent method of delivering NIV through nasal cannula instead of tight-fitting face mask.

Continuous Positive Airway Pressure

This mode can be used in patients, who are breathing spontaneously (a must). At end expiration, pressure in airways equals to pressure at mouth and both equates with normal atmospheric pressure. Surfactant prevents collapse of the alveoli which would have otherwise collapsed at this low end-expiratory pressure.

In diseased state, the alveoli collapse at low end-expiratory pressures due to lack of surfactant. So hypoxia occurs as a result of V/Q mismatch and shunting. Large number of alveoli collapses during disease process in lungs leading to decreased lung compliance. Once lung compliance decreases, more energy is needed to inflate the alveoli. So, higher inflation pressures are needed to open the diseased alveoli. Thus "WOB" (work of breathing) increases. Such high pressures needed to open diseased alveoli may also result in alveolar rupture leading to barotrauma.

Continuous positive airway pressure and PEEP both thus act as "internal splints" for unstable alveolar units. CPAP also elevates end expiratory pressure above atmospheric pressure thus keeping unstable alveolar units from collapsing and then finally "recruiting" them for useful ventilation. CPAP also helps

in the recruitment of collapsed alveoli thereby increasing functional residual capacity (FRC) of lung.

Continuous positive airway pressure thus decreases "WOB". CPAP can reverse hypoxia by restoration of ventilation to perfused areas (recruitment) thereby improving lung compliance. Stabilization of upper airways is also a purpose of this mode.

Bilevel Positive Airway Pressure

Continuous positive airway pressure does not provide support during inspiration as it only maintains positive pressure in airways. So, PSV was added to provide pressure support (PS) during inspiration in patients with poor respiratory effort. This resulted in creation of a new mode called BiPAP. So, BiPAP has two components providing pressures at two levels, i.e., inspiratory and expiratory level—(1) PSV, which provides inspiratory pressure and (2) PEEP, which provides expiratory pressure. BiPAP and CPAP both have disadvantage of propensity toward hyperinflation of lung.

PHYSIOLOGIC CHANGES WITH NIV: HOW DOES NIPPV WORKS?

While critically ill patient on NIV, this is very important that emergency physician should be aware about the physiologic changes on vital system (respiratory and cardiovascular). Primary goal of NIV is to decrease the WOB and improve gas exchange and oxygen saturation. Positive pressure application in NIV reduces the WOB by 60% through several mechanisms, similarly PS application also reduces the WOB by decreasing the inspiratory transpulmonary pressure. PEEP and PS help in improving ventilation perfusion mismatch, oxygenation, and removal of carbon dioxide removal. Positive pressure ventilation causes changes in circulatory system as well in the form of decrease in preload and afterload. This can help in cases of acute cardiogenic pulmonary edema. In preload-dependent patient, positive pressure alters the dynamics of intrathoracic pressure (decreases the negative intrathoracic pressure) and results in hypotension. So, the use of positive pressure cautiously in patient who is preload dependent. In brief *NIV, mechanism of action* is summarized here.

Noninvasive positive-pressure ventilation works by:

- Decreasing inspiratory WOB
- Decreasing inspiratory muscles work
- Decreasing "pressure time product" (PTP) of inspiratory muscle—an index for muscle O_2 consumption (PTP of diaphragm is reduced by 25% with PSV alone, while with PSV + PEEP, it goes down to 40%)

SELECTION CRITERIA FOR NIPPV

First and foremost, criteria are patient should be *conscious and spontaneously breathing*. Patient should have the ability to protect airway himself, be cooperative and also should be hemodynamically stable. Care should be taken that there are no excessive respiratory secretions present in such patients, undergoing a trial of NIPPV. Selecting patients for NIPPV requires careful consideration of its indications and contraindications. A trial of NIPPV is worthwhile in most patients who do not require emergent intubation and have a disease known to respond to NIPPV, assuming that they lack contraindications. The need for emergent intubation is an absolute contraindication to NIPPV. Further Indications and contraindications are discussed in **Table 1**.

TABLE 1: Indication and contraindications for noninvasive ventilation.

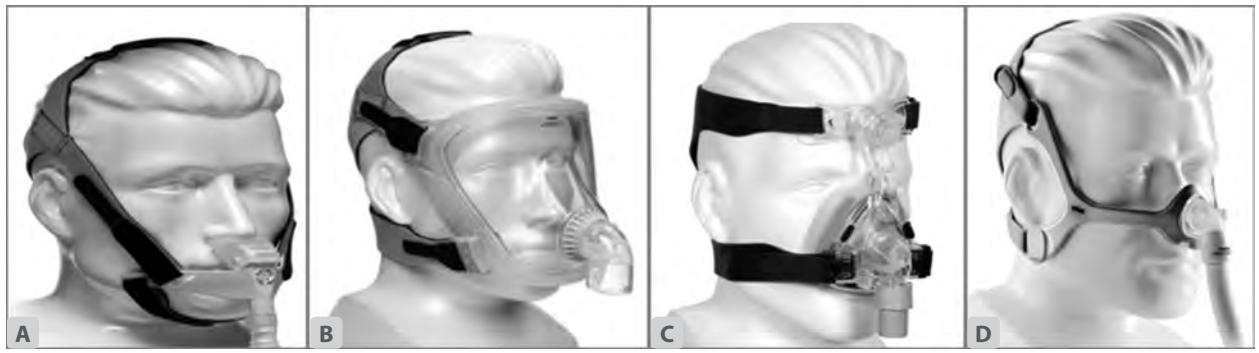
Indications	*Contraindication*
• Acute exacerbation of chronic obstructive pulmonary disease where $PaCO_2$ > 45 mm Hg or pH < 7.30 • Cardiogenic pulmonary edema • Acute hypoxemic respiratory failure • Obstructive sleep apnea–hypopnea syndrome • Congestive heart failure • Obesity hypoventilation syndrome • Immunocompromised host with acute respiratory failure • Postextubation and respiratory failure after extubation • Facilitate weaning • Asthma and status asthmaticus	• Patients having no spontaneous breathing • Unconscious patient • Severe hemodynamic instability of the patient • Upper airway obstruction • Facial trauma in a patient • Pneumothorax • Inability to cooperate, protect the airway, or clear secretions • High aspiration risk • Prolonged duration of mechanical ventilation anticipated • Recent esophageal anastomosis

INTERFACE OR MASK FOR NIPPV

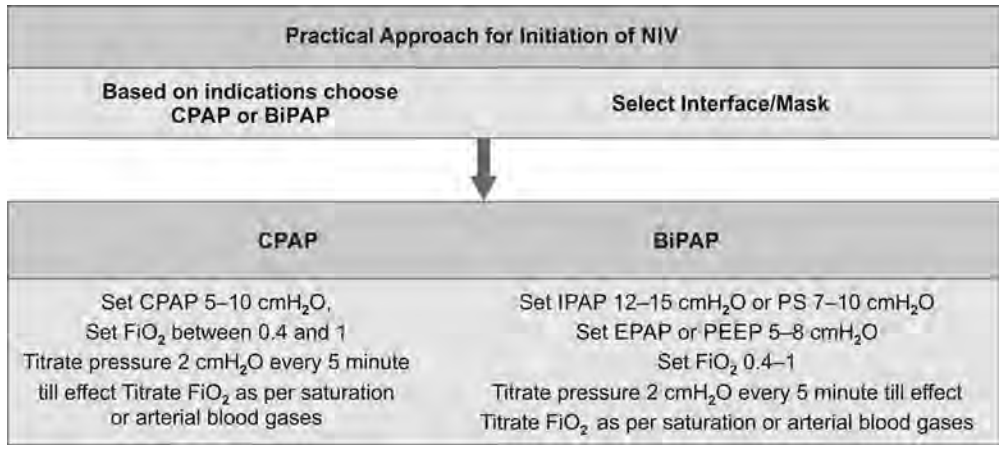
Interface or masks are devices, which connect ventilator tubing to facial region of the patient, during NIV. Patient-ventilator interfaces available for NIPPV include a full-face mask/oronasal mask/nasal mask/nasal prongs/helmets (**Figs. 1A** to **D**). The full-face mask includes the eyes, nose, and mouth, while the oronasal mask includes the nose and mouth, but not the eyes. A simple nasal mask is also available. Straps hold the interface in place and should be adjusted to avoid excess pressure on the nose or the face. The straps should be loose enough to allow one or two fingers to pass between the face and the strap. When a nasal mask is used, a chin strap is usually necessary to maintain closure of the mouth. The efficacy of the various interfaces has been debated over years. The face mask confers physiologic improvement, but the nasal mask is better tolerated. Whichever mask is selected, it is helpful to keep the following points in mind:

- Most patients with acute respiratory failure are mouth breathers; therefore, NIPPV delivered by a nasal mask may result in a larger air leak through the mouth thus leading to a bad outcome.
- The nasal air passages offer significant resistance to airflow, which can reduce the beneficial effects of NIPPV, if low positive pressure is used.
- The monitoring for aspiration in NIPPV patients is often difficult.
- Humidification of the inspired air is difficult through any form of masks.

The helmet interface has been used to improve patient tolerance in many cases. Moreover, the helmet interface allows patients to talk, read, and drink through a straw, while minimizing complications such as skin necrosis, gastric



FIGS. 1A TO D: Different types of interface/mask attachments.



Practical Approach for Initiation of NIV
Based on indications choose CPAP or BiPAP
Select Interface/Mask
CPAP
BiPAP
Set CPAP 5–10 cmH2O,
Set FiO2 between 0.4 and 1
Titrate pressure 2 cmH2O every 5 minute till effect Titrate FiO2 as per saturation or arterial blood gases
Set IPAP 12–15 cmH2O or PS 7–10 cmH2O
Set EPAP or PEEP 5–8 cmH2O
Set FiO2 0.4–1
Titrate pressure 2 cmH2O every 5 minute till effect
Titrate FiO2 as per saturation or arterial blood gases

(BiPAP: bilevel positive airway pressure; CPAP: continuous positive airway pressure; FiO_2: fraction of inspired oxygen; NIV: noninvasive ventilation)

FIG. 2: Practical Approach for Initiation of NIV.

distension, and eye irritation. But this interface may cause accumulation of CO_2 within the helmet, may produce noise sufficiently high enough to cause hearing damage, and may also to lead to more patient-ventilator asynchrony, and less relief of inspiratory effort of the patient.

HOW TO INITIATE NIPPV IN PATIENTS?

As per medical condition, appropriate patient is selected for the NIV as per indications. Emergency physician should be able to choose the mode of ventilation, type of interface PEEP/CPAP level, IPAP/PS level, and FiO_2 level. While setting the CPAP/PEEP, start with 5 cmH_2O and increase the PEEP by 2 cmH_2O every 10–15 minutes with goal of improving the oxygen saturation. *Initiation of NIV* should be done through *graded steps* as given below, and practical approach for initiation of NIV is given in **Figure 2**.

- Selection of proper interface is foremost followed by acclimatization of the patient with the interface
- Start with low pressure/volume in spontaneous mode
- O_2 supplementation should be continued @ 3–5 L/min and adjusted as per pressure changes.
- Initial IPAP should be started at 8–10 cmH_2O while EPAP at 3–4 cmH_2O.
- An IPAP:EPAP ratio should be kept constant at 2.5:1.
- Gradual increase of both pressures at 1–3 cmH_2O increments can be done.
- Care should be taken that pressure should not exceed > 20 cmH_2O.

MONITORING OF PATIENTS ON NIPPV

After NIPPV is initiated, the patient should be observed closely for the first 4–6 hours to troubleshoot, provide reassurance, and look for deterioration of clinical condition of the patient. Improvement of the pH and arterial carbon dioxide tension ($PaCO_2$) within one and a half to two hours predicts success. In contrast, conditions such as worsening encephalopathy or agitation, inability to clear secretions, inability to tolerate any of the interfaces, hemodynamic instability, or decreased oxygenation may indicate toward failure. The use of sedatives and analgesics is sometimes employed by clinicians to increase tolerance and comfort of NIPPV as well as to treat comorbid anxiety or pain.

PREDICTORS OF SUCCESS OF NIPPV

One of the most consistent signs of favorable response to NIPPV is drop-in respiratory rate within 1st to 2nd hour of starting of NIPPV. The following parameters should be considered for successful NIPPV trial.

- Arterial carbon dioxide tension > 45 and < 90 mm Hg at initiation of NIPPV
- pH > 7.1 at initiation of NIPPV
- Less air-leakage via interface during NIPPV
- Ability of the patient to coordinate breathing with the ventilator
- Lower severity of illness (APACHE SCORES) and young age of the patient

Periodic assessment of clinical indication of the patient remains as a best predictor of success. This is very critical to predict which patients will fail NIV and require intubation. Frequent reassessment of clinical variables in patients on NIV is necessary, which indicate the likelihood of success or failure, should be assessed after 30–60 minutes of treatment.

- *Predictors of failure of NIPPV*: Sepsis as a cause of the respiratory failure, ARDS, and higher severity score (SAPS II)
- *Predictors of success of NIPPV*: Improving pH, improving $PaCO_2$, improving PaO_2/FiO_2 ratio

WHAT TYPE OF VENTILATORS CAN BE USED FOR NIPPV?

Noninvasive ventilation can be delivered via all standard type of ventilators found in most intensive care units of hospitals or by a portable ventilator. Nowadays *"hybrid ventilators"* offering both forms (invasive and noninvasive) of ventilatory support are also available. However, the standard invasive ICU ventilator has numerous advantages over the BIPAP/CPAP machines. The advantages are:

- A precise concentration of oxygen can be delivered, i.e., FiO_2 can be set.
- Separate inspiratory and expiratory tubing minimizes the rebreathing of carbon dioxide.
- Large mask leaks or patient's disconnection can be readily detected.
- Better monitoring and alarm features are present in standard ventilators.
- Higher inspiratory pressures (>20 cmH_2O) can be given if need arises.
- Backup ventilation is present when needed.

In addition, certain modes can only be delivered by a standard ICU ventilator (e.g., volume controlled, pressure controlled, and time-limited PSV, etc.)

WHAT MODES OF VENTILATOR CAN BE USED FOR NONINVASIVE VENTILATION?

Noninvasive positive-pressure ventilation can be delivered using the same modes that are used for invasive mechanical ventilation, although certain modes may be used more frequently:

- Assist control mode is the most common mode chosen by doctors who want a guaranteed minute ventilation.
- Pressure support ventilation is the most common mode chosen by doctors who focus on patient's comfort and synchrony.
- Continuous positive airway pressure/BiPAP is used for patients with acute respiratory failure.
- Proportional assist ventilation delivers an inspiratory pressure that is proportional to patient effort. This allows better patient-ventilator synchrony.

HOW TO SET THE VENTILATOR FOR NIPPV?

The selected mode determines which parameters need to be set during the initiation of NIV, e.g., assist control mode requires a tidal volume, respiratory rate, inspiratory flow rate, PEEP, and (FiO_2) to be set. BiPAP mode delivers both IPAP and EPAP like invasive ventilation. Patient of chronic obstructive lung disease and acute severe asthma commonly present to ED with acute dyspnea. Emergency physician must be aware about the initiation, adjustment, and weaning of NIPPV in these patient (**Table 2**).

WEANING

Weaning from NIPPV may be accomplished by progressively decreasing the amount of positive airway pressure, permitting the patient to be disconnected from the NIPPV for progressively longer durations, or a combination of both.

COMPLICATIONS OF NIPPV

These are common complications:

- Leakage via mask leading to multiple adjustments
- Intolerance of positive pressure by patient
- Gastric distention due to positive pressure
- Aspiration (rare)
- Facial skin breakdown (long-term use)
- Increased gastric pressure may lead to abdominal compartment syndrome
- Hypotension
- Barotrauma

TABLE 2: Managing COPD/asthma by noninvasive respiratory support.

	Noninvasive positive pressure ventilation (NIPPV)	***High-flow nasal cannula (HFNC)***
Initiation	*COPD*: EPAP 5–8, IPAP 5–10, FiO_2 80–100% *Asthma*: EPAP 0–5, IPAP 5–10, FiO_2 100%	*Start:* • Flow: 50% of maximum • FiO_2: 100%
Adjustment	• Titrate up IPAP (asthma and COPD) and EPAP (COPD) as tolerated to reduce work of breathing—monitor changes in tidal volume and minute ventilation • To increase ventilation, increase the gradient between IPAP: EPAP • Wean FiO_2 as tolerated to keep O_2 sat > 88%	*Adjust:* • Increase flow to reduce work of breathing and increase CO_2 clearance • Wean FiO_2 as tolerated to keep O_2 sat > 88%
Weaning	Wean: Reduce IPAP: EPAP gradient as work of breathing improves	Wean: Reduce flow as work of breathing improves

(COPD: chronic obstructive pulmonary disease; EPAP: expiratory positive airway pressure; IPAP: inspiratory positive airway pressure; FiO_2: fraction of inspired oxygen)

HIGH-FLOW NASAL CANNULA

Traditionally, we are using nasal cannula for providing supplemental oxygen for hypoxic patient. With this nasal cannula, 25–35% of supplemental oxygen can be delivered to the patient. Interest was developed regarding delivering the greater oxygen concentration with higher flow rates of oxygen by using HFNC. Since year 2000, HFCN was commercially available, which consists of specialized nasal cannula oxygen, delivery device, and humidification system. *Since the use of HFNC is becoming common, ability to produce positive airway pressure is questioned and various physiologic studies suggest the quality and quantity of positive pressure effect generated by HFNC are meager*. Mild-to-moderate hypoxic patient responds well to HFNC provides reliable improvement in oxygen saturation. HFNC is helpful for hypoxic respiratory failure and in patient after cardiac surgery. HFNC should not be used as first-line therapy for COPD and acute cardiogenic pulmonary edema, in these conditions traditional NIV is much beneficial.

SUMMARY

Emergency physician frequently manages acute respiratory failure in emergency department and selected patient can be managed successfully by NIV. Emergency physician should know their beneficial and detrimental physiologic changes associated with their use. NIV is delivery of the positive pressure ventilation through well-fitted nasal facial or oronasal mask in patient of hypoxic respiratory failure. NIV can be used in acute asthma COPD acute cardiogenic pulmonary edema traumatic respiratory failure community acquired pneumonia. CPAP or BiPAP modes can be used to deliver the positive pressure NIV. Patient should be monitored closely; hourly vital signs should be documented as physiologic changes occur in patient on NIV. Emergency physician should aware of failure of NIV which is common so require constant vigilance and reassessment of patient with acute respiratory failure.

CHAPTER

Mechanical Ventilation

Mrinal Sircar, Saurabh Mehra, Devendra Richhariya

INTRODUCTION

Mechanical ventilation and intubation are an indispensable part of emergency room (ER) management. The indication for mechanical ventilation is either to provide assistance in breathing and/or airway protection. This applies to diverse conditions including trauma, sepsis, exacerbations of asthma and chronic obstructive airway disease (COPD), severe pneumonia, congestive cardiac failure, and neurological disorders associated with low Glasgow Coma Scale (GCS) or loss of protective airway reflexes, etc. All those working in ER need to be well versed in providing mechanical ventilation in ER as also during transport to ICU, operating theatres or for imaging or while transporting patients by ambulance.

PHYSIOLOGY OF BREATHING

Spontaneous breathing involves contraction of diaphragm and intercostal muscles to cause expansion of thorax and movement of air into lungs. Physiologically, development of a pressure gradient between the alveoli and the atmosphere causes air movement into lungs. Since this involves generation of a negative pressure, spontaneous ventilation is negative pressure ventilation. The expiration is a passive phenomenon, however; in diseased states it may require active contraction of accessory muscles. The ventilation involves four pressures *(mentioned below)* and four pressure gradients (**Table 1**) which must be understood to know the physiology of breathing (**Fig. 1**).

1. *Airway opening pressure (P_{awo}) (or airway pressure or mouth pressure)*: It is zero or atmospheric pressure unless a positive pressure is applied.
2. *Pressure at body surface (P_{bs})*: It is zero or atmospheric pressure.
3. *Intrapleural pressure (P_{pl})*: It is the pressure in the pleural space, i.e., space between the parietal and visceral pleurae. It is negative as there is no air in the pleural space. At the end of expiration in a spontaneously breathing person, it is about –5 cmH_2O. However, in an upright lung it varies depending upon where it is measured. P_{pl} increases by 0.3 cmH_2O/cm vertical distance of lung. The cause of this vertical gradient is the weight of the lung itself. So it is around –3 cmH_2O at the lung base and –7 cmH_2O at the lung apex.
4. *Alveolar pressure ($P_{A\ or}P_{alv}$) (or Intrapulmonary pressure or lung pressure)*: It also varies with the phase of ventilation. P_A is –1 cmH_2O during spontaneous inspiration and becomes positive during expiration (+1 cmH_2O).

TABLE 1: Pressure gradients during spontaneous breathing.

Transairway pressure (P_{ta})	Airway pressure – alveolar pressure ($P_{aw} - P_{alv}$)
Transpulmonary pressure (P_{TP} or P_L) or transalveolar pressure	Alveolar pressure – pleural pressure ($P_{alv} - P_{pl}$)
Transthoracic pressure (P_w)	Alveolar pressure – body surface pressure ($P_{alv} - P_{bs}$)
Transrespiratory pressure (P_{tr})	Airway opening pressure – body surface pressure ($P_{awo} - P_{bs}$)

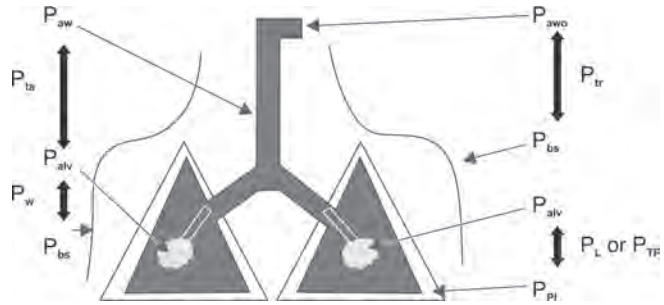

FIG. 1: Various pressures and pressure gradients of the respiratory system.

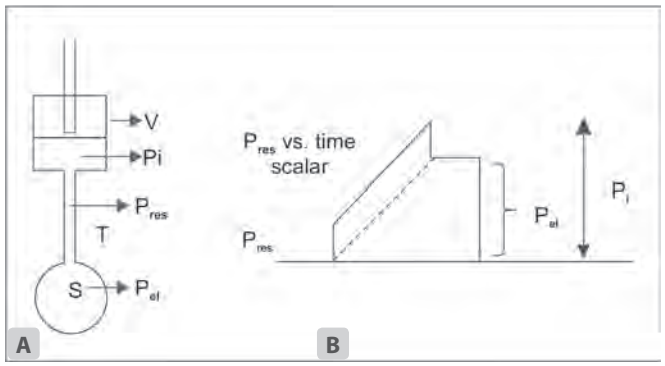
MECHANICAL DETERMINANTS OF "PATIENT–VENTILATOR" INTERACTIONS

To *understand the interaction between a ventilator and a patient*, we assume that lung may be represented as a simplified linear model with a tube (T) and a balloon or hollow sphere (S). The sphere is inflated by applying a pressure (Pi) near the tube inlet (**Figs. 2A** and **B**).



FIGS. 2A AND B: Figure A shows a simple linear system with a ventilator (V) applying a pressure (Pi) to the inlet of tube (T) leading to inflation of hollow sphere (S); Figure B shows the resulting pressure versus time waveform.

The pressure applied to the tube inlet Pi, is equal to the sum of two pressures, an elastic pressure of the sphere (P_{el}) and a resistive pressure of the tube (P_{res}).

$$\mathbf{Pi = P_{el} + P_{res}} \qquad \textbf{(}\textit{Equation 1}\textbf{)}$$

P_{el} reflects the elastic properties of lungs and chest wall, whereas P_{res} reflects the resistive properties of endotracheal tube and airways. We know from principles of physics that,

Elastic recoil pressure (P_{el}) = Elastance × Volume = E × V and

Flow resistance pressure (P_{res}) = Resistance × Flow = R × $\dot{V}$ (Ohm's Law) So, Equation 1 can be stated as:

$$\mathbf{Pi = EV + RV\dot{}} \qquad \textbf{(}\textit{Equation 2}\textbf{)}$$

For a patient on ventilator, Pi has two components, i.e., P_{mus} (pressure generated by the respiratory muscles) and P_{vent} (pressure delivered by the ventilator)

So, Equation 2 can be written as:

$$\mathbf{P_{mus} + P_{vent} = EV + RV\dot{}} \qquad \textit{(Equation 3)}$$

Compliance (C) of the respiratory system is determined by measuring the change of volume (ΔV) that occurs when pressure gradient (ΔP) is applied to the system: Normal values of compliance and resistance is shown in **Table 2**.

$$\text{Compliance (C)} = \Delta V/\Delta P$$

It is inversely proportional to elastance.

Resistance of respiratory system includes resistance to the flow of gases in airways (airway resistance) or resistance offered by the lung tissue and the chest wall (tissue resistance).

$$\text{Airway resistance } (R_{aw}) = \text{Transairway pressure/Flow}$$

Time constant: It tells us the time lung units or the acini take to fill and empty. It is the product of the compliance and resistance.

One time constant = 0.1 L/cmH_2O (C) × 1 cmH_2O/L/s (R)

Normally, one time constant is 0.1 second. One time constant means the time to exhale 63% of volume, similarly two-, three-, four- and five-time constants are the time to exhale 86, 95, 98, and 100% volume.

Because lung is a heterogeneous structure, time constants can vary in different regions of lungs. This is exacerbated in diseased states such acute severe asthma or acute respiratory distress syndrome (ARDS).

TABLE 2: Normal values of compliance and resistance.

	Compliance (mL/cmH_2O)	*Resistance (cmH_2O/L/s)*
Spontaneously breathing	100 (range 50–170)	0.6–2.4 (at 0.5 L/s flow)
Intubated and mechanically ventilated	• 40–50 (males) • 35–45 (females) • Can vary up to 100 in either gender	• 5–7 • Can be higher depending on patients clinical condition or circuit determinants

BOX 1: Common indications of mechanical ventilation.

- Cardiopulmonary arrest
- Neurological problems (stroke, myasthenia gravis, meningitis, encephalitis, tumors, high intracranial pressure, drug overdoses causing unconsciousness, etc.)
- Pulmonary problems—asthma, COPD, ARDS, and pneumonia
- Trauma
- Congestive cardiac failure
- *Shock*: Septic shock, cardiogenic shock, hemorrhagic shock, etc.

(ARDS: acute respiratory distress syndrome; COPD: chronic obstructive airway disease)

The clinical importance of time constant lies in the fact that inspiratory time less than three-time constants will lead to incomplete delivery of tidal volume. Similarly, if the expiratory time is less than three-time constants it will lead to incomplete exhalation.

INDICATIONS OF MECHANICAL VENTILATION

Tracheal intubation with cuffed endotracheal/tracheostomy tubes protects from aspiration and ventilation supports the breathing. Patients who have diminished airway reflexes or have respiratory insufficiency as evident by hypoxemia, hypercarbia, or severe respiratory distress are the likely candidates to receive mechanical ventilation. Common indications are shown in **Box 1**.

TYPES OF MECHANICAL VENTILATION

Mechanical ventilation can be categorized as (1) invasive or noninvasive, (2) positive pressure or negative pressure, and pressure control or volume control or dual mode. Positive pressure ventilators are the ones used in clinical practice. A positive (higher than the atmospheric) pressure is applied to the patient's airway which creates a flow of gases into the lungs. Such a pressure can be applied to endotracheal tube, tracheostomy tube, or noninvasively to the face of the patient. However, in this chapter we will limit our discussion to the invasive mechanical ventilation only. *Volume control ventilation* is the one in which

volume is set and pressure is the independent variable, while in pressure control ventilation, pressure is set and volume is an independent variable. Before moving on we will discuss about the *"variables"* in the ventilation.

- *Control variables*: Control variables are the main variables the ventilator adjusts to produce inspiration. They include pressure, volume, flow, and time.
- *Phase variables*: Phase variables control the four phases of a breath (i.e., beginning of inspiration, inspiration, end inspiration, and expiration). *Types of phase variables include:*
  - *Trigger variable*: It is a preset variable which decides the beginning of inspiration. It can be pressure (pressure triggering), flow (flow triggering), volume (volume triggering), or time (time triggering). Traditionally, pressure has been used, but modern ventilators have flow triggering which is now considered better for patients. Patients who have a spontaneous effort should generate the set amount of pressure or flow or volume that can be sensed by ventilator as a patient effort and then it can be supported by a positive pressure breath. When the ventilator starts inspiration according to the set rate and the I:E ratio, it is called time triggering.
  - *Target variable (limit variable)*: A target variable is one that can reach and maintain a preset level before inspiration ends. It can be flow, volume, or pressure. Achieving the target of limit does not mean end of inspiration. Some use the term limit variable; however, limit is a term which is generally used in reference to alarm settings.
  - *Cycle variable*: It decides the cycling (termination of the inspiration and beginning of the expiration). It can be time, flow, pressure, or volume cycled, e.g., decrease in flow to a particular proportion of the peak flow will cause the ventilator to cycle to expiration.
  - *Baseline variable*: It is the parameter controlled during exhalation. The pressure level from which a ventilator breath begins is called the baseline pressure. Baseline pressure can be zero (atmospheric), which is also called zero end-expiratory pressure (ZEEP), or it can be positive if the baseline pressure is above zero [positive end-expiratory pressure (PEEP)].

Types of Breaths during Mechanical Ventilation

- *Mandatory breaths*: They are time triggered, volume or pressure limited, and time cycled.
- *Assisted breaths*: They are patient triggered, limited by the ventilator (volume or pressure limiting), and cycled by ventilator (time cycling).
- *Spontaneous breaths*: They are triggered limited and cycled by the patient. The variables, however, can be pressure, flow, or volume.

MODES OF VENTILATION

The relationship between various possible types of breath and the inspiratory phase variables is called a mode of ventilation. Mode can be volume targeted, pressure targeted, or combined.

Volume-targeted Mode

In this mode, the machine delivers a volume set on the control panel by the physician irrespective of the pressure generated within the system. There are several inspiratory flow profiles, e.g., square wave, sine wave, ascending ramp, and descending ramp (decelerating) patterns (**Fig. 3**). Descending ramp pattern is associated with lower peak airway pressure and higher mean airway pressure. Expiratory flow is always decelerating in a mechanical breath irrespective of the inspiratory flow pattern. **Figure 4** shows a complete mechanical breath with a square wave flow inspiratory pattern. Changes in the mechanical properties of the lungs from atelectasis, edema, or bronchoconstriction may cause high inflation pressures (increasing the risk of barotrauma).

Pressure-targeted Mode

A predefined target pressure is set on the control panel of the ventilator. The ventilator generates flow to achieve the same pressure during the inspiration; the volume, however, is an independent variable which will depend on the impedance of the respiratory system. The underlying reason for mechanical ventilation guides the selection of the mode of ventilation. Volume-targeted ventilation should be used when strict control of tidal volume is required, e.g., ARDS. Conversely, in patients with asthma and COPD, strict control of airway pressure is desired so pressure-targeted ventilation is preferred.

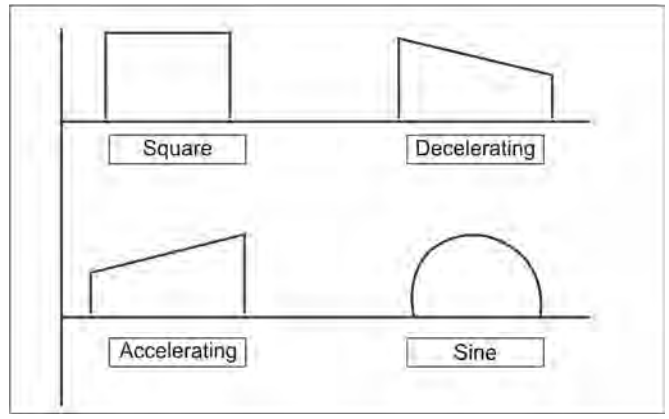


FIG. 3: Four different types of inspiratory flow patterns.

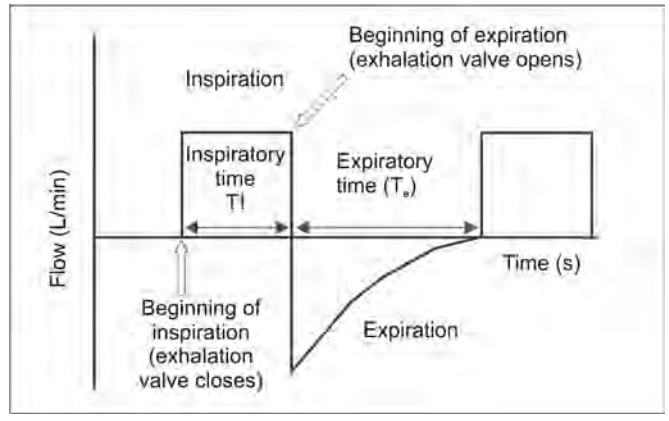

FIG. 4: Flow time scalar with constant flow waveform.

Control Mode or Controlled Mandatory Ventilation

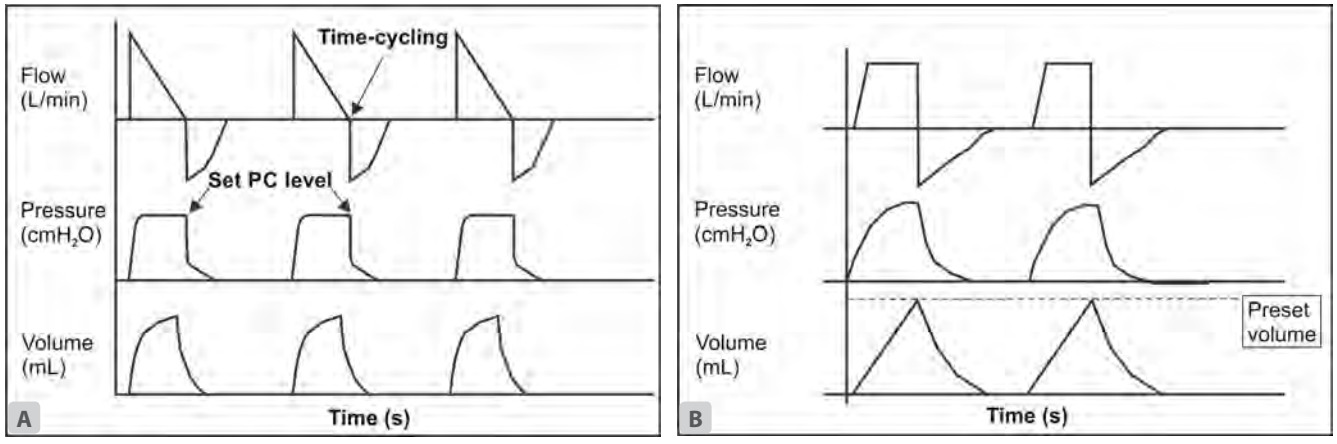
Controlled mandatory ventilation (CMV) mode is appropriate for the patients who are either deeply sedated, paralyzed or have no spontaneous efforts of their own. The breaths delivered are time triggered. No matter how strong is the patient's breathing effort, the ventilator does not deliver gas flow unless it is time triggered. **Figures 5A** and **B** respectively show ventilator waveforms for pressure and volume control CMV. It is used when the aim is to provide complete rest to the patient or in cases such as chest trauma where paradoxical movements of chest due to flail segment impede the ventilation.

Assist-control (AC) Ventilation

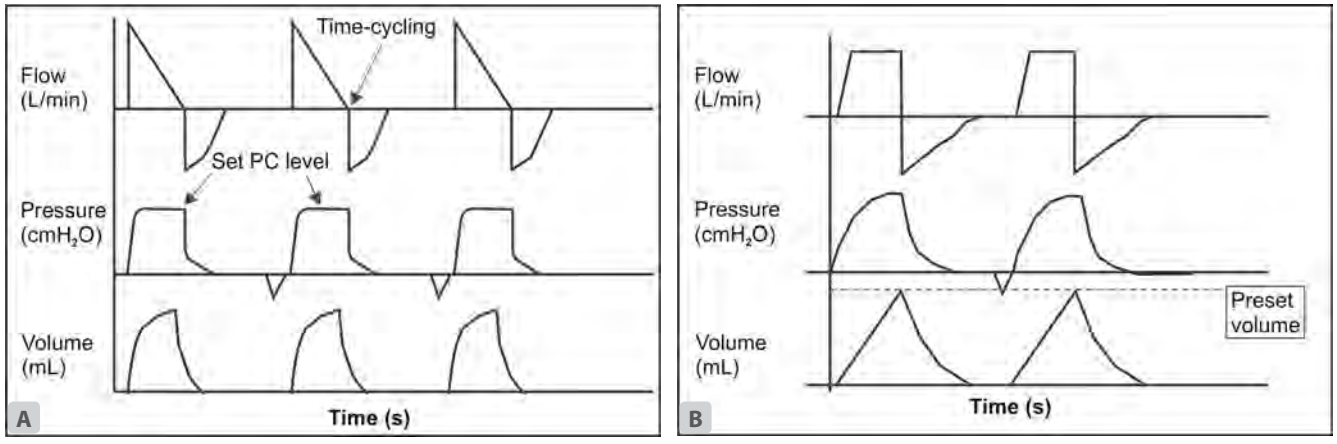
It is a time-triggered or patient triggered CMV mode. It is the appropriate mode of ventilation, when we want to provide full support to the patient, but patient has spontaneous efforts. *There are two types of breaths: (1) controlled, and (2) assisted*. Control breaths are time triggered, pressure or volume targeted, and time cycled. Assisted breaths are patient triggered, volume or pressure targeted and time cycled. The sensitivity level is set in the ventilator and when the ventilator senses a spontaneous effort, mechanical breath is delivered to achieve the same target as the control breaths. The major problem with this mode is that all the appropriately sensed efforts are converted to a mechanical breath which may lead to hyperventilation and respiratory alkalosis when the patient's respiratory rate (RR) is high. Also because it involves assisted breaths there may be inappropriate sensing if the trigger sensitivity is not correctly set leading to wasted efforts or there may be a delayed response time of the ventilator which can cause a patient-ventilator dyssynchrony. AC ventilation can be either a pressure controlled (**Fig. 6A**) or volume controlled (**Fig. 6B**). In volume control mode, setting of adequate gas flow is very important. If flow is less then patient will have flow hunger and dyssynchrony will result. Patients may not stop breathing even when the flow ceases and this may cause dyssynchrony. We may need to adjust the sensitivity. Several studies have shown that the decelerating ramp flow curve associated with PC mode may improve gas distribution and allows the patient to vary inspiratory gas flow during spontaneous breathing efforts.

Intermittent Mandatory Ventilation and Synchronized Intermittent Mandatory Ventilation

Intermittent mandatory ventilation (IMV) involves delivery of breaths (volume or pressure targeted) at set intervals (according to the set RR). However, the patient can breathe spontaneously between mandatory breaths at any desired baseline pressure without receiving a mandatory breath



FIGS. 5A AND B: Control mode ventilation: (A) Pressure control; (B) Volume control.



FIGS. 6A AND B: Assist-control ventilation: (A) Pressure control; (B) Volume control.

(contrast from AC mode). Synchronized intermittent mandatory ventilation (SIMV) is similar to IMV except that the mandatory breaths may be either patient triggered or time triggered (**Fig. 7**). IMV has an inherent drawback of stacking of breaths, which happens when patient takes a breath at the time of a mandatory breath. To overcome this, SIMV was developed in which ventilator waits for the patient to take a spontaneous breath. If it does not sense patient effort, then it delivers time-triggered breath. *Advantage of IMV and SIMV over AC mode* is that patient can breathe spontaneously to his own tidal volume, thus avoiding hyperventilation which may be seen in AC mode. Both IMV and SIMV have been used to wean patients from mechanical ventilation. As the mandatory rate is lowered, the patient gradually assumes a greater part of the work of breathing (WOB). However, IMV or SIMV can significantly increase WOB for spontaneous breaths. The spontaneous breaths can be supported with pressure support [SIMV + PSV (pressure support ventilation)], if we want to reduce the WOB. Both IMV and SIMV were used as a weaning mode, however, studies have shown that they do not fasten the weaning process rather can delay it.

Dual Modes of Ventilation

Newer ventilators offer many dual modes of ventilation. For the ER physician, all of them are not important; however, we will discuss one of such modes in brief. *Pressure-regulated volume control (PRVC)*—problem with regular volume control is high airway pressures which can cause barotrauma. PRVC was developed with purpose to deliver set tidal volumes at minimum pressure level. It is a volume targeted, pressure limited, and time-cycled mode. The ventilator automatically adjusts inspiratory pressure control level according to the changes in the properties of lung on a breath to breath basis. However, it has inherent limitations. If patient demand and effort increase higher tidal volumes are generated and the pressure support level is decreased. It means patient is getting less support when he actually requires more.

Pressure Support Ventilation

It is a patient-triggered, pressure-limited, and flow-cycled ventilation (**Fig. 8**). The ventilator provides a constant pressure during inspiration once it senses that the patient has made an inspiratory effort. Inspiratory pressure, PEEP, flow-cycle criteria, and the sensitivity level are set. Rise time is the time taken to reach the target pressure. It can be changed according to the comfort of the patient. High rise time and inadequate flows can result in patient ventilator asynchrony. Inspiratory flow in PSV ends when the ventilator senses that the flow has dropped to a certain level (flow cycling). Breathing through endotracheal tube increases the WOB. PSV overcomes WOB for spontaneously breathing patients breathing through a ventilator circuit. Patients who have a high respiratory drive and flow requirements may benefit by PSV compared to VC-CMV. High pressure settings than required by patient and air leaks may cause patient-ventilator dyssynchrony.

Continuous Positive Airway Pressure (CPAP)

Ventilators can also provide CPAP for spontaneously breathing patients. It helps in preventing atelectasis and treating and preventing hypoxemia.

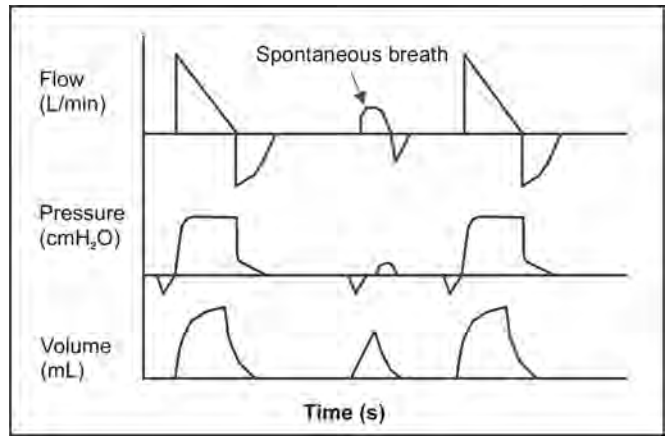


FIG. 7: Synchronized intermittent mandatory ventilation mode.

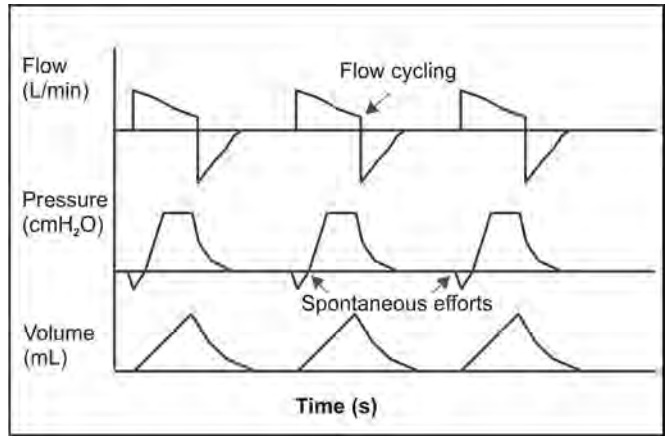

FIG. 8: Pressure support ventilation mode.

INITIATION OF VENTILATION

Initially, a controlled or assist-control mode is selected to decrease the WOB and provide complete relaxation to the respiratory muscles. Later, mode can be changed to either a SIMV or a PSV.

- *Fraction of inspired oxygen (FiO_2)*: For patients with severe hypoxemia, the initial FiO_2 should be set at 100%. ABG should be done to see the PaO_2, which should be targeted at 80 and 100 mm Hg for most patients, except those with COPD and ARDS where lower targets may be allowed. FiO_2 should be titrated and brought down to <50%, if feasible.
- *Respiratory rate*: It refers to the number of breaths per minute intended to maintain pCO_2 in normal range or patient's normal. It varies from 12 to 20 depending upon the clinical condition.
- *Minute ventilation (V_E)*: In resting patients with healthy lungs and metabolic rates, a V_E setting between 80 and 100 mL/kg usually results in normocapnia. However, most of the patients presenting to ER have a different from normal metabolic rate. V_E varies directly with the metabolic rate. Metabolic rate is estimated on the basis of an individual's gender and body surface area (BSA). BSA can be calculated using the Du Bois BSA formula:

$$BSA = 0.007184 \times Ht^{0.725} \times W^{0.425}$$

where BSA = body surface area in square meters, Ht = body height in centimeters, and W = body weight in kilograms.

$V_E = 4 \times BSA$ (men) $V_E = 3.5 \times BSA$ (women)

Minute ventilation requirements change in many pathological conditions. Example, V_E increases by 5% for every degree F above 99°F or 9% per degree C above 37°C. Metabolic acidosis causes a 20% rise in V_E.

- *Tidal volume*: The normal spontaneous tidal volume (V_T) for a healthy adult is about 5–7 mL per kg body weight. Earlier total body weight was used to derive the tidal volume. But now ideal or the predicted body weight (PBW) is used. PBW (in kg) may be derived as:

  Men = 50 + 2.3 × (height in inches – 60)
  Women = 45.5 + 2.3 × (height in inches – 60)

  For patients presenting to ER with apparently normal lungs, such as patients with a drug overdose an initial V_T of 5–7 mL/kg and a rate of 10–20 breaths/min are generally accepted. A V_T of >9–10 mL/kg is not recommended because of the risk of high pressures.
- *Pressure control setting*: It should be selected to achieve the target tidal volume as mentioned above. Care should be taken that the pressure should not be too high so as to avoid barotrauma. It will vary according to the compliance of lung and chest wall and airway resistance. Those with compliant lungs and low airway resistance will require less pressure to deliver the same tidal volume.
- *I:E ratio*: It refers to the ratio of the inspiratory to the expiratory time. Different ventilators have different settings. Some will allow to directly set I:E ratio, some however; will allow setting of inspiratory time and rate only and will decide I:E ratio from the set values. Usually, I:E ratio is kept at 1:2, however, it may be required to change the I:E ratio in certain situations. It will be discussed under the section "ventilation in special conditions."
- *Total cycle time (TCT)*: It is the time of one cycle of inspiration and expiration. If RR is kept at 10 breaths/min, then one cycle of inspiration and expiration will be 6 seconds, i.e., TCT will be 6 seconds. Now either we can set I:E ratio as 1:2 which will make T_i as 2 seconds and T_E as 4 seconds. Some ventilators do not have I:E setting, but require setting T_i. Setting T_i as 2 seconds will set I:E ratio as 1:2.

  Some ventilators use gas flow rate to decide the I:E ratio. Increasing the flow rate will cause Ti to decrease and T_E to increase. In the above example, Ti is 2 second. If the tidal volume set is 500 mL, then this 500 mL volume needs to be delivered to the patient in a time of 2 seconds which will equal to a flow of 250 mL/s or 15 L/m. Flow rate affects RR and tidal volume of a spontaneously breathing patient.
- *Positive end-expiratory pressure*: PEEP is defined as positive pressure at the end of exhalation during either spontaneous breathing or mechanical ventilation. **Figure 9** shows pressure time scalar in which the baseline pressure is elevated (PEEP). Usually, clinicians set a minimum PEEP of 5 cmH_2O. The explanation behind this practice is that the glottis usually provides a physiological PEEP of around 5 cmH_2O in spontaneously breathing nonintubated patients. Intubation of trachea removes this PEEP. So PEEP may be applied through the ventilator to prevent the atelectasis. However, some patients may require higher PEEP, e.g., pulmonary edema and ARDS.

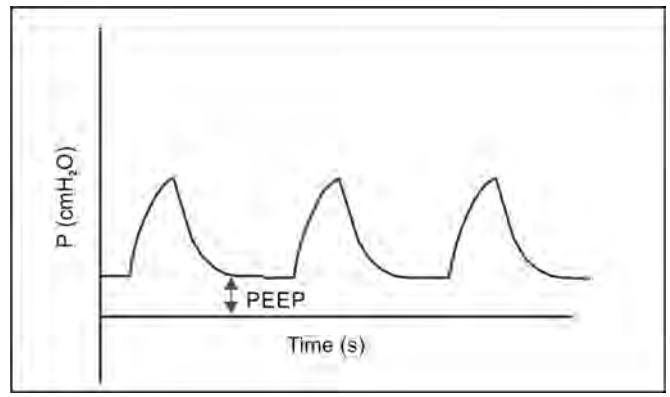

FIG. 9: Pressure time scalar showing elevated baseline pressure.

- *Trigger or sensitivity*: It can be set as pressure (1–5 cmH_2O) or flow (1–5 L/m). High trigger will mean that ventilator will ignore those spontaneous efforts of the patient which produce a pressure or flow less than that which is set in ventilator. These spontaneous breaths will not be supported by the ventilator.

MONITORING AFTER INITIATING VENTILATION

- Constant vigilance is required after intubation and setting ventilator. Optimum delivery of breaths needs to be ensured.
- Monitor vitals and oxygen saturation after intubation.
- Monitor the parameters on the ventilator screen, e.g., if PC mode is used, see how much volume is being delivered to the patient. It may be grossly inadequate if lung compliance is poor. In VC mode, peak airway pressure is influenced greatly by airway resistance and therefore is not reflective of end-inspiratory alveolar pressure. Alveolar pressure at end inspiration in VC mode is approximated by the P_{plat}, which can be measured with the ventilator at the end of inspiration by means of an inspiratory hold maneuver.
- Check alarm limits in the ventilator. The ventilator may be cutting off the delivery of gases in inspiration if the pressure limit gets exceeded (too low-pressure limit).
- Do arterial blood gas (ABG) after 15 minutes. Adjust the parameters (if required) according to the ABG report**.**
- Do a chest X-ray to check for endotracheal tube and nasogastric tube position and to rule out complications such as tube malposition, lung collapse or pneumothorax, etc.
- After ensuring effective ventilation, the most important goal is to provide comfort to the patient. Initiate sedation infusion according to your institutional protocol.
- Avoid neuromuscular blockers. However, they may be necessary in some cases such as ARDS.
- Periodic reevaluation of patient is needed. Initiate liaison with the intensive care unit (ICU) team for further management and shifting to ICU and anesthetist if patient is due to go to operating room or with radiology team if an imaging procedure such as computed tomography (CT) scan is planned.

COMPLICATIONS OF INTUBATION AND VENTILATION

The complications of intubation are depending on the patient airway anatomy, the urgency of the procedure, and the skill of the emergency physician. Mechanical ventilation is always known to save lives of critically ill patients, but also associated with multiple complications. Some of them are temporary and unrelated to ventilatory support but many are a direct result of positive-pressure ventilation, e.g., barotrauma. Infection, nosocomial pneumonia associated with various clinical factors, and concurrent intubation are one of them. Further complications of intubation and mechanical ventilation are summarized in **Table 3**.

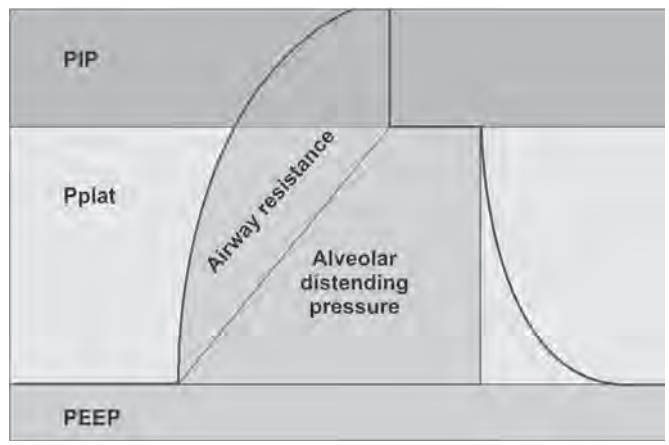
AIRWAY PRESSURES, ALARMS, AND TROUBLESHOOTING

In a volume-targeted mode, the ventilator delivers a set tidal volume with airway pressures being dependent on the resistance and compliance of the pulmonary system. Pressure-targeted modes can be successfully used but require significantly greater vigilance. The pressure measured at the airway opening can be divided into the pressure to overcome resistance in the airways and the pressure to overcome the elasticity of the lung and chest wall (**Fig. 10**). With few exceptions, the peak pressure represents the total pressure required to overcome both resistive (e.g., bronchospasm and airway edema) and elastic forces (e.g., stiff lungs or chest wall), whereas the *plateau pressure represents only the contribution of elastic forces*, as it is measured in the absence of gas flow. Patients with obstructive lung disease often have high peak pressures due to the resistance from bronchospasm and airflow obstruction. The peak inspiratory pressure (PIP) is evaluated continuously without any maneuvers on the ventilator, as it is the pressure read at the airway opening at the end of inspiration.

- *The plateau pressure* is determined by performing an inspiratory hold on the ventilator that closes the inspiratory valve at end-inspiration and allows the pressure to equilibrate with the alveoli in the absence of gas flow. Patients who have dynamic hyperinflation and significant auto-PEEP will have both high peak and plateau pressures and are at risk of pneumothorax, which is why mechanical ventilation in asthmatics can be dangerous. Although peak pressure >50 and plateau pressure >30 have been associated with barotrauma, it is unlikely that these represent threshold values and risk likely increases with increasing pressure. Elevated peak pressure should only confer risk of barotrauma when it is symptomatic of elevated plateau pressure. When the plateau pressure is elevated, one must evaluate factors reducing respiratory system compliance, often auto-PEEP and air trapping in the context of obstructive lung disease. When auto-PEEP (intrinsic PEEP) is suspected the flow waveforms should be examined, as air trapping it is the most likely culprit.
- *Auto-PEEP* is measured by performing an expiratory hold on the ventilator, which closes the expiratory valve and allows pressure to equilibrate with the alveoli at rest. The total pressure measured will be higher than the set PEEP (**Fig. 11**) in the presence of auto-PEEP. Auto-PEEP may be grossly underestimated due to regional obstruction, which is most pronounced in patients with the fixed bronchospasm and mucous plugs with normal to decreased lung compliance as seen in asthma as opposed to dynamic airway collapse and increased lung compliance as seen in patients with emphysema and COPD. If a lung unit has an auto-PEEP that exceeds the pressure required to obstruct the efflux of gas, the pressure will not be reflected at the airway opening, underestimating the total PEEP. In cases of obstructive lung disease with significant auto-PEEP, externally applied PEEP may reduce WOB by lowering the threshold pressure needed to trigger the ventilator but it is a double-edged sword. Externally applied PEEP greater than this threshold will worsen dynamic hyperinflation and increase the risk of pneumothorax. This is the risk of PEEP both invasively and noninvasively in patients with respiratory failure secondary to obstructive lung disease.

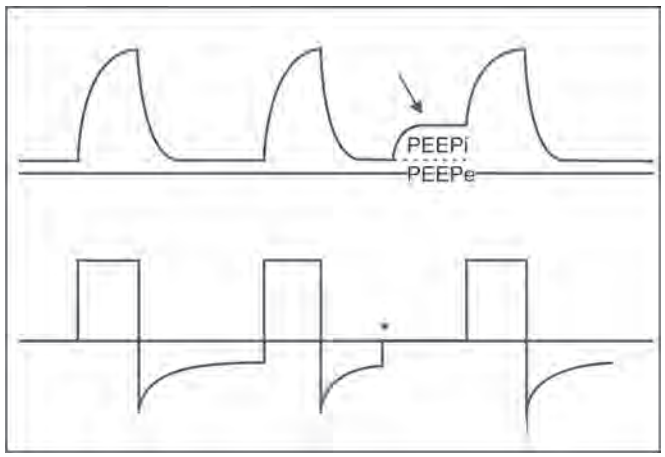
TABLE 3: Complication of intubation and mechanical ventilation.

Intubation	*Mechanical ventilation*
Hypoxemia during intubation	Hemodynamic collapse—decreased venous return
Failed intubation, esophageal intubation, and unilateral intubation	Inability to ventilate—difficult to ventilate situations, e.g., severe exacerbations of asthma and COPD and ARDS
Injury to teeth	Air trapping, auto-PEEP
Hemodynamic response to intubation—hypertension and tachycardia	Pneumothorax
Hemodynamic collapse—secondary to sedatives and positive pressure ventilation	Atelectasis
Injury to trachea, vocal cords	Tube blockage, lung collapse
Bleeding	Accidental extubation
	Decreased renal blood flow



(PEEP: positive end-expiratory pressure; PIP: peak inspiratory pressure; Pplat: plateau pressure)

FIG. 10: *Airway pressures*. This pressure waveform on the ventilator shows time on the X-axis and pressure on the Y-axis. The ventilator must overcome two pressures to deliver a breath, the airway resistive pressure, and the alveolar distending pressure. The starting and ending pressure for each breath will be from the set PEEP.



(PEEP: positive end-expiratory pressure)

FIG. 11: *Air trapping and auto-PEEP*. Air trapping and auto-PEEP can be evaluated with an expiratory hold maneuver. If the expiratory limb of the flow waveform (bottom green) does not return to baseline before the subsequent breath that volume of gas is "trapped" in the lung while the next volume-targeted breath is delivered as seen here. Holding the expiratory valve closed with an expiratory hold maneuver on the ventilator (asterisk) will allow the pressures to equilibrate between the alveoli and the airway opening. This will demonstrate a total PEEP (arrow), with the components being extrinsically set PEEP and the difference between the total PEEP and set PEEP being the intrinsic, or auto-PEEP.

TABLE 4: Causes of high peak pressure.

High peak pressure but normal of low plateau pressure (mechanism involved—increased respiratory system resistance to flow)	*High peak pressure but high plateau pressure*: Mechanism involved (decreased respiratory compliance—increased stiffness of ling)
Causes: • Bronchospasm • Mucous plugging • Obstructed (secretions) or kinked tracheal tube or ventilator tubing • Endobronchial tumors • Extrinsic compression • Foreign body aspiration	*Causes*: • Lung overdistension—dynamic hyperinflation—"breath stacking," auto-PEEP, and right mainstem intubation • Decreased lung compliance—ARDS, edema, fibrosis, collapse, and consolidation • Pleural factors—effusion, tension pneumothorax • External factors—obesity, ascites, burn eschar, supine positioning, and abdominal hypertension

- *Peak pressure alarms* are frequently encountered in patients undergoing mechanical ventilation for obstructive lung disease. These alarms occur when the ventilator senses the peak pressure during a breath going over a preset maximum. In the setting of a high peak pressure with a normal plateau pressure, one might reasonably assume that the alarm is of little consequence, as they are a consequence of airways resistance and not transmitted to the lung parenchyma. However, this is not the case and "alarm" is a bit of a misnomer, as when the pressure threshold is reached for the alarm, the ventilator acts as a pop-off valve and stops delivering the breath, which results in tidal volumes less than the set volume even in volume control modes, sometimes severely decreasing V_E. Peak pressure alarms in an unstable patient should result in disconnection of the ventilator and hand ventilation of the patient. Troubleshooting stable patients is done on the ventilator by first observing the actual delivered tidal volume and then measuring the plateau pressure to develop a differential. Causes of both high peak and plateau pressures are factors that reduce the compliance of the respiratory system, whereas factors that cause increased resistance to airflow elevate only the peak pressure (**Table 4**). If peak pressure alarming persists despite considering this differential and treating the modifiable causes, most importantly auto-PEEP, then the peak pressure alarm setting may be increased, accepting that this may be associated with an increased risk of barotrauma, particularly in cases where respiratory system compliance is reduced. Increasing the peak pressure alarm can be helpful but risks patient harm when done incorrectly, namely when decreased compliance is the cause of the elevated peak pressure (plateau pressure is elevated). All patients on mechanical ventilation should be monitored with continuous waveform capnography. Common ventilator-associated problem and their solution (troubleshooting) is summarized in **Box 2**.

MECHANICAL VENTILATION IN SPECIAL CONDITIONS

Bronchial Asthma

Severe bronchospasm causes longer time constant and severe inhomogeneity of time constant of lung units leading to air trapping. This is also called auto-PEEP. In other words, there is insufficient time for complete inspired air to flow out of the lungs before the next inspiration occurs. This can cause increased intrathoracic pressure and decreased venous return resulting in hemodynamic collapse. So the target of ventilation in such patients should be to minimize air trapping and achieve hemodynamic stability. It can be achieved by providing long expiratory times which can be achieved by the following settings:

f = 8–10 breaths/min;
VT = 4–8 mL/kg;
T_I = ≤1 sec
I:E ratio – 1:4–1:5
Gas flow = 80–100 LPM
PEEP 0–5 cmH_2O (in case severe asthma it should be kept at zero)
Descending flow waveform pattern
P_{plat} <30 cmH_2O

Permissive hypercapnia refers to the strategy of accepting a higher PCO_2 while maintaining a pH > 7.2. It aims to avoid air trapping. If Pplat > 30 cmH_2O and pCO_2 > 90 mm Hg—deeper sedation and/or paralysis should be considered.

Chronic Obstructive Airway Disease

Pressure control-CMV may be ideal for such patients as it provides flow on demand to meet the patient's needs. Basic principle of ventilation is same as in asthma. Aim is to minimize

BOX 2: Troubleshooting in patient on mechanical ventilation.

- *Not able to achieve patient-ventilator synchrony?*
  - Ensure patient is under adequate analgesics and sedation
  - Evaluate ventilator waveforms
  - Administer a neuromuscular blocking agent (NMBA)
  - Consider a pressure-targeted mode
- *Not able to achieve a respiratory rate?*
  - Reduce tidal volume
  - Deepen sedation
  - Consider NMBA
  - Rescue maneuvers—extracorporeal CO_2 removal with ECMO or induced hypothermia
  - Increase inspiratory flow rate/increase peak pressure alarm setting
- *Not able to maintain an adequate pH despite required ventilator settings?*
  - If hemodynamically stable, may consider allowing a lower pH if closely monitored
  - Rescue maneuvers—infusion of a buffer (sodium bicarbonate), extracorporeal CO_2 removal with venovenous ECMO, or induced hypothermia
- *Venous blood gas is not improving, and patient is on noninvasive support*
  - *Increase IPAP*: EPAP gradient if on BiPAP
  - Increase flow if on HFNC
  - Invasive mechanical ventilation (exception: asthmatics)
- *Patient becomes suddenly hypotensive?*
  - Disconnect ventilator and decompress the chest
  - Evaluate for pneumothorax
- *The peak pressure continues to alarm?*
  - Evaluate plateau pressure
  - Low plateau pressure—bronchodilators, pulmonary toilette, eliminate endotracheal tube biting, or obstruction
  - High plateau pressure—evaluate and treat causes of decreased respiratory compliance, particularly dynamic hyperinflation in the context of obstructive lung disease
  - Reduce inspiratory flow if patient factors allow, consider expert consultation, consider increasing peak pressure alarm setting as a last resort

(BiPAP: bi-level positive airway pressure; ECMO: extracorporeal membrane oxygenation; EPAP: expiratory positive airway pressure; HFNC: high-flow nasal cannula; IPAP: inspiratory positive airway pressure)

auto-PEEP or air trapping which occurs because of expiratory flow limitation. Ventilator settings will be similar to those for asthma. Controlled hypoventilation refers to the strategy of ventilation in which we aim a normal pH by targeting patient's baseline PCO_2. When patients are spontaneously breathing and having trouble triggering breaths due to air trapping and auto-PEEP, setting the PEEP at about 75–80% of intrinsic PEEP may make triggering easier.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome patients can be one of the most difficult ones to intubate and ventilate in ER. Intubation has a high risk of hypoxemia during the procedure and ventilating the lungs even after a successful intubation can be a nightmare.

Acute respiratory distress syndrome lungs are poorly compliant and need higher PEEP levels. A lung protective ventilation strategy gives a higher priority to the lung protection compared to the traditional goals of acid base balance. It minimizes mechanical over inflation of lung and lung inflammation or biotrauma. Open lung approach should be followed, which includes using maneuvers to open the collapsed lung, to maintain them in the same state without causing over distension.

Initiate ventilation with FiO_2 100%, RR—15–25 breaths/min, tidal volume 6–8 mL/kg of PBW and a PEEP of 10–15 cmH_2O. TV should be gradually brought down to 6 mL/kg. P_{plat} should be targeted to <30 cmH_2O. I:E ratio should be kept between 1: 2 and 1: 1.5.

Later the PEEP may need to be titrated to find the optimum PEEP. It is the PEEP level which optimizes oxygenation while having the least detrimental effect on hemodynamics, oxygen delivery, and airway pressures. It has also been defined as the level of PEEP at which the static compliance is highest. There are a number of strategies to find optimum PEEP. These methods most commonly consist of using a $PEEP/FiO_2$ table aimed at providing acceptable oxygenation, titrating PEEP to reach a maximal compliance using stress index, or a decremental PEEP approach. Recruitment maneuvers refer to a strategy of ventilation which involves transient application higher transpulmonary pressures to open previously atelectatic alveoli. Several methods have been described, the most commonly used of which is a sustained inflation breath; e.g., CPAP of 40 cmH_2O for 40 seconds. Another method is a stepwise increase in PEEP accompanied by low levels of pressure control ventilation. The best recruitment technique is still unknown and may be according to specific circumstance. It is worth remembering although P_{plat} target of <30 cmH_2O is accepted as a rule, but patients who are obese or have ascites or abdominal distension may need higher P_{plat}.

Severe Acute Respiratory Syndrome (SARS-CoV-2 COVID-19)

Once the decision is taken to intubate the patient, full personal protective equipment (PPE that at minimum includes an N95 mask, protective eye wear, fluid impervious gowns, and gloves) should be used to perform the intubation by most experienced physician. Preferably use video laryngoscopy if available. Surviving Sepsis Campaign recommendation and ventilator strategy for ARDS (tidal volumes of 4–8 mL/kg of predicted body weight; higher PEEP strategy), are used in SARS-CoV-2 COVID-19 patient also. Gattinoni et al., have observed on the basis of small cohort of patients that there are two primary groups of patient in this scenario—(1) L-type with low elastance (normal compliance), low lung weight, and low lung recruitability; and (2) H-type with high elastance (low compliance), high lung weight, and high lung recruitability. Thus, the respiratory management and ventilatory strategies in these two patient types will be different. L-type patients are more likely to respond to nasal cannula (NC), high-flow nasal cannula (HFNC), and noninvasive positive pressure ventilation (NIPPV) than H-type patients. H-type patients should be approached as in a traditional severe ARDS scenario where one would be treated with an escalating PEEP strategy. It

is important to note that the observations from Gattinoni et al., are based on small studies thus larger studies are required for better understanding of heterogeneous COVID-19 pulmonary syndrome (**Flowchart 1**).

Head Trauma

Head trauma patients may have an increased intracranial blood volume or elevated intracranial pressure (ICP). Such patients need intubation and mechanical ventilation for either poor sensorium or decreased respiratory drive. The aim is to provide sufficient ventilation to keep pCO_2 in normal range. Higher pCO_2 can cause cerebral vasodilatation leading to increase in ICP. However, higher intrathoracic pressure must be avoided as they may be transmitted to the brain causing elevation of ICP. So PEEP should be judiciously used.

Pregnant Patient

Pregnancy results in a number of physiologic changes that have a direct bearing on the ventilatory strategy. Important changes which must be remembered are:

- Increased metabolic rate
- Increased V_E
- Respiratory alkalosis (pCO_2 about 30 mm Hg)
- Reduced chest wall compliance
- Mucosal edema and increased vascularity
- Increased intra-abdominal pressure

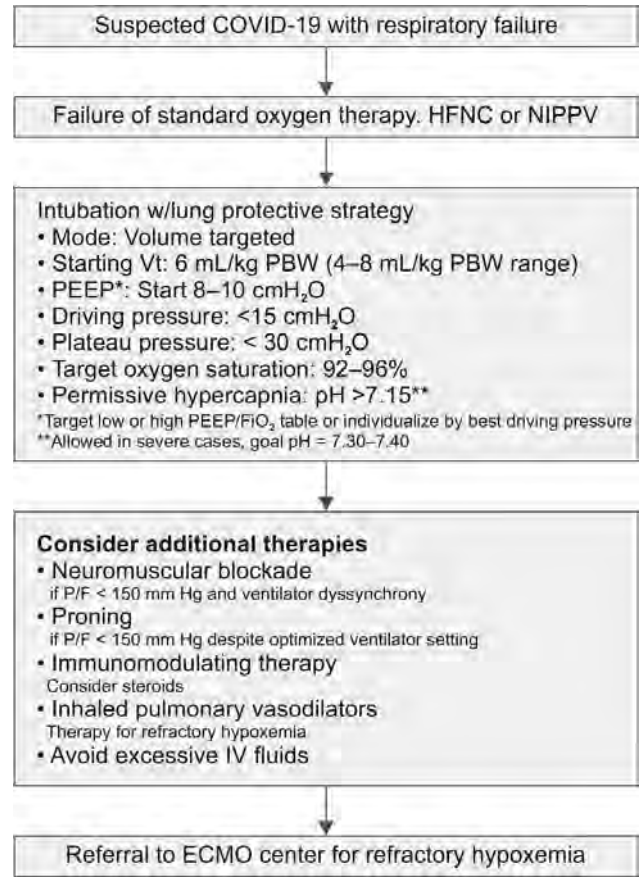
Therefore, in the pregnant mechanically ventilated patient, the minute volume setting should be adjusted to a pCO_2 target between 28 and 32 mm Hg. Higher peak airway pressures may be acceptable due to reduced chest wall compliance. Smaller diameter endotracheal tubes should be used. A rapid sequence intubation is mandatory in view of apparent full stomach and high risk of pulmonary aspiration. Long-acting sedative agents should not be used if delivery is imminent, as they may depress the fetus.

Transporting Intubated Patients

Patients need to be shifted to ICU after initial resuscitation. Some patients may be directly shifted to the operating room; some may require a radiologic procedure such as CT scan or MRI before shifting to ICU. Although transporting any critically ill patient involves risk, but patients on vasopressors, ARDS patients and those who have difficult airway have a much higher risk of adverse events.

Manual resuscitators are still used frequently in the transport of patients from ER. However, alteration in patient's respiratory status occurs frequently when manual resuscitators are used for transportation as compared to the transport ventilators. So a transport ventilator is recommended in such a case because it provides stable V_E and also frees the caregiver to perform other tasks. Adverse events include but are not limited to incorrect measurement of vitals, arrhythmias, hypotension, hypertension, increased ICP, endotracheal tube blockage, loss of airway, and cardiac arrest. Following points should be remembered:

- There should be a written protocol and a dedicated transport team.



Suspected COVID-19 with respiratory failure
Failure of standard oxygen therapy. HFNC or NIPPV
Intubation w/lung protective strategy
• Mode: Volume targeted
• Starting Vt: 6 mL/kg PBW (4–8 mL/kg PBW range)
• PEEP*: Start 8–10 cmH2O
• Driving pressure: <15 cmH2O
• Plateau pressure: < 30 cmH2O
• Target oxygen saturation: 92–96%
• Permissive hypercapnia: pH >7.15**
*Target low or high PEEP/FiO2 table or individualize by best driving pressure
**Allowed in severe cases, goal pH = 7.30–7.40
Consider additional therapies
• Neuromuscular blockade
if P/F < 150 mm Hg and ventilator dyssynchrony
• Proning
if P/F < 150 mm Hg despite optimized ventilator setting
• Immunomodulating therapy
Consider steroids
• Inhaled pulmonary vasodilators
Therapy for refractory hypoxemia
• Avoid excessive IV fluids
Referral to ECMO center for refractory hypoxemia

FLOWCHART 1: Ventilatory support strategy for COVID-19 patient.

- Transport ventilator should be preferred to a manual resuscitator.
- Monitoring during transport should include cardiac monitor [including electrocardiogram (ECG), blood pressure (BP) monitoring, pulse oximetry, and end-tidal CO_2 ($etCO_2$) monitoring] with defibrillating capacity. Other equipment should include airway management equipment, oxygen supplies, resuscitation drugs, and intravenous fluids.
- If patient is to be shifted to MRI suite, it must be ensured that the ventilator, gas hoses that plug into wall outlets and syringe pumps are MRI compatible.

SUMMARY

Prompt evaluation of patients presenting to ER should identify those who may need intubation and mechanical ventilation. Ensure patient comfort and safety. Constant vigilance is required after intubation and setting ventilator. Blood gas analysis should be performed to confirm effective ventilation. Avoid fall in blood pressure and immediately treat if occurs. Sudden drastic change in measured ventilatory or hemodynamic parameters should prompt evaluation for life-threatening conditions and assessment of the ventilator settings.

40 CHAPTER

Sedation and Analgesics for Mechanically Ventilated Patients

Manish Garg, Devendra Richhariya

INTRODUCTION

Patients are now spending more and more time in emergency department (ED) due to nonavailability critical care bed. Emergency physicians are now taking care of mechanically ventilated patients more often for and longer periods of time. Problem such as pain, agitation, and anxiety is commonly associated with mechanically ventilated patient. A systematic approach is required for delivering sedation and analgesia in mechanically ventilated patient including goals, specific medication target, specific situation, and other methods such as retrain other than pharmacological management.

After the rapid sequence intubation (RSI), pharmacologic management avoids discomfort during paralysis. Pain is treated aggressively with objective scoring system is used for its assessment. If possible, lighter sedation is the first choice over the deep sedation. As mechanically ventilated patients are being managed in emergency for longer period of time, standard assessment and medication protocol are best practices for ED.

GOALS AND PRINCIPLES

Significant discomfort and anxiety related to their care is prime concern in critically ill-ventilated patient. Initially goal should be mild sedation with lowest possible dose to address any specific need with patient safety. Deep sedation is independent factor for mortality in mechanically ventilated patient in ED and critical care unit. Various painful procedures are required to perform in critically ill patient such as endotracheal intubation, invasive procedures such as central and arterial line insertion, and routine care of decubitus ulcer. Adequate pharmacologic management for analgosedation (prophylactic analgesia) is instituted before performing the procedure. Patients are also in discomfort and agitated because not able to communicate, and posttraumatic disorder. "Analgesia first or only analgesia "is the best policy to start with, further analgesia dose is titrated according to pain assessment tool. In spite of the adequate analgesic, if patient remains agitated or anxious, sedation is used.

Timing of Medications

The short-acting sedative medications are used for RSI. Therefore, management of symptom starts immediately with adequate sedation following intubation. Then administering *fentanyl,* a *minimum of a 50–100 μg bolus intravenous (IV)* immediately after intubation is recommended who receives longer-acting paralytics (**Flowchart 1**).

Qualities of Ideal Medications

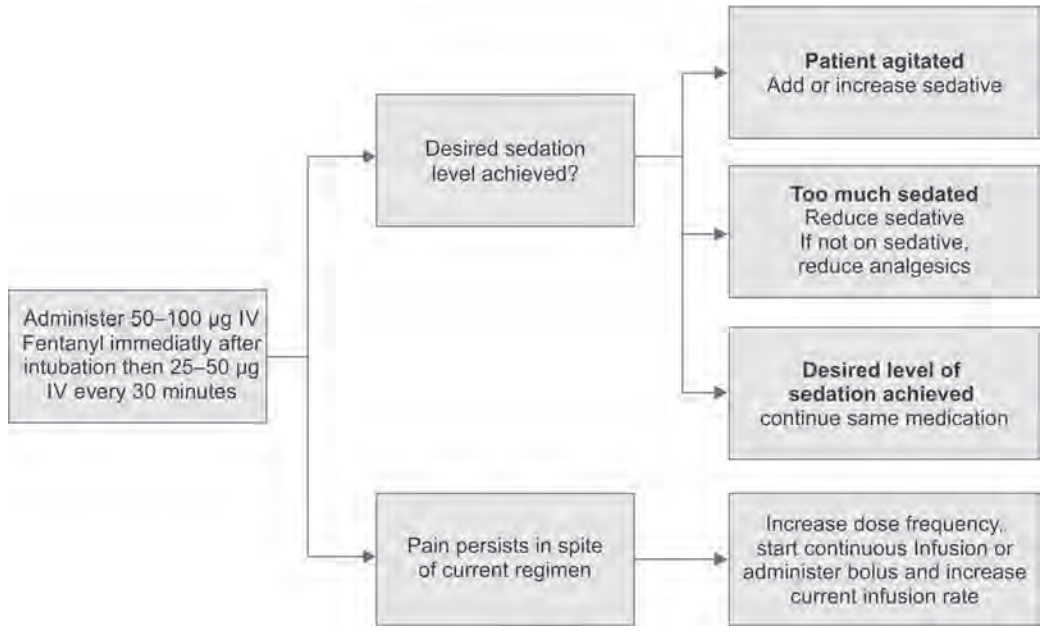
- Rapid onset
- Short-acting
- Adequately controls the symptoms
- No immediate or late adverse effects

Unfortunately, no ideal medication presents. Medications are typically divided into two classes first for analgesia and second those for sedation, as discussed earlier in this chapter our goal is to control the pain first to address agitation and anxiety.

MEDICATIONS

Analgesia

For mechanically ventilated patients, opiates remain the first choice of pain management. Fentanyl, hydromorphone, morphine, and remifentanil are common intravenous agents. Fentanyl or hydromorphone is well tolerated but other factors such as patient factors, pharmacokinetic profile, cost, and institutional availability play an important role while choosing the agent**.** Various analgesic agents and their doses are summarized in **Table 1**. Intermittent dosing or infusion dosing is depending on the patient's need and requirement and based on validated pain assessment score. But general policy is to start analgesics with intermittent doses and then escalating it to a continuous infusion. Opiates are important as pain management therapy in mechanically ventilated patient but because of side-effect profile other common adjuncts can also be used to reduce the opioids requirement,



Administer 50–100 µg IV Fentanyl immediatly after intubation then 25–50 µg IV every 30 minutes
Desired sedation level achieved?
Patient agitated
Add or increase sedative
Too much sedated
Reduce sedative
If not on sedative, reduce analgesics
Desired level of sedation achieved
continue same medication
Pain persists in spite of current regimen
Increase dose frequency, start continuous Infusion or administer bolus and increase current infusion rate

FLOWCHART 1: Basic algorithm for management of sedation and analgesia in a mechanically ventilated patient in emergency department.

TABLE 1: Common opioids analgesic for mechanically ventilated patients.

Medication	*Bolus/intermittent dose*	*Infusion dose*	*Comments*
Fentanyl	0.35–0.5 µg/kg intravenous every 0.5–1 h (50–100 mg boluses are typically well tolerated)	0.7–10 µg/kg/h (infusions >200–300 mg/h are generally not required)	*Onset of action*: 1–2 min, half-life 2–4 h, consider as first-line agent. Relatively hemodynamically stable Accumulates if hepatic impairment
Remifentanil	–	*Loading dose*: 1.5 µg/kg IV Maintenance dose: 0.5–15 µg/kg/h IV	Onset of action 1–3 min Half-life 3–10 min, does not accumulate with renal or hepatic impairment
Morphine	2–4 mg IV every 1–2 h	2–30 mg/h	Onset of action 5–10 min, half-life 3–4 h Not recommended in patients with renal impairment or as first-line agent
Hydromorphone	0.2–0.6 mg IV every 1–2 h	0.5–3 mg/h	Onset of action 5–15 min, half-life 2–3 h Consider as first-line agent, can accumulate with renal/hepatic impairment

e.g., acetaminophen, ketamine, and neuropathic agents (gabapentin, pregabalin and carbamazepine).

Sedation

In most of the patients, pain can be controlled by analgesic alone and few patients require sedative medication because they experience anxiety and agitation despite adequate pain medication. There are various sedatives available for acute episodes of anxiety and agitation and can be used as bolus as well as continuous infusion (**Table 2**). Benzodiazepines (e.g., lorazepam or midazolam) is used as infusion but associated with prolonged effects of delirium and adverse outcome in critically ill patient so benzodiazepine is not a first choice of agent. Propofol or dexmedetomidine is used as first-line agents in critically ill and mechanically ventilated patients according to recommendations. Recommendations are based on literature which concludes that propofol takes shorter times to achieve light sedation and shorter times to extubation in comparison to benzodiazepines, and shorter times to extubation and reduced delirium with dexmedetomidine in comparison to benzodiazepines. Comparison of the clinical outcomes of propofol with dexmedetomidine is limited and superiority to one another need to be further investigated. Dexmedetomidine poses lower risk of delirium and may be more cost-effective when compared with other sedatives.

In mechanically ventilated critically ill patients, ketamine is not commonly used as a continuous sedative but is an option for use as an adjunct or as single agent for symptoms that are difficult to control. On the basis of clinical scenario, desired level of sedation is achieved.As discussed earlier, deep sedation is directly related to prolonged mechanical ventilation and increased mortality, but in some clinical scenario such as acute respiratory distress syndrome, deeper levels of sedation are achieved during pharmacologic paralysis.

TABLE 2: Common medications for sedation in mechanically ventilated patient.

Medications	*Bolus dose*	*Infusion dose*	*Comments*
Propofol	5 µg/kg/min over 5 min	5–50 µg/kg/min	Onset of action in 1–2 min, half-life 3–12 h Consider as first-line agent Can cause respiratory depression, hypotension, hypertriglyceridemia, and propofol infusion syndrome
Midazolam	0.01–0.05 mg/kg loading over several minutes	0.02–0.1 mg/kg/h	Onset of action in 2–5 min, half-life 3–12 h Can cause respiratory depression and hypotension
Ketamine	0.5–1 mg/kg over 1–2 min	1–2 µg/kg/min titrating up as needed to 10–20 µg/kg/min	Onset of action <5 min Half-life α-15 min β-300 min Also has analgesic effect
Dexmedetomidine	1 µg/kg over 10 min	0.2–1.5 µg/kg/h	Onset of action 5–10 min Half-life 2–3 h Can cause bradycardia and hypotension Should not be used for deep sedation or continuous paralysis is needed Otherwise consider as first-line agent

TABLE 3: Pain-scoring scales for intubated patients.

Critical Care Pain Observation Tools (CPOT)			*Behavioral Pain Scale (BPS)*		
Facial expression	Neutral	0	Facial expression	Relaxed	1
	Tense	1		Partially tight	2
	Grimacing	2		Fully tight	3
				Grimacing	4
Body movement	Absent	0	Upper limb movement	No movement	1
	Protective	1		Partially bent	2
	Restless	2		Fully bent	3
				Permanently retracted	4
Muscle tension	Relaxed	0	Compliance with mechanical ventilation	Tolerating	1
	Tense	1		Coughing but tolerating	2
	Very Rigid	2		Fighting	3
				Unable to control	4
CPOT- Evaluation of pain in patients who are unable to report it. *CPOT score ≤ 2 minimal/no pain* *CPOT score ≥ 2 unacceptable pain, add analgesic sedation*			BPS is used to assess pain in intubated patient		

ASSESSMENT

Frequent reassessment of patient is required of mechanically ventilated patient on continuous analgesic and sedative infusion. During ED stay, their requirement of doses may change and doses need to be adjusted because under-dose or overuse of these medications can adversely affect the outcome of the patient. The tools used for monitoring the patient on analgesics and sedation are pain-scoring scale and sedation-scoring scales. These tools are vital to managing critically ill patients.

Pain-scoring Scales

Pain scales which are used to assess the mechanically ventilated critically ill patient are based on nonverbal factors such as body movement, facial expressions, and compliance with the ventilator because these patients are unable to communicate effectively and cannot self-report pain. The *Critical Care Pain Observation Tool (CPOT*) and the *Behavioral Pain Scale (BPS)* are two most commonly recommended scores, are used for this challenging task (**Table 3**). These scales use nonverbal parameters to determine the need for analgesia, are simple to use, widely recommended in current guidelines.

Sedation Scoring

In most critically ill mechanically ventilated patients, the goal for sedation is to achieve a state whereby the patient is spontaneously alert and arousable or can be aroused with verbal stimuli. *Richmond Agitation–Sedation Scale (RASS)* (**Table 4**) *and the Riker Sedation–Agitation Scale* are most

TABLE 4: Richmond Agitation–Sedation Scale (RASS).		
Description of patient	Combative	+ 4
	Very agitative	+ 3
	Agitative	+ 2
	Restless	+ 1
	Alert and calm	0
	Drowsy	– 1
	Mild sedation	– 2
	Moderate sedation	– 3
	Deep sedation	– 4
	Unarousable sedation	– 5
Patients with a RASS of -3 or less should have their sedation decreased or modified in order to achieve a RASS of -2–0. Patients with a RASS of 2–4 are not sedated enough and should be assessed for pain, anxiety, or delirium. The underlying etiology of the agitation should be investigated and appropriately treated to achieve a RASS of -2–0. A RASS score should be obtained on all hospitalized patients and at regular interval in all mechanically ventilated patients. Unless a patient meets indication for deep sedation, a protocol for minimal sedation (RASS -2–0) should be used		

commonly used and helpful to standardize the level of a patient's consciousness. Sedation-scoring scales are also helpful to standardize communication between healthcare workers and specify targets for medication titration.

Protocol for Minimizing the Sedation and Analgesia

There are no prospectively validated protocols specifically for analgesics and sedation administration for ED. Therefore, multidisciplinary approach is adopted in which ED team, nursing team, and critical care team should formulate a uniform protocol for ED, similar to ICU which promotes simplicity and uniformity in the sedation and analgesia goals for critically ill patients.

Many strategies can be applied to minimize the risk of over-sedation, commonly used strategy is the daily interruption of sedation in which turning off continuous infusions of analgesia and sedatives at specific times and allowing the patient to wake up, as soon as patient becomes uncomfortable, these infusions can be restarted at the lower rates. Daily interruption of sedation and patient assessment enable us to know lowest possible doses of medications are required for a desired level of sedation. Careful observation by nurses and staff is required with daily interruption of because there is an increased risk of self-extubation and self-harm by the patient. In another strategy, nurses are allowed to administer medications intermittently and keep the patients at specific sedation preferably targeting the light sedation without the need to fully wake.

Light sedation can be achieved for patients who are mechanically ventilated by either method**.** As in many ED settings, awakening trials are unlikely to be practical, use of a nurse-driven protocol targeting light sedation on mechanically ventilated patients in the ED can recommended.

SPECIAL SITUATIONS

Hypotension with Sedation

Common problem in mechanically ventilated patients is hypotension. Hypotension can be due to various reasons such as patient pathology, positive pressure ventilation, and medications. Many medications commonly used for pain and sedation also contribute to exaggerate hypotension. A stepwise approach is recommended for patient on mechanical ventilation and on sedation. Before evaluating and addressing other life-threatening causes do not assume that a patient's hemodynamic insult is medication related.

- First step is to check whether the patient is fully resuscitated or management is fully instituted for original pathology. If patients need further escalation of therapy of the original condition (e.g., additional blood product resuscitation in hemorrhagic shock), it needs to be corrected.
- Reduce dose or discontinue sedative/or analgesic, if the patient's level of sedation is achieved or no clinical evidence of pain. Patients who are in pain or agitated continue appropriate analgesic and sedation and support hemodynamic further resuscitation.

Persistently Agitated Patient

A few patients create danger to both to themselves and to staff and are challenging to manage because they remain continuously agitated despite adequate pain management and sedation. The causes for these situations can be high medication tolerance (opioid dependence), delirium, acute substance use or withdrawal, psychiatric illness, and preexisting cognitive impairment.

Underlying cause of the patient's agitation (e.g., persistent pain, alcohol withdrawal, and head injury) needs aggressive treatment. Acute severe symptoms can be treated with one-time bolus dose before titrating the infusion rate**.** Adding an additional sedative agent or alternative agent is an option if required (e.g., ketamine). In severely agitated patients who are not intubated, adding an antipsychotic can be considered. Benzodiazepines should be avoided, as it can worsen agitation.

Paralyzed Patient

For initiation of deep sedation boluses of 250 μg/kg propofol and 1 mg of hydromorphone followed by continuous infusion rates of 20 μ/kg/min and 1 mg/h, respectively. Once a patient is no longer paralyzed, light sedation should again be targeted whenever possible. Analgesic and sedative drugs should be continuously administered with the goal of deep sedation until the paralytic is withdrawn and an assessment can be made as traditional pain-scoring systems cannot be performed in these patients.

Status Epilepticus

Status epilepticus (SE) patient is often intubated and deeply sedated for airway protection and additional antiepileptic therapy is started, if refractory to existing antiepileptic medi-

cations. Neurocritical Care Society (NCS) suggests continuous infusion of antiepileptic drugs such as midazolam, propofol, or pentobarbital till clinical or electroencephalograph (EEG) evidence of cessation of seizures (titrating to continuous EEG).

Physical Restraints

The decision to use physical restraint (PR) is debatable and varies, mostly depends on patient and staff-specific factors and only be used as a bridge to adequate chemical restraints. PRs are often used to prevent patients from removing essential devices, inflicting self-harm, unplanned extubation, musculoskeletal injuries, psychological trauma, and also preventing staff from injuries. The need for their use should be continuously reassessed and they should be removed once it is safe to do so.

SUMMARY

Significant pain and anxiety are associated with mechanically ventilated patients and associated various procedures with their care. A systematic approach is applied to treat these symptoms in aggressive manner. Appropriate analgesics and sedation started immediately following intubation. Aggressive treatment is required for pain, use medications for sedation as a supplement to achieve adequate analgesia, not as a substitute for it. Use objective scoring systems to frequently assess patients' levels of pain and sedation and adjust medications based on these assessments. Whenever possible, target lighter levels of sedation over deep sedation aim to standardize patient assessment and medication protocols across the ED and ICU.

Extubation in Emergency Department

41 CHAPTER

Joanne Hng Mei Hwa, Ahmad Zulkarnain Ahmad Zahedi

INTRODUCTION

Emergency medicine specialty has been managing airway and becoming adept at inserting an endotracheal tube for definitive airway. The common goal is to safely protect the airway while maintaining adequate oxygenation and ventilation until the underlying disease process is reversed. Most guidelines have focused on intubation, with little to guide the process of weaning from mechanical ventilation and extubation. The rate of critically ill patients requiring intubation in emergency department (ED) is rising and limited intensive care unit (ICU) resources prolong their stay in ED. Some patients' clinical conditions improve during their extended stay in ED and emergency physicians infrequently encounter a dynamic clinical decision-making as a result. Nevertheless, there are no available studies which published algorithms or guidelines in assessing patients for possible extubation in ED. Moreover, the extubation protocols may vary according to local settings and needs. This chapter aims to provide an understanding in depth, safe and practical approach on extubation in ED and resuscitation unit.

PATIENT SELECTION AND THE "ABC" PROCEDURAL CONSIDERATION

Patient Selection

Resolution of the initial indication for intubation and its process is important. The first consideration for ED extubation is complete resolution of underlying conditions for which the invasive mechanical ventilation is started. Clinician should be aware of initial indication of the mechanical ventilation otherwise extubation failure may occur. There should be no documented airway trauma, challenging airway, or complicated at initial intubation. Clinician has to make sure that no other anticipated factors which will require continuous mechanical ventilation, e.g., intracranial pathologies (severe brain injury and brainstem stroke), cervical spine instability or injury**,** acute airway trauma**,** acute lung injury, plan for imminent emergency procedure, surgery, or interfacility transfer and transport**.** Intoxication, drug overdose, clinical emergency procedure requiring procedural sedation analgesia (i.e. endoscopy), traumatic brain injury with improving mental status, and a negative CT and palliative extubation are the common indications in which extubation can be considered (**Fig. 1**).

Airway Patency Assessment: Ability to Maintain Airway Patency

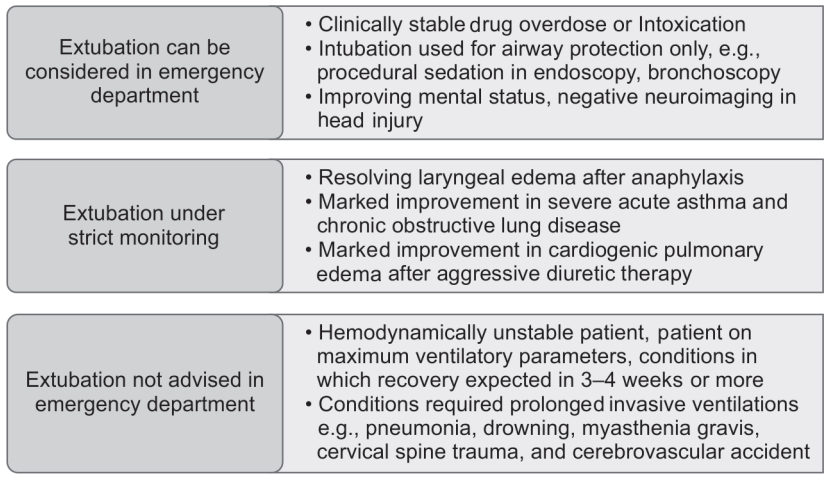
The paramount of maintaining a patent airway is the ability to cough with the clearance of secretions adequately and effectively. One of the independent clinical variables, predicted reintubation is copious amount of endotracheal secretion. The patient should be assessed by the ability to lift his or her head off the bed and produce a strong cough before extubation is conducted. Moreover, the patient should not have any known or documented glottic swelling, upper airway obstruction, or any difficult laryngoscopic intubation at the initial ED or prehospital care (PHC) airway management.

Pulmonary and Breathing Assessment: Patient Able to Maintain on a Minimal Ventilator Setting

The clinical respiratory parameters of adequate oxygenation are defined as oxygen saturation > 92% and PaO_2 > 70 mm Hg, with adequate ventilation defined as $PaCO_2$ 38–42 mm Hg. A patient is stratified as low risk for extubation failure, if he or she could oxygenate and ventilate on low ventilatory settings, either with continuous positive airway pressure (CPAP) alone or with minimal pressure support (PS). As a guide, a patient with spontaneous breathing should generally be able to produce a ≥5 mL/kg ideal body weight of tidal volume on CPAP or minimal PS, as well as an adequate oxygenation with a fraction of inspired oxygen (FiO_2) <40% with a positive end-expiratory pressure (PEEP) ≤8. Precise critical decision on the timeliness of extubation is important owing to the complications of a failed extubation.

Spontaneous Breathing Trial

Spontaneous breathing trial (SBT) can be a very helpful approach to early and successful ventilator liberation, in



Extubation can be considered in emergency department
• Clinically stable drug overdose or Intoxication
• Intubation used for airway protection only, e.g., procedural sedation in endoscopy, bronchoscopy
• Improving mental status, negative neuroimaging in head injury
Extubation under strict monitoring
• Resolving laryngeal edema after anaphylaxis
• Marked improvement in severe acute asthma and chronic obstructive lung disease
• Marked improvement in cardiogenic pulmonary edema after aggressive diuretic therapy
Extubation not advised in emergency department
• Hemodynamically unstable patient, patient on maximum ventilatory parameters, conditions in which recovery expected in 3–4 weeks or more
• Conditions required prolonged invasive ventilations e.g., pneumonia, drowning, myasthenia gravis, cervical spine trauma, and cerebrovascular accident

FIG. 1: Indications/contraindications for emergency department extubation.

patients intubated initially for underlying cardiopulmonary pathologies. There are three potential ventilator setting (**Box 1**) options for SBT described as follows:

Pressure support SBT is the recommended screening method for extubation readiness in current extubation guidelines by the CHEST and American Thoracic Society, comparing to the other two options which are less sensitive, especially in patients who have been mechanically ventilated for >24 hours.

Nwakanma and colleagues advocated the use of a low PS or CPAP—only approaches for ED extubation and the duration of the trial between 30 and 120 minutes. In addition to, a set of predictors of a successful SBT was extracted from the study conducted in ED by *Weingart and colleagues as below* (**Box 2**).

Another dynamic assessment that can be measured during an SBT to determine extubation preparedness is known as the *rapid shallow breathing index (RSBI*). RSBI is defined as respiratory rate (breaths per minutes) divided by tidal volume (L). A high RSBI indicates the patient's inability to tolerate independent breathing. Whereas a lower RSBI cut-off indicates an optimal breathing and the latter is more specific inpatient selection, hence potentially reduces the risk of extubating patient with borderline parameters. In ED setting, an RSBI of <75 breaths/min/L using the PS or CPAP SBT only approach is recommended.

Reintubation represents a major setback that is not only psychologically discouraging to patients, but also associated with morbidity and mortality. Therefore, extubation evaluation should be a holistic assessment which consists of patient's general clinical conditions, ability to manage secretions, respiratory effort, work of breathing, and hemodynamic and neurological status. Arterial blood gas may be a helpful adjunct, but it should not be solely relied on. Whenever there is hindrance, extubation should not be done in ED but deferred to ICU.

BOX 1: Suggested ventilator setting for spontaneous breathing trial.

- Pressure support spontaneous breathing trial with 5 cmH_2O pressure support and a positive end-expiratory pressure (PEEP) of ≤5 cmH_2O to overcome the resistance of the endotracheal tube
- Only continuous positive airway pressure with PEEP ≤ 5cmH_2O
- T-piece trial with supplemental oxygen only via the endotracheal tube

BOX 2: Parameters suggestive of successful spontaneous breathing trial.

- Respiratory rate between 8 and 30 breaths/min
- Oxygen saturation >92%, PaO_2 > 70 mm Hg (on FiO_2 <0.4 and PEEP ≤8 cmH_2O)
- Heart rate between 60 and 140 beats/min
- Systolic blood pressure between 90 and 200 mm Hg, or <20% change from baseline systolic blood pressure
- Spontaneous tidal volume >5 mL/kg ideal body weight
- No signs of increased work of breathing, severe anxiety, or altered mental status

(FiO_2: fraction of inspired oxygen; PaO_2: partial pressure of oxygen; PEEP: positive end-expiratory pressure)

Cardiovascular Assessment: Stability of Circulatory/Hemodynamic Parameters

Weaning-induced pulmonary edema is a well-recognized cause for extubation failure. Main risk factors include chronic obstructive lung disease, structural cardiomyopathy (dilated/hypertrophied cardiomyopathy and valvular heart disease), reduced ejection fraction left ventricular failure, and obesity.

The readiness for extubation is crucially determined by the hemodynamic stability of the patient. The patient should be liberated from the administration of inotropes or vasopressors prior to extubation. The following are proposed criteria for hemodynamic stability (**Box 3**).

Neurological Assessment: Ability to Follow Commands with Full Consciousness

It is important to ensure that the patient is fully awake and is breathing independently before an extubation is done. Patient should be allowed adequate time to regain full conscious level, while sedation is slowly weaned or tapered down. The patient

BOX 3: Hemodynamic parameter (stable) suggestive for extubation.

- Oxygen saturation > 92% (on FiO_2 < 0.4)
- Respiratory rate < 30 breaths/min
- Heart rate < 100 bpm
- Systolic blood pressure > 90 mm Hg unsupported by vasopressors
- No ongoing cardiac ischemia or unstable cardiac arrhythmia

may experience discomfort, anxiety, agitation, or restlessness when sedation is discontinued. Dexmedetomidine (DMT) may be used to ease the patient and facilitate the extubation process. It is an excellent anxiolytic agent which has an onset of therapeutic effect in 15–40 minutes, without affecting the patient's respiratory drive and effort. Nevertheless, it is crucial for the attending physician to be certain that the patient's agitation is not due to hypoxic respiratory distress or cardiovascular derangement. This can be done either by a spontaneous achieved normal or high tidal volume in a patient, or a point of care arterial blood gas. A clinically tachypneic patient with ventilatory insufficiency will have a normal or high PCO_2, whereas a low PCO_2 and respiratory alkalosis may be associated with agitation. A neurological examination should be done and documented once the patient is fully awake and follows commands. The patient should always be asked to lift his or her head during neurological assessment, or to raise his or her arm in the air for 15 seconds to elicit strength and to ensure the remaining effect of neuromuscular blocking agents is not present.

POSTEXTUBATION COMPLICATIONS AND MANAGEMENT

Postextubation Cardiopulmonary Dysfunction

Postextubation cardiopulmonary dysfunction is a known complication occurred during the transition from positive pressure to negative pressure of ventilation, resulting in an increased left ventricular transmural pressure, afterload, postextubation hypoxemia, myocardial ischemia, life-threatening arrhythmias, subsequent risk of reintubation, and poor outcome. Clinical presentations are similar to acute cardiogenic pulmonary edema, which include tachypnea, increased work of breathing, hyperdynamic responses, and progressive hypoxemic respiratory failure. Point-of-care lung ultrasound will demonstrate new B-lines to suggest "wet lungs". Noninvasive ventilation (NIV) and intravenous nitroglycerine remain the mainstays of acute management. Diuretics may also be helpful in fluid removal. Critical decision to reintubate a patient who has failed to tolerate NIV or rapidly deteriorates despite aggressive medical interventions, should be prompt.

Postextubation Hypoxemia

Further ventilation-perfusion mismatch and impaired gas exchange are contributed by increased airway resistance, shunt, derecruitment and atelectasis, and worsen postextubation hypoxemia. A prospective study conducted by Soummer and colleagues had demonstrated the use of lung ultrasound as a predictive tool for postextubation distress after a successful SBT. A higher incidence of development of B-lines or consolidation on lung ultrasound was found in >30% of the studied cohort who developed postextubation respiratory distress.

Additionally, two randomized clinical trials on post-extubation high-flow nasal cannula (HFNC) had demonstrated its potential benefits in reducing reintubation rate in patients with postextubation hypoxemic respiratory failure safely and effectively.

Postextubation Stridor

Postextubation stridor is defined as the presence of inspiratory noise following extubation and it indicates >50% narrowing of the airway passage, which commonly occurs at the glottic and infraglottic anatomical sites. Laryngeal edema is frequently caused by endotracheal intubation where the endotracheal tube abuts the trachea, and it usually occurs after 36 hours postintubation. This can then result in postextubation stridor and respiratory failure with subsequent reintubation that is associated with high morbidity and mortality. Therefore, the documentation of preexisting laryngeal edema, airway trauma, difficult, or multiple intubation attempts is crucial before an extubation is proceeded. Several tests have been evaluated for the assessment of airway patency before extubation and the identification of patients at potential risks for postextubation laryngeal edema. These tests include the cuff leak test (CLT) and airway ultrasonography.

The CLT is a noninvasive and easy to perform method to predict postextubation stridor. The measurement of the cuff leak volume in a mechanical-ventilated patient is the difference between the inspiratory tidal volume before the endotracheal tube cuff is deflated and the averaged expiratory tidal volume, on volume control intermittent mandatory ventilation (IMV). The tidal volume should temporarily be titrated up to 8–10 mL/kg ideal body weight when the patient is on volume control IMV, in order to correctly demonstrate the presence of a cuff leak. The measured cuff leak can be either an audible leak or volume loss >24% tidal volume by approximation, and this volume of air leak should be >110 mL. The associated risk of postextubation stridor and respiratory distress secondary to laryngeal edema is increased with small (volume <110 mL) or absent cuff leak. Hence, the administration of intravenous glucocorticoid treatment (intravenous methylprednisolone 40–125 mg every 6–8 h; or intravenous dexamethasone 5 mg every 6 h) and nebulized epinephrine (5–10 mL of undiluted 1:10,000 0.1 mg/mL; or 0.5 mL of a 2.25% racemic epinephrine diluted in a 2–4 mL volume) may help to reduce the laryngeal swelling and subsequent postextubation stridor. It is also important to note that a negative CLT can occur with a relatively oversized endotracheal tube to patient's trachea, or the secretion around the deflated endotracheal tube cuff. Unfortunately, even patients with low-risk factors for postextubation laryngeal edema which include absence of traumatic or difficult intubation, use of small endotracheal tube size, low cuff pressure, and duration of intubation of <6 days, may still experience severe respiratory distress or postextubation stridor and hence potential reintubation.

The airway patency may also be assessed using ultrasonography. The difference of air column width at the level of the vocal cords between pre- and postendotracheal cuff deflation can be measured. A lower air column width difference and air column width during endotracheal cuff deflation were

found in patients who developed postextubation stridor in the studies by Ding et al., and Sutherasan et al., respectively.

Postextubation Agitation and Delirium

Agitation and delirium are two common entities in critically ill patients and the causes can either be an underlying pathological condition or secondary to intubation or sedative agents, occur during weaning process. Delirium is an organic dysfunction with complex pathophysiology, including inflammatory response to neuronal injury, hormonal influences, alterations in neurotransmission, and neural network connectivity. The hallmark of delirium is alteration of mental status and its course of fluctuation, with impaired cognitive function. The patient mostly presents as hypoactive and infrequently hyperactive or mixed delirium. In the ICU, patients with delirium are often associated with prolonged mechanical ventilation, prolonged length of hospitalization, and increased risk of mortality. Whereas in the ED, acute delirium is often due to the underlying presenting illness. Therefore, the decision for extubation should be carefully considered.

PALLIATIVE EXTUBATION IN EMERGENCY DEPARTMENT

Palliative extubation is an intentional withdrawal of mechanical ventilation support to liberate patient and patient's families from prolonged suffering. It is performed on the patient who is unknowingly intubated against his or her prior expressed will, or diagnosed with a nonsurvivable medical condition after intubation that would not be consistent with a favorable quality of life. These patients are ideal candidates for palliative ED extubation. The act of withdrawal of life support can be emotionally and ethically challenging. It is important to effectively communicate in a compassionate but a direct manner with the patient's family. The discussion should include details regarding the patient's current clinical status, prognosis, expected outcome, and postextubation care. Once extubation is decided collectively, it ought to be accomplished to offer comfort. Medications such as opioid infusion and benzodiazepines should be part of a standard care. They also help to reduce postextubation dyspnea and pain.

SUMMARY

Emergency department extubation is feasible. It can be safely performed after a careful and logical consideration, as well as patient selection. The application of available guidelines or protocols, understanding, preparing to intervene any potentially life-threatening complications and subsequent disposition, is cornerstones. **Figure 2** provides a proposed ED extubation pathway.

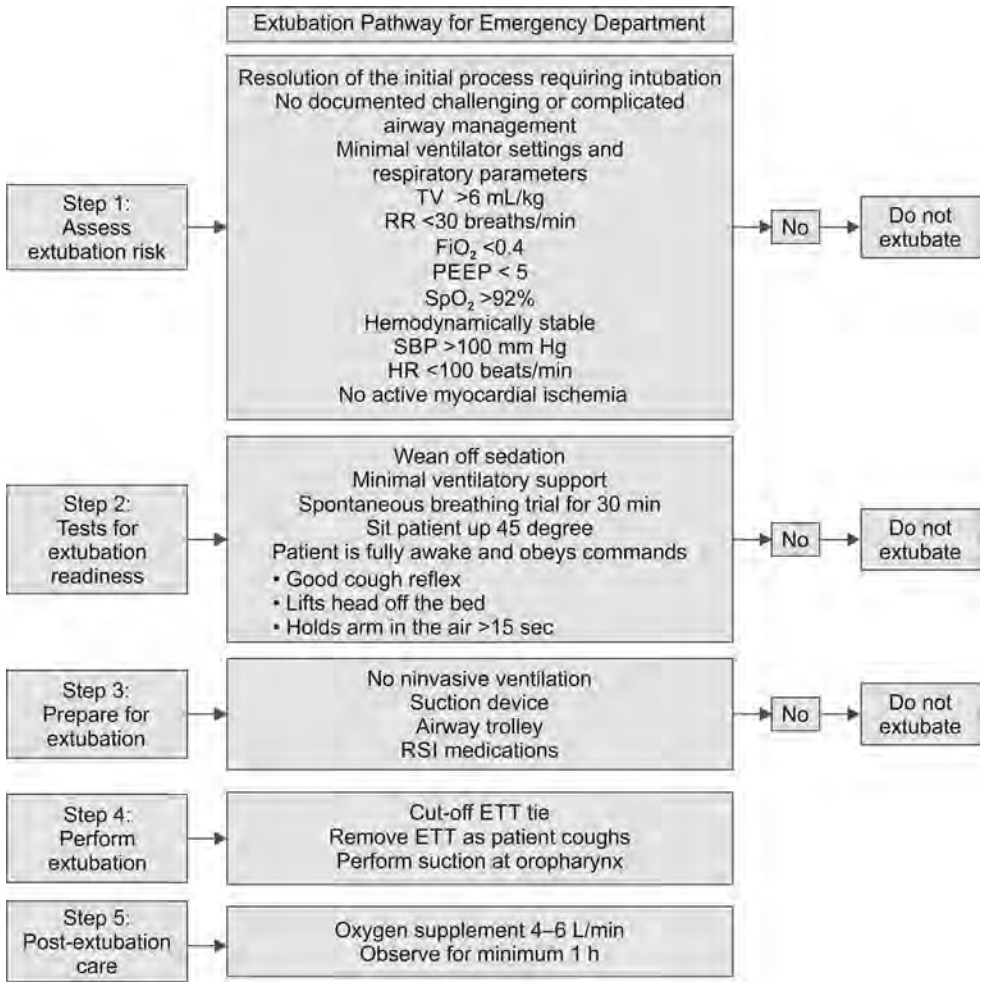


FIG. 2: Extubation pathway for emergency department.

42 CHAPTER

Vascular Access

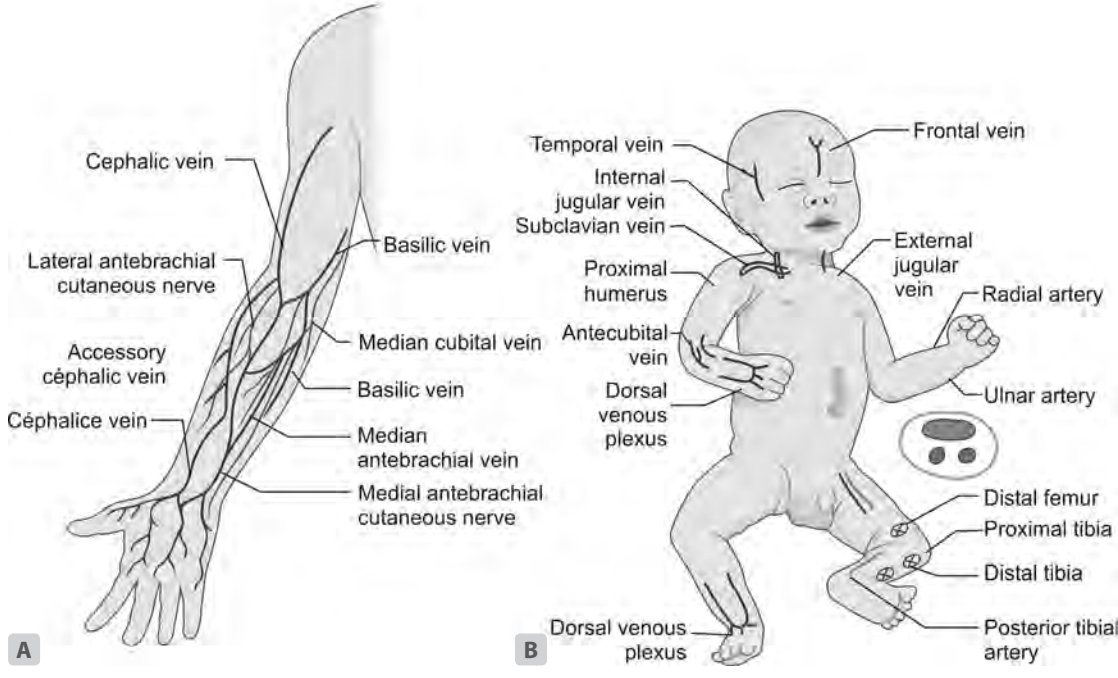
Eric Revue

INTRODUCTION

Vascular access is a necessary component of the delivery of medical treatment in emergency situations. The main principles of vascular access need knowledge of the basic anatomy, techniques, ultrasound, indications, and contraindications are essential to emergency care. More than 60% of patients in acute care worldwide require a vascular access device (VAD). Multiple factors determine the site for vascular access and knowledge of infusion rate is a key in the resuscitation of patients with severe hypovolemia or hemorrhage situations. Vascular access site for adult and pediatric age is shown in **Figures 1A** and **B**. Over a 30% of adults, > 50% of children who require a peripheral intravenous catheter (PIVC), are reported to have difficult venous access (DiVA). DiVA is defined by nonvisible and nonpalpable veins where a highly experienced operator is required with the use of technological help to insert a vascular device. Patients with chronic and complex disease, chemotherapy, who have a history of intravenous drug use, are obese, malnutrition, are known to suffer from DiVA.

BASIC KNOWLEDGE OF PATHOPHYSIOLOGY

According to Poiseuille's law, the rate of flow is directly proportional to the catheter radius and the pressure gradient, and inversely proportional to the dynamic fluid viscosity and catheter length. Flow rates are maximized by using the largest internal diameter catheter possible. Flow rates increase with larger catheter radius, use of more pressure, decreasing viscosity (co-administration of crystalloid with viscous blood products), or decreasing catheter length (peripheral angiocatheter vs. triple-lumen catheter).



FIGS. 1A AND B: Vascular access site for adult and pediatric age.

HOW TO CHOOSE APPROPRIATE VASCULAR DEVICE?

The placement of any device except the short peripheral catheter must be made by a trained or supervised operator, in a dust-controlled room under conditions surgical asepsis, under local anesthesia (buffered lidocaine with molar bicarbonate) with or without sedation or even hypnosis in adults. The use of a checklist is highly recommended. Various catheters used in general practice are shown in **Table 1**. Emergency physician should choose the appropriate catheter (depending on the total duration) as shown in **Table 2**. Multiple factors are involved and are deciding factors for choosing the appropriate VAD (**Fig. 2**), e.g., patient clinical conditions, treatment plan risk factors involved, vein conditions, and medications involved

PERIPHERAL ACCESS

Peripheral catheters are considered appropriate for treatment of peripherally compatible medications and solutions (<900 mOsm/L, not vesicant or irritant) and duration of treatment < 6 days with transition to midline or PICC when duration is extended. Peripheral catheters need access into the veins and arteries of the arms and legs for pediatric or neonatal applications. Peripheral access has a lower risk of infection (0.5/1,000 catheter days). Prescribed therapy and patient need to determine the type of peripheral cannula for the use. Various peripheral cannulae are available commercially for different clinical situations with different dimensions (external catheter diameters, length, and water flow rates) (**Table 3**). Other factors which could influence the fluid flow rates are type of fluid, viscosity and temperature of fluid, height of the container, and the use of connectors.

Peripheral Catheter Indications

Peripheral catheters are the preferred access for all patients where no indication is present for central venous access. Short PIVCs are the most frequently used invasive medical devices in for urgent procedures. PIVC treatment involves the infusion of peripherally compatible solutions for 5 days or less. Patient has adequate veins to accommodate catheter size and length. Emergent use with placement in the external jugular or foot veins (emergent or <4 days) (**Figs. 3A** to **D**). For those requiring multiple attempts such as obese patients, diabetes or other chronic conditions, difficult intravenous access (DIVA), and the VAD the needs of the treatment plan with the lowest risk selection of a VAD should be based on specific indications. When multiple peripheral catheter attempts fail, the designation of DIVA may lead to assessment with a greater success with ultrasound-guided peripheral catheter access after training and reduced need and avoidance of central venous access devices (CVADs).

TABLE 1: Catheter used for venous and arterial access.

Catheters	*Entry*	*Length*	*Comments*
Short peripheral venous catheters	Forearm and hands veins	<3 inches	Prolonged use phlebitis
Peripheral arterial catheters	Radial artery (preferred), femoral axillary, brachial	<3 inches	Infection risk is low
Midline catheters	Inserted through antecubital fossa to basilic or cephalic veins but does not enter central veins	3–8 inches	Low rate of infections
Central venous catheters (nontunneled)	Percutaneously inserted to subclavian internal jugular femoral veins	>8 cm, depends on patient size	Infection (most of CRBSI)
Central venous catheters (tunneled)	Implanted into subclavian, internal jugular and femoral	>8 cm, depends on patient size	Lower rate of infection than nontunneled
Peripherally inserted central venous catheter (PICC)	Inserted into the basilic cephalic and enters the superior vena cava	>20 cm, depending on patient size	Lower rate of infection than nontunneled
Pulmonary artery catheters	Inserted to subclavian internal jugular or femoral through Teflon introducer	>30 cm, depending on patient size	Infection similar to central venous catheters
Totally implantable catheters	Tunneled beneath the skin and have subcutaneous port-subclavian and internal jugular	>8 cm, depending on patient size	Lower risk of CRBSI

TABLE 2: How to choose the catheter?

Duration	*< 5 days*	*6–14 days*	*< 14 days*	*>14 days*
Catheter	Peripheral venous catheter	Peripheral catheter especially if bad venous	Midline or PICC	Peripheral venous catheter
ICU, and if hemodynamic monitoring, or high infusion rate		Preferred nontunneled central venous catheter		PICC line preferred to midline
Cancer patient's chemotherapy parenteral nutrition	Central venous access			

(ICU: intensive care unit; PICC: peripherally inserted central venous catheter)

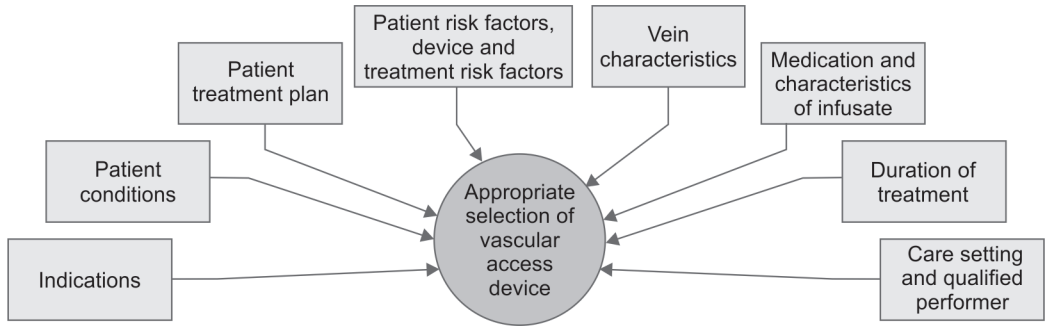


FIG. 2: Important factors while choosing appropriate vascular access device (VAD).

TABLE 3: Selection of peripheral cannula as per prescribed therapy. ***(For color version, see plate 2)***

Color	*Gauge size*	*External diameter (mm)*	*Length (mm)*	*Water flow rate (mL/min)*	*Recommended uses*
Orange	14G	2.1 mm	45 mm	~240 mL/min	Trauma, Rapid blood transfusion, Surgery[1]
Gray	16G	1.8 mm	45 mm	~180 mL/min	Rapid fluid replacement, Trauma, Rapid blood transfusion[1]
 Green	18G	1.3 mm	32 mm	~90 mL/min	Rapid fluid replacement, Trauma, Rapid blood transfusion[1]
 Pink	20G	1.1 mm	32 mm	~60 mL/min	Most infusions, Rapid fluid replacement, Trauma, Routine blood transfusion[1]
 Blue	22G	0.9 mm	25 mm	~36 mL/min	Most infusions neonate, pediatric, older adults, Routine blood transfusion[1]
 Yellow	24G	0.7 mm	19 mm	~20 mL/min	Most infusions neonate, pediatric, older adults, Routine blood transfusion, Neonate or Pediatric blood transfusion[1]
 Purple	26G	0.6 mm	19 mm	~13 mL/min	Pediatrics, Neonate[1]

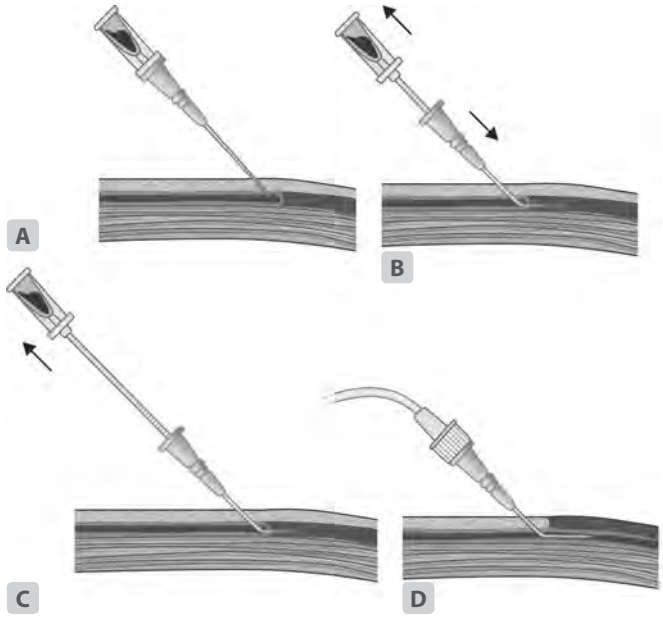
Ultrasound-guided Peripheral Catheter Indications

Use visualization technology to establish peripheral access using longer catheters for the purpose of intravenous treatment less than 5 days or more than 15 days (with transition to midline or PICC).

For patients with one or more failed attempts, inability to identify veins visually or those identified as DIVA commonly



FIGS. 3A TO D: Peripheral venous access technique—(A) insertion of needle, (B) Proceed needle further as blood seen on the top, (C) Remove the needle and catheter is advanced further, (D) Catheter is attached to tubing and secured.

inserted in the forearm, antecubital fossa or upper arm. For contrast based radiological studies requiring upper extremity access in larger veins with 20-, 18- or 16-gauge catheter (where visible veins to accommodate catheter size are not present)

CENTRAL VENOUS CATHETERS

Central venous access devices exceed >10 million worldwide, with significant risk to the patient. Vascular access has great importance in the treatment of patients submitted to prolonged chemotherapy. The central veins are the target for placement of the internal section of central venous catheters (CVCs) and their tips.

Large numbers of CVADs are performed yearly, the majority via the upper body for short-and long-term access. Ultrasound and electrocardiogram (ECG) guidance increase the successful placement of needles, guidewires, and catheters, but significant number of catheter misplacements can still occur, particularly if operators are not fully proficient in such techniques.

Indications for a Central Venous Catheter

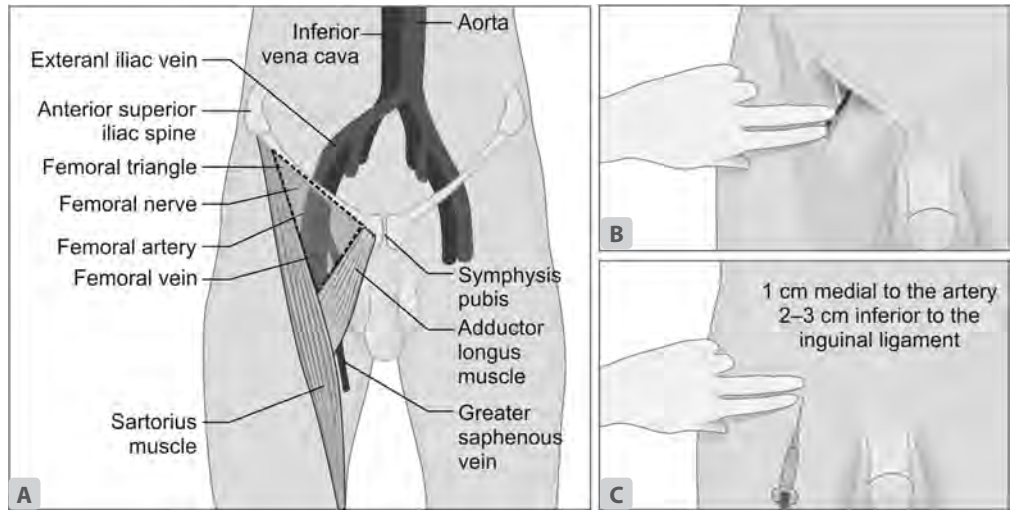
In the emergency department, CVCs are inserted for a large number of different indications: administering drugs (vasopressors/inotropes and antibiotics), monitoring central venous pressure (CVP), measurement of central venous oxygen saturation ($ScvO_2$), poor peripheral venous access, cardiac catheterization, and transvenous cardiac pacing. Many different types of catheters exist, for example, tunneled or nontunneled, monolumen or multilumen, dialysis catheters, and peripherally inserted central catheters (PICCS). In intensive care unit (ICU), in recent studies, the use of the central catheter subclavicle way should have less complications than the jugular or femoral access. In this trial, subclavian-vein catheterization was associated with a lower risk of bloodstream infection and symptomatic thrombosis and a higher risk of pneumothorax than jugular-vein or femoral-vein catheterization. There is a lack of standard minimal requirements for the training of insertion techniques and maintenance of CVADs. The insertion method and site selected affect the amount of risk involved related to trauma, colonization. The decision to choose a particular type or size of the device contributes to the risk for infection or thrombosis. Emergency physicians, anesthetics, intensivists, and nurses are also involved in the placement of CVADs using ultrasound guidance need appropriate training to ensure patient safety and avoid major complications with the insertion of CVADs. Basic knowledge of anatomy, ultrasound physics, and imaging, and infection prevention strategies are necessary for adequate understanding and safety of the insertion procedure.

Femoral Vein Catheter Insertion—Technique

Employ the *"landmark technique"* to isolate the location of the femoral vein for puncture (**Figs. 4A** to **C**). Use your index finger to locate the arterial pulsation along the inguinal ligament at the midpoint between the anterior superior iliac spine and the pubic symphysis. Then move 1–2 cm inferior to this position as the needle puncture must be performed below the inguinal ligament. Next, move 1–2 cm medially as the vein lies medial to the artery. Use your index and middle fingers to locate the distal and proximal pulsations of the femoral artery, respectively. Just medial to your fingertips should be the general course of the femoral vein. Hence, you should puncture just medial to your index finger in a direction just medial to your middle finger.

Internal Jugular Vein Catheter Insertion—Technique

If an ultrasound machine is not immediately available and central venous access via the right jugular vein is required, a simple three-finger technique for insertion of a central venous access line into the right internal jugular vein has proven to be a reliable method for accomplishing this task. Basic anatomy of neck area is shown in **Figure 5**. Place the patients supine with their head turned gently to the left. This technique of the central venous access via the right jugular vein will be successful no matter how much or how little the head can or cannot be turned. The practitioner's left ring finger is placed in the patient's sternal notch, and the adjoining middle and index fingertips are brought together such that they are in the midline over the trachea. This group of fingers is then rolled over the trachea and down into the space between the trachea and medial head of the medial sternocleidomastoid muscle. The pads of the three fingers must stay in contact with the trachea. When done properly, the left ring finger is now in contact with the sternoclavicular joint and the medial head of the sternocleidomastoid muscle is bunched into a mound lateral to the fingers. In the middle of the mound and at the level of the left index finger insert the finder needle at a 45° angle to the skin aiming toward the patient's ipsilateral nipple with gentle suction applied to the syringe. Once the vein has been entered and venous blood positively identified in the syringe, the larger introducer needle is inserted directly over the top of the smaller finder needle at the same angle and direction of the finder needle (**Fig. 6**). Proceed to place a catheter with the Seldinger technique. This completes the central venous access via the right jugular vein procedure. Check the postprocedure chest radiograph, by using mammography or blood gas for proper central venous line catheter placement.



FIGS. 4A TO C: Landmark technique for insertion of central venous catheter at femoral vein site.

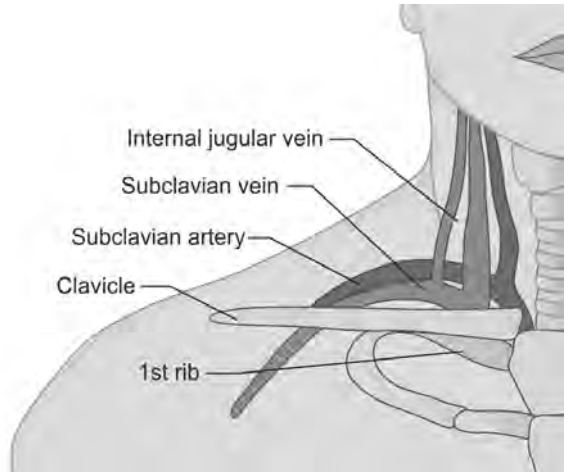


FIG. 5: Anatomy of neck area.

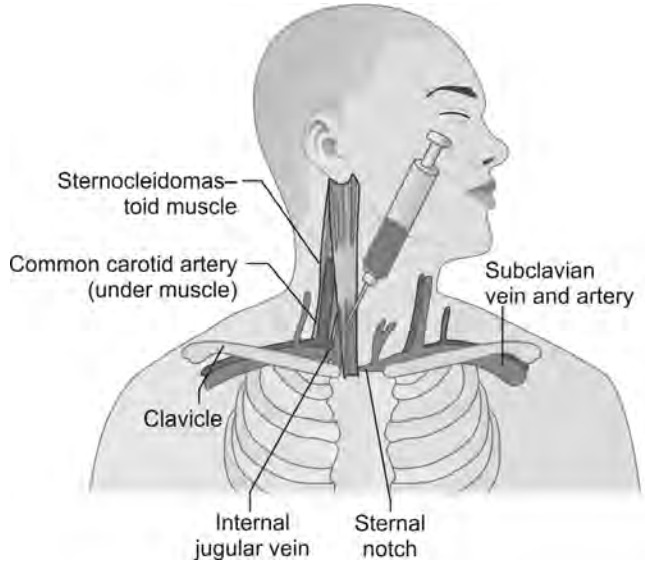

FIG. 6: Internal jugular vein catheter insertion technique.

Subclavian Vein Catheter Insertion—Technique

Subclavian vein catheter insertion is good choice for long term as this allows the patient to move the neck freely. Supraclavicular and infraclavicular approaches (**Figs. 7A** and **B**) are the two traditional approach used for subclavian vein catheterization. Supraclavicular approach provides good sonographic visualization. Both approaches are associated with risk of developing the pneumothorax. Insertion of a central venous access, whether it is being used for a short or a long period of time, is a common procedure, which is often undertaken by emergency physicians, intensivists, and anesthetists. The associated morbidities include punctured arteries for almost 10% of cases and hemothorax or pneumothorax for about 3%. These complications can be serious or even fatal.

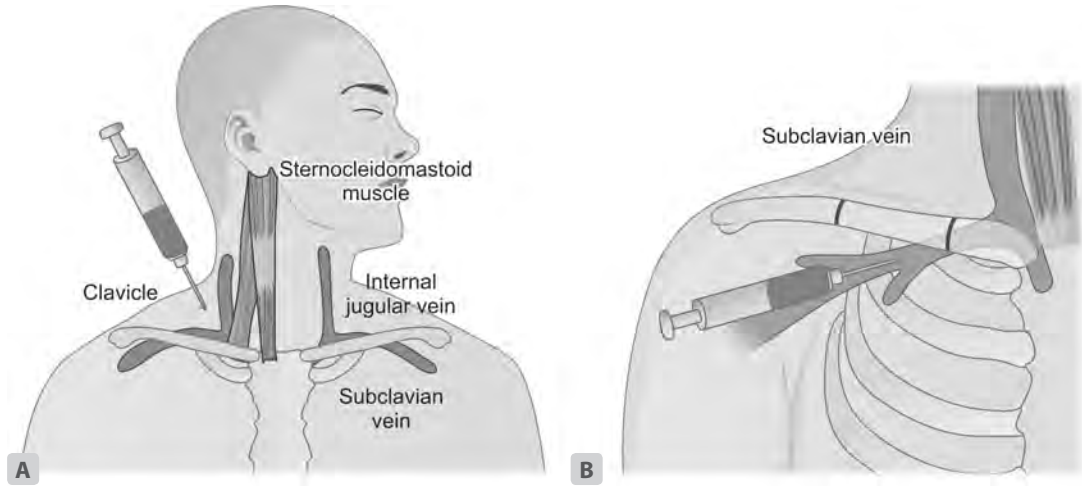
Nontunneled Central Venous Catheters

Nontunneled CVCs are commonly used for internal jugular access with acute care patients who are unstable and who require hemodynamic monitoring or large fluid infusions.

Nontunneled catheter indications—unstable patients requiring hemodynamic monitoring, multiple medications, large fluid infusions, blood or blood products or continuous parenteral nutrition, and short-term critical access. Nontunneled CVCs are preferred over PICCs for access up to 14 days. Chemotherapy treatment anticipated for >3 months. Antimicrobial nontunneled catheters are often used for these critical patients to reduce the risk of infection by approximately 40%.

Tunneled Central Venous Catheters

Tunneled CVCs are inserted into internal jugular or subclavian veins with a subcutaneous tunnel are indicated for use with intravenous treatment >31 days or for patients not considered candidates for a PICC due to vein size or thrombosis risk. *Tunneled catheter indications*—patients receiving treatment exceeding 31 days. Infusion of vesicant, irritant, parenteral nutrition, or chemotherapeutic agents regardless of duration; patients likely to receive cyclic or intermittent ongoing therapy



FIGS. 7A AND B: (A) Supraclavicular approach; (B) infraclavicular approach to subclavian vein.

exceeding 31 days; and- -Patients with >6 hospitalizations annually with expected duration of therapy > 15 days per hospitalization.

Totally Implanted Catheter with Subcutaneous Ports

Patients with expected treatment > 6 months [neutral rating for 3–6 months (duration of treatment)]. Patients requiring intermittent or cyclic infusion treatment, rather than continuous, for >6 months.

MIDLINE CATHETERS

Midlines are appropriate for patients with peripherally compatible solutions or medications for duration of treatment > 6 days. Midlines are preferred for patients requiring infusions up to 14 days, but may be used in a manner consistent with the clinically indicated removal of peripheral catheters. *Midline catheter indications*—treatment involves peripherally appropriate solutions that will likely exceed 6 days. It is preferred for patients requiring infusions of up to 14 days and in patients with DIVA despite ultrasound-guided peripheral catheter attempts. Single-lumen midline is placed unless specific indication for dual lumen with compatible infusions.

PERIPHERALLY INSERTED CENTRAL CATHETERS

This long-term intravenous device is a central catheter. It is inserted under ultrasound by a peripheral vein deep in the arm and can be tunneled. There are PICC authorizing injections at 5 mL/s.

Technique of Peripherally Inserted Central Catheters

The size of the catheter must be adapted to the vein as the risk of thrombosis increases with the diameter of the catheter. The Trendelenburg technique and the Valsalva maneuver can increase the diameter of the chin strap and prevent collapse (up to 50%). Single-lumen PICCs preferred unless specific indication for additional lumen. Use smaller gauge PICC with fewer lumen to reduce risk of deep vein thrombosis (DVT) (Grove and Pevec, 2000; Evans et al., 2013). Measure vein size to establish appropriate catheter size of >45% of vein diameter (Sharp et al., 2015). Position of terminal tip of PICC in lower third of the superior vena cava, cavoatrial junction, or right atrium.

Peripherally Inserted Central Catheter Indications

- Patient requires intravenous access for >14 days. For proposed treatment of 6 or more days ultrasound-guided or midline catheter preferred over PICC.
- Clinically stable patient requiring intravenous therapy with peripherally incompatible solutions. Hemodynamically unstable patients where cardiac monitoring or use of vasopressors is necessary in cases <14 days and >15 days (CVCs favored over PICCs).
- For use with continuous infusions of vesicant, parenteral nutrition, chemically irritating, or nonperipherally compatible solutions for any duration
- For cyclic chemotherapy with active cancer where treatment is >3 months. Consideration given to discontinuation of PICC when each cycle complete (peripheral catheter preferred when >3 months).
- Use with patients receiving frequent phlebotomy of every 8 hours or more often with duration of 6 days or more
- For burn patients where early implementation of PICC decreases risk of bacteremia.
- For use in patients in palliative treatment, actively dying or in hospice requiring intravenous solutions

Peripherally Inserted Central Catheter Contraindications

Do not insert the peripheral catheter near skin or infected lesions, on the side of an axillary dissection, lymphedema, and hemiplegia. No PICC in renal failure insufficiency who may need an arteriovenous fistula.

USE OF ULTRASOUND FOR CENTRAL VENOUS CATHETER INSERTION

Ultrasound guidance for the insertion of CVADs has become standard practice, and mitigates serious procedural complications such as pneumothorax and accidental arterial puncture. There is an emerging trend for the use of this technology to aid in the insertion of PIVCs for patients with DiVA guidelines on the use of ultrasound guidance for vascular access (**Table 4**). The spread of ultrasound scanners in emergency departments and ICUs has made ultrasound-guided catheterization possible.

TABLE 4: Recommendation for use of ultrasound for central venous access

Guidelines	*Strong recommendation*	*Weak recommendation*
Guideline 1: Internal jugular vein in adults	X	
Guideline 2: Subclavian vein in adults	X	
Guideline 3: Femoral vein in adults	X

Guideline 9: Radial artery in children		X
Guideline 10: Peripheral veins in children		X

REMOVAL OF CATHETER

Removal of a CVC (PICC, CVC, and tunneled catheter) after notification of physician and when catheter has not been used for any clinical purpose for 48 hours or longer. Removal of catheter when patient no longer has a clinical indication for use or the original use has been met.

Removal of catheter when used only for blood samples in stable patient when peripheral veins available. Removal of catheter only by clinician trained for removal of specific device.

ARTERIAL ACCESS

Peripheral arterial catheters are widely used in the care of critically ill patients. They are a vital component of contemporary management of patients in ICU and are usually inserted into a peripheral artery for continuous blood pressure (BP) monitoring and blood sampling for frequent blood gas analysis. Arterial cannulation provides easy and convenient access, allowing multiple blood samplings.

High Indications

- Cardiac surgery with extracorporeal circulation
- Pheochromocytoma surgery
- Neurosurgery with high risk deep decrease BP (hypotension)
- Hepatic and pulmonary transplants

Strong Recommendation

- Surgery with sudden and/or significant variations in blood volume
- Major vascular surgery with aortic clamping
- Risk hemorrhagic surgery (spine surgery)
- Cardiovascular conditions require precise intraoperative control of BP:
  - Coronary insufficiency
  - Severe high blood pressure (HBP)
  - Heart failure and cardiac insufficiency
  - Hemorrhagic and hypovolemic shock

Technique

The radial artery is preferred for securing arterial blood and for cannulation to provide continuous BP monitoring and arterial blood sampling. If the radial artery cannot be cannulated, the femoral artery offers a viable alternative. Arterial line placement can be performed via multiple methods. The choice of methods is determined by location, operator preference, and available equipment.

- *Step 1*: Use a prepackaged radial artery catheterization kit, include iodine or chlorhexidine solution, dorsal wrist extensor splint, 1% lidocaine for local anesthesia, 4 × 4 gauze squares, adhesive tape, nylon suture (3-0 or 4-0), needle driver, catheter-over-the-needle, and compatible spring-wire guide.
- *Step 2*: Extend the patient's wrist to identify the radial artery insertion site. Secure arm and hand with tape if needed. Palpate the radial artery to determine its location. Clean the skin with antiseptic solution, arrange sterile drape, and inject anesthetic.
- *Step 3*: With a one-piece catheter-over-the-wire, puncture the artery and insert the cannula in a continuous motion at an approximately 45° angle (**Fig. 8**). After noting a flash of blood in the needle hub, stabilize the catheter-over-the-needle.

Allen's Testing

Appreciate the vascularization of the hand by the radial artery and the ulnar artery, respectively.

- The patient flexes his wrist strongly. Apply pressure on both arteries at the wrist. The patient then reopens his hand.
- Relieve the pressure on the radial artery. The color of the skin did not return after 30 seconds, the pressure was released on the ulnar side.
- Then repeat the test, first releasing the pressure on the ulnar artery.
- This test allows to know what is the predominant vascular supply radial or ulnar.

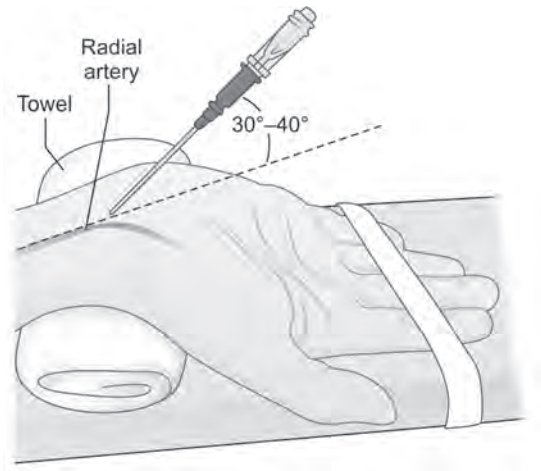

FIG. 8: The radial artery catheterization needs a control by the Allen's Test. If the patient suffers from a Raynaud's disease, the catheter is not indicated.

Source: Ramsey L. (2018). Arterial line placement: Basics for medical students. [online] Available from https://www.emra.org/emresident/article/arterial-line-placement/ [Last accessed July, 2021].

Other Sites

- *Femoral artery*: Preferred in emergency conditions. Large diameter and deep anatomical situation. Disadvantages—limited intraoperative accessibility risks of kinking and disconnection.
- *Foot artery:* Superficial artery with a collateral vascular network not detectable in 20% of cases not very accessible during the intraoperative phase.
- *Humeral artery:* To be avoided. Use only if no substitution is possible.

ARTERIAL BLOOD PRESSURE

Arterial blood pressure (ABP) is the pressure generated by the interaction of cardiac output with the arterial wall resistance. As the cardiac output is ejected from left ventricle, it travels downstream from aorta to different arterial branches, arterioles, and meta-arterioles perfusing different organs. Hence, ABP has been used traditionally as a marker of global tissue perfusion. During resuscitation in emergency room usually we target mean ABP of >65–70 mm Hg. In certain condition due to altered physiology and hemodynamics, different MAP is targeted (**Table 5**). *ABP measurement:* Routinely, noninvasive BP is measured in patients but in shock state they are unreliable; hence direct BP measurement by placing indwelling arterial catheter in a peripheral artery is preferable during shock resuscitation. It provides beat-to-beat display of characteristic arterial pressure waveforms and values. The arterial catheter is commonly placed in radial or femoral artery. Femoral artery catheter is recommended when noninvasive cardiac output measurement is planned. The indwelling catheter is connected to monitor through tubing and transducer assembly (**Fig. 9**). Transducer is the mainstay of the system and should be calibrated ("zeroing") to the ambient pressure at the ipsilateral mid-axillary line fourth intercostal space. Transducer converts mechanical energy of the pulse wave into electrical waves which are transmitted to and displayed on the monitor. The waves must be interpreted with corresponding ECG display.

TABLE 5: Mean blood pressure targets during resuscitation in special clinical conditions.

Higher MAP target (85–90 mm Hg)	*Lower MAP target (55–60 mm Hg)*
Traumatic brain injury	Polytrauma (damage-controlled resuscitation)
Cerebrovascular accident	Hemorrhagic shock
Chronic hypertension	
Hypertensive nephropathy	
Eclampsia	

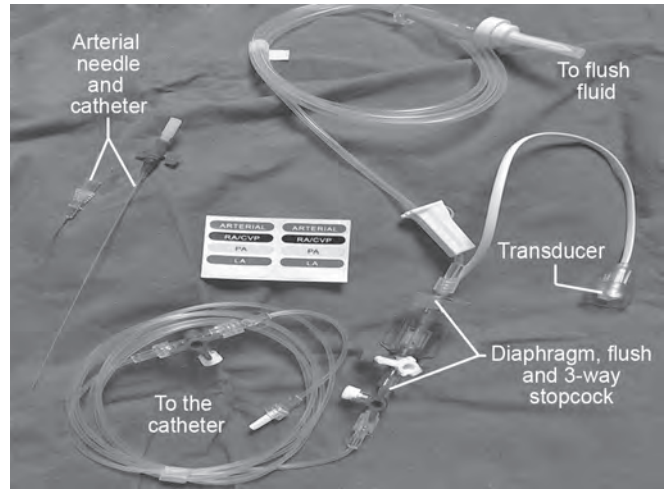

FIG. 9: Pressure line components of invasive pressure monitoring.

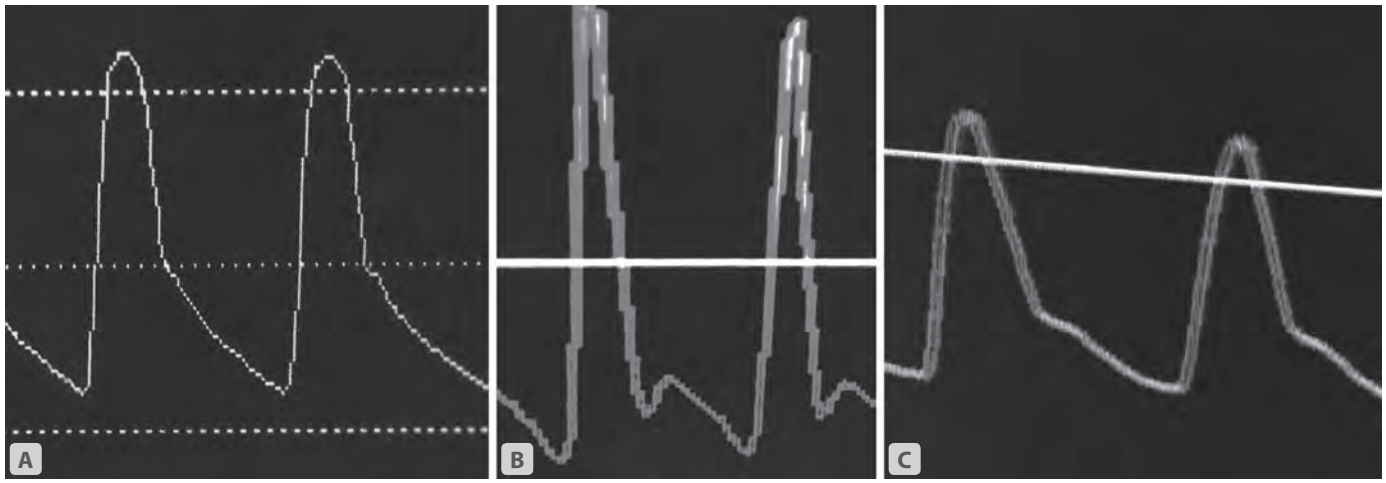
Interpretations

- The arterial wave may be displayed underdamped/overdamped (**Figs. 10A** to **C**) due to erroneous system. This will display incorrect systolic/diastolic pressure value but mean pressure will be correct. Common causes of erroneous direct arterial BP display are given in **Table 6**
- The beat-to-beat variation in ABP plethysmography with breathing phases happens due to heart lung interaction. In a spontaneously breathing patient at end inspiration, there is decrease in left ventricular stroke volume which is displayed as decreased SBP while during positive pressure ventilation, there is increased SBP value in plethysmograph at end inspiration. Any exacerbation of these variations in display usually indicates hypovolemic state and fluid challenge must be given. In monitors displaying dynamic parameters, it is possible to measure these variations and these are termed systolic pressure variation (SPV) and pulse pressure variation (PPV). SPV variation of 15% and PPV variation of >12% again signify hypovolemia.

EMERGENCY CONDITIONS WHERE FEMORAL ARTERY ACCESS IS RECOMMENDED

- For intraaortic balloon pump/tandem heart/ECMO/Impella device placement for hemodynamic support
- For percutaneous structural heart procedures (balloon valvuloplasty, percutaneous valves, etc.)



FIGS. 10A TO C: Invasive arterial waveforms (A) normal wave form with smooth pick and dicrotic notch. (B) Underdamped wave with sharp tall picked systolic wave. (C) Damped wave pattern with nondiscernible dicrotic notch.

TABLE 6: Common causes of erroneous direct arterial BP display.

Causes of overdamped	*Causes of underdamped*
Air bubble in tubing	Long tubing
Clot/Kink of tube/catheter	Increased vascular resistance (e.g., very high vasopressor dose)
Low flush bag pressure	

- Peripheral vascular angiography and intervention (transradial access can be used with the use of longer length catheters)
- For invasive hemodynamic monitoring (radial access preferred)
- Coronary angiography and intervention (preferred over radial for procedures requiring larger sheath size)

Femoral access should be strongly considered in situations where larger sheath size (8 Fr or higher) is required or in patients with prior difficult radial access. The ideal site of femoral arterial puncture (not skin puncture) is at the common femoral artery (CFA) at a point approximately 1 cm lateral to the most medial aspect of the femoral head, midway between its superior and inferior borders *(Rupp's rule)*.

Procedure

- Prepare the femoral artery site using antiseptic solution and dry it using a dry gauge.
- Cover the site with a sterile drape, with an opening at the site of the femoral access site.
- Prepare the patient prior to a potentially painful step of the procedure (e.g., administering local anesthesia) by informing him or her of the next step to ensure adequate patient cooperation.
- Identify the ideal femoral artery puncture site.
- Feel the femoral arterial pulsation at the site of skin entry with the tips of the middle and index fingers, and parallel to the course of the femoral artery.
- Make a 2–4 mm nick parallel to the skin crease at the identified site of the femoral artery puncture. The nick can be enlarged and deepened using the tip of a small curved forceps. The nick and tunnel approach may not be necessary for smaller size sheaths.
- Puncture the artery using an 18-gauge arterial cannulation needle using a modified Seldinger technique with an anterior wall puncture. Enter the skin at a 30–45° degree angle so as to cannulate the artery 2 cm superior to the skin incision.
- Ensure pulsatile blood flow before wire advancement.
- Remove the dilator leaving behind the J-tipped guidewire and flush the side port of the sheath.

Complications

- Bleeding at the puncture site (hematoma)
- Thrombosis and occlusion of the radial artery (1.5–35%)
- Local or general infection from the catheter
- Pseudoaneurysm (mean incidence 0.09%)
- Injury of a nerve causing pain or transient functional impairment
- Obstruction of the arterial catheter with a clot
- Atheroma thrombus with arterial ischemia
- Arterial spasm

INTRAOSSEOUS DEVICE

In an out-of-hospital emergency setting, rapid vascular access is often needed to infuse fluids and administer drugs. In some urgent situations, the conventional procedure by peripheral venous cannulation cannot be performed rapidly due to difficult conditions like an out-of-hospital cardiac arrest. In difficult or impossible cases, central venous access or intraosseous (IO) access (**Fig. 11**) may be used in emergency situations, especially in children. IO vascular access is an effective first alternative to failed or delayed peripheral or central IV access in emergent situations. The technique involves the placement of a vascular device with the tip of the IO catheter in the bone matrix with a dwell time of 24 hours. Delivery of crystalloids, colloids, or medications through this catheter immediately infuses into the systemic circulation via the bone marrow cavity.

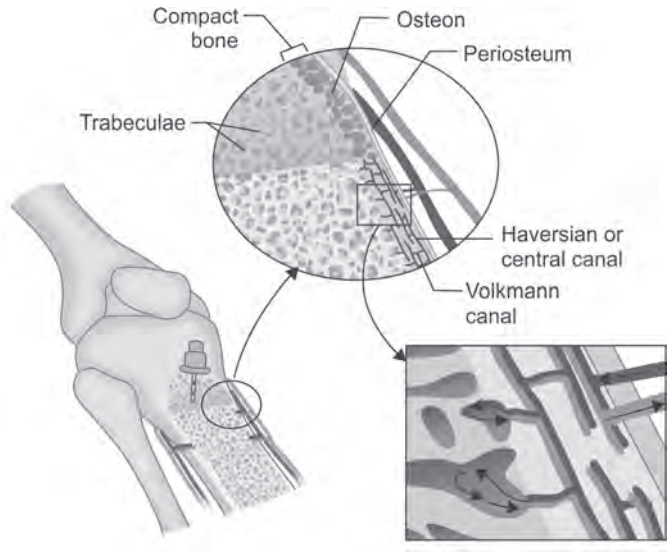


FIG. 11: Intraosseous vascular access.

Source: Tintinalli JE, Ma OJ, Yealy DM, Meckler GD, Stapczynski JS, Cline DM, et al. Tintinalli's Emergency Medicine: A Comprehensive Study Guide, 8th edition. United States: McGraw-Hill Education; 2015.

Clinical Situations in which IO Access may be Considered

The following clinical situations represent patient groups in whom vascular access is notably difficult or who need access repeatedly but characteristically have limited vascular access.

Intraosseous access can be considered clinically appropriate on the basis of a short-term need for patients:

- With chronic disease who have been admitted to the hospital for treatment of a medical event, for example, the deteriorating patient with chronic obstructive pulmonary disease.
- With limited vascular access due to aggressive treatment modalities, for example, fistulas, grafts, shunts, mastectomies, or multiple central line placements
- For whom, rapid response teams are called to prevent an emergent situation and in whom obtaining peripheral or central IV access is difficult.
- Who experience an unexpected medical event that causes their peripheral or central IV device to become nonfunctional, for example, infiltration or occlusion, and difficult to reestablish.
- Who have limited peripheral access due to morbid obesity.
- Who experience intractable pain.
- Who are in the early stages of sepsis.
- Who are receiving palliative or hospice care.
- Who are undergoing anesthesia and experience prolonged, difficult, or failed IV access

Contraindications to IO Access

Intraosseous access should be avoided in the following situations:

- Fractures in the same extremity as the targeted bone
- Previous surgery involving hardware in the bone targeted for IO access
- Infection at the insertion site or within the targeted bone
- Local vascular compromise
- Previous failed IO insertion within 24 hours in the targeted bone
- Inability to locate the landmarks

TABLE 7: Complications of indwelling vascular catheters.

Common	*Arterial catheter*	*Central venous Catheter*
Hemorrhage **Hematoma** **Infection**	Arterial thrombosis AV fistula pseudoaneurysm Distal limb ischemia and gangrene	Deep vein thrombosis Limb swelling Thrombotic venous occlusion Pneumothorax

Complications of IO Access

Few complications are reported in connection with IO access. Most are avoidable with proper education and training.

Complications associated with IO access include extravasation from dislodgement, iatrogenic fracture, growth plate injury, infection, fat emboli, compartment syndrome, and osteomyelitis

COMPLICATIONS

Intravascular catheters use puts patients at risk for local and systemic infectious complications, including local site infection, septic thrombophlebitis, endocarditis, and other metastatic infections (e.g., lung or brain abscess, and osteomyelitis). Serious complications of infection and thrombosis require applying evidence-based indications and avoiding potential overuse of PICCs. Due to low insertion-related complications, reduced cost, and placement primarily by vascular access teams, the use of PICCs is popular. Mechanical complications include occlusion, infiltration, and accidental removal. Vascular complications include venous thrombotic occlusion and phlebitis. Infectious complications may be bacterial or fungal, and local or systemic bloodstream infections [catheter-related bloodstream infections (CR-BSIs)]. PICC venous thrombosis is known to also impact the risk of lower-extremity thrombosis and potentially contribute to incidence of pulmonary emboli. Selecting the intravenous device with the lowest risk that most effectively supports, the patient's treatment plan should be performed based on available evidence and specified indications (**Table 7**).

SUMMARY

Choosing the right catheter in urgent situations depends on many factors due to the patient's anatomy, comorbidities, hemostasis disorders, expected duration and type of treatments, and the infusion rate required. The ability to preserve vessel health for future medical needs requires clinical education and training in three areas—(1) device selection, (2) placement, and (3) daily device care. Selection of the most appropriate VAD is necessary to avoid the potentially serious complications of infection and/or thrombosis. Selection of a central VAD (CVAD) should be based on indications for that specific device rather than the inability to gain peripheral access. The use of 2% alcoholic chlorhexidine without predetergent on clean

and healthy skin is strongly recommended for skin antisepsis. Ultrasound-guided punctures are recommended in case percutaneous punctures. The position of the distal end of the catheter is fundamental to reduce the risk of thrombosis of CVCs. Extravasation complication is essential to recognize. All VADs have a risk of infection and other complications for the patient and should be removed as soon as no longer medically necessary. Prevention is crucial. Always consider patient's safety. *Mnemonic of what an Emergency Physician needs to think before access: "POCUS" Prevention*: anticipation is the key *O*rganize *C*lean and use 2% Alcoholic chlorhexidine Ultrasound are recommended *Sa*fety first.

CHAPTER

Intravenous Fluids

Ripenmeet Salhotra, Supradip Ghosh

INTRODUCTION

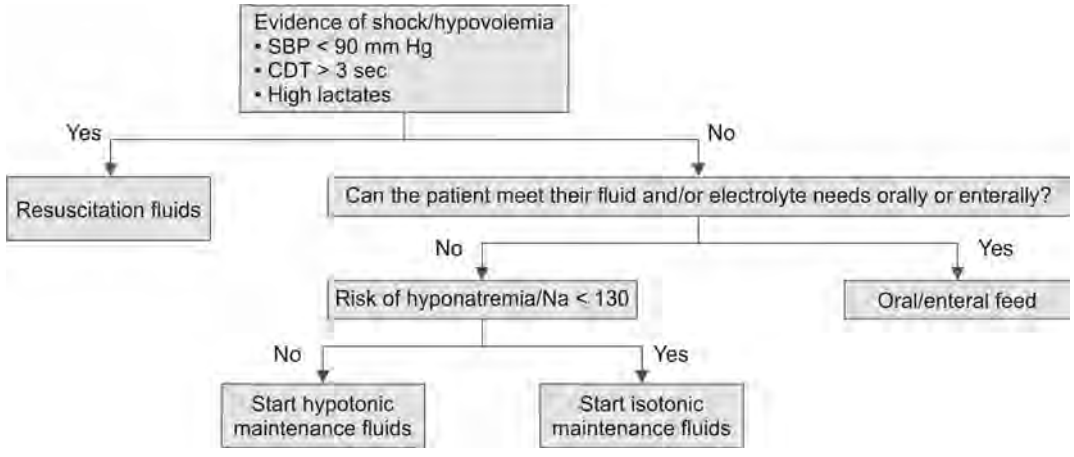
Intravenous (IV) fluid therapy is one of the most commonly provided treatments in both the emergency department (ED) and in-patients. Common indications for its use are resuscitation of a patient in shock and providing maintenance fluids to a patient who cannot take orally. Several types of IV fluids are available and each possesses specific benefits and disadvantages in a given clinical scenario. IV fluids can be divided into two broad categories—(1) crystalloids and (2) colloids. Colloids can further be classified as natural (albumin) or synthetic. Resuscitation fluids are frequently administered in ED to a patient with hypoperfusion with an aim to increase the stroke volume. Isotonic crystalloids and colloids are used for fluid resuscitation. IV fluid therapy is unnecessary and even harmful in the absence of signs of hypoperfusion such as hypotension, raised capillary refill time (CRT), high lactates, etc. Maintenance fluids should be provided to such well-perfused patients in case they are unable to accept oral or enteral feeding (**Flowchart 1**).

CRYSTALLOIDS

Crystalloids are the oldest forms of IV fluids. They are basically are simple solutions of electrolytes and/or sugars in water. They include isotonic solutions primarily used in resuscitation and hypotonic solutions used as maintenance fluid therapy. Electrolyte composition of some popular commercially available crystalloids is shown in **Table 1**.

Normal Saline (0.9% Saline)

The most popular crystalloid in clinical practice, 0.9% saline, contains 154 mmol/L of sodium and chloride each. Thus, concentration of both sodium (plasma sodium ~140 mmol/L) and chloride (plasma chloride ~100 mmol/L) are much higher than in plasma, resulting in a strong ion difference (SID) of 0. SID is the difference between the predominantly positive charge (sodium) and negative charge (chloride) in plasma. Normal SID of plasma is about 40. Any decrease in SID produces acidosis and conversely any increase produces alkalosis.



(SBP: spontaneous bacterial peritonitis; CRT: catheter-related thrombosis)

FLOWCHART 1: Approach to intravenous fluids administration in ED.

Infusion of large volumes of 0.9% saline leads to higher chloride concentrations in plasma and a decrease in SID. This decrease in SID (and hence bicarbonate) leads to hyperchloremic acidosis (**Fig. 1**). Several observational studies correlate resuscitation with saline and subsequent hyperchloremic acidosis with worse outcomes including acute kidney injury and mortality. Notably increased chloride concentrations in renal tubules lead to arteriolar vasoconstriction and reduce glomerular filtration. Despite these adverse effects, it remains the most used crystalloid in the world because it is relatively cheap, widely available, familiarity, and compatibility with blood and most medications. On its own, it should be the crystalloid of choice in patients with raised intracranial pressure (because of high osmolality of ~308) and in patients with metabolic alkalosis especially following vomiting and nasogastric aspiration.

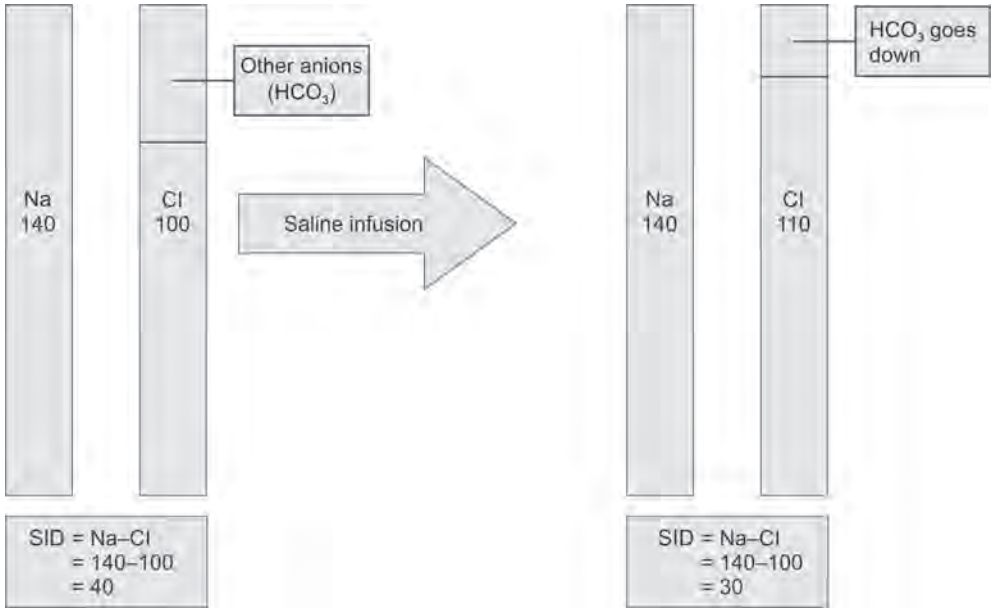
TABLE 1: Electrolyte composition of commonly available crystalloids.

Contents (mmol/L)	*Plasma*	*Normal saline*	*Ringer's lactate*	*Plas-malyte*	*Stero-fundin*
Osmolality	275–295	308	280	295	304
Sodium	135–145	154	130	140	140
Chloride	95–105	154	109	98	127
Potassium	4–5	0	4.5	5	4
Bicarbonate	24	0	0	0	0
Calcium	2.2–2.6	0	2.7	0	2.5
Magnesium	0.8–1.2	0	0	1.5	1
Lactate	0.8–1.8	0	28	0	0
Acetate	0	0	0	27	24
Gluconate	0	0	0	23	0
Maleate	0	0	0	0	5
pH	7.35–7.45	4.5–7.0	5.0–7.0	4.0–6.5	5.1–5.9

BALANCED SALT SOLUTIONS

Balanced crystalloids which are also known as *"physiological solutions"* have a chemical composition approximating that of extracellular fluid. These solutions employ metabolizable anions such as lactate, acetate, gluconate, or maleate to maintain electroneutrality, as bicarbonate is unstable in plastic. They have concentrations of chloride similar to plasma and hence devoid of harmful hyperchloremic metabolic acidosis. They may be somewhat hypotonic to plasma and should be avoided in patients with raised intracranial pressure. Besides, calcium in some of these fluids can bind to certain medications and citrated blood and should not be coadministered with these agents. In the SALT-ED trial, there was no difference in primary outcome of hospital free days when saline was compared to balanced crystalloids in non-critically ill ED patients. However, patients receiving saline had higher increase in creatinine. In another recent SMART trial, critically ill patients were randomized to receive saline or balanced crystalloids. The primary outcome which was a composite of death, new RRT and rise in creatinine favored balanced crystalloids. This difference was more pronounced in patients with sepsis.

Most commonly used balanced solution, the lactated Ringer's solution contains lactate which can raise plasma lactate making it harder to use trends in lactate to guide fluid management. Concerns also have been raised regarding the presence of potassium in the solution and theoretical risk hyperkalemia in vulnerable patients (e.g., renal failure). However, this has been refuted by a number of studies, which showed that in reality rise in potassium is more common with 0.9% saline than Ringer's lactate.



(Na: sodium; Cl: chloride)

FIG. 1: Effect of 0.9% saline transfusion on strong ion difference (SID).

Another newer balanced solution named plasmalyte containing acetate and gluconate as buffers and claims to eliminate the problems with the use of lactate. Unlike lactate predominantly getting metabolized in liver, metabolism of acetate happens in most cells of body. Also metabolism of acetate is faster compared to lactate. At least theoretically, acetate has been known to produce vasodilatation and hypotension; however, this has not been substantiated in several clinical studies. Plasmalyte contains higher sodium and lower chloride and thus resembles the electrolyte composition of plasma more closely than Ringer's Lactate. In spite of these, no studies have proven it to be superior to much cheaper Ringer's lactate in terms of clinical outcomes.

COLLOIDS

Colloids unlike crystalloids consist of large molecules and are believed to stay in the intravascular space for longer duration before leaking into the interstitium. They are used as resuscitation fluids in ED, critically ill, and during surgery (**Table 2**). In the past, it was thought that colloids are three to four times more effective than crystalloids in restoring the intravascular volume. This, however, was not substantiated in several recent trials, which suggested that only marginally lesser volume of colloids is required to produce similar hemodynamic effect when compared to crystalloids.

Albumin

The natural colloid albumin is available in iso-oncotic (4% and 5%) or hyperoncotic (20% and 25%) concentrations. Use of albumin in resuscitation of critically ill patients is safe and even showed a trend toward improved outcomes as compared to crystalloids in patients with sepsis. However, harm was seen when albumin was used in patients with traumatic brain injury and one must be careful to avoid it in this group of patients. Nevertheless, cost and availability remain an important hurdle in use of albumin that led to the development of synthetic colloids.

Synthetic Colloids

Hydroxyethyl starch (HES) is polydisperse solutions of hydroxylated carbohydrate molecules of various sizes. They are a group of synthetic colloids which differ in their concentration, molecular weight, molecular substitution, and carrier solution. For example, a product labeled 6% HES 140/0.4 contains a 6% solution of HES of mean molecular weight 140 kDa and a molecular substitution of 0.4. Newer or third generation HES solutions have lower molecular weight and substitutions resulting in more rapid metabolism and clearance and fewer adverse effects without loss of efficacy.

Several large multicenter randomized controlled trials have suggested that use of HES is associated with increased incidence of acute kidney injury and probably mortality in critically ill patients in general and septic patients in particular. Its use remains contraindicated in critically ill patients with sepsis. Though evidence for harm caused by HES in noncritically ill patients in ED or undergoing surgery is not so obvious neither is there any evidence of its usefulness in these patients. The case is more or less similar for other synthetic colloids such as Gelatins. Besides, synthetic colloids are also associated with other important adverse effects such as coagulopathy, anaphylactoid reactions, and pruritus. The routine use of synthetic colloids is currently not recommended.

Specific clinical situations sometimes warrant particular type of resuscitation fluid. Also, patient's acid-base status and electrolyte requirement must be considered before selecting appropriate type of fluid. For example, 0.9% saline is preferred if metabolic alkalosis is present due to its acidosis causing properties. Some fluids must also be avoided in certain conditions. For example, balanced crystalloids and albumin should be avoided in traumatic brain injury and synthetic colloids in sepsis (**Table 3**).

MAINTENANCE FLUIDS

The goal of maintenance fluid therapy is to sustain normal water and electrolyte balance and volume status. It should only

TABLE 2: Properties of colloids.

Colloid	*Types available*	*Used for*	*Adverse effects*
HES	• 6% and 10% • Molecular weight (MW): 130–670 • Molecular substitution (MS): 0.4–0.7	Resuscitation fluid	• Renal injury • Pruritus • Coagulopathy • Anaphylactoid reactions
Gelatins	• Urea cross-linked (e.g., Haemaccel) • Succinylated (e.g., Gelofusine)	Resuscitation fluid	• Renal injury • Coagulopathy • Anaphylactoid reactions
Dextrans	• 10% dextran-40 • 6% dextran-70	• Rarely used in resuscitation • Used to improve microcirculatory flow	• Renal injury • Coagulopathy • Anaphylactoid reactions
Albumin	• Iso-oncotic 4% and 5% • Hyperoncotic 20% and 25%	Resuscitation fluid (septic shock)	Increased mortality in traumatic brain injury

(HES: hydroxyethyl starch)

be undertaken if oral or enteral feeding is not possible and must be distinguished from fluid resuscitation. This must consider sensible losses from urine and stool and insensible losses from respiratory tract and skin. Routine prescription constitutes 25–30 mL/kg/day of water and approximately 1 mmol/kg/day of potassium, sodium, and chloride and approximately 50–100 g/day of glucose to limit starvation ketosis (e.g., glucose 5% contains 5 g/100 mL) (**Box 1**). Additional fluid and electrolyte supplements may be needed to replace the extra ongoing losses, such as nasogastric drainage, polyuria, or diarrhea. For example, water requirements increase by 100–150 mL/day for each degree of body temperature elevation above 37°C. Hypotonic fluids with dextrose and potassium are suitable maintenance fluids. Examples of commonly used hypotonic fluid formulations for maintenance include 0.18% saline +4% dextrose with added potassium and isolyte M (**Table 4**). Acutely ill patients are sometimes susceptible to hyponatremia resulting from impaired free-water excretion due to nonosmotic release of antidiuretic hormone. This will be worsened if hypotonic fluids are used as maintenance fluids. Serum sodium concentration must be monitored and maintenance fluids must be switched to isotonic crystalloids, if possibility of hyponatremia exists. Besides dextrose containing fluids must be avoided in patients with uncontrolled diabetes mellitus or hypokalemia.

Battery operated infusion devices or the IV pump is used for accurate precise and safe administration of fluid as well as various drugs also. Sometimes when infusion pumps are not available and healthcare worker uses "dial-a-flow" in which number of drops/minutes are infused to achieve the desired hourly infusion rate. A healthcare provider should have knowledge about the drop/minute reference guide (**Table 5**) so they can infuse desired level of fluid even in the absence of infusion pumps.

TABLE 3: Preferred resuscitation fluids in specific clinical situations.

Clinical situation	*Preferred resuscitation fluid*
Burns resuscitation	Balanced crystalloids, albumin
Hemorrhagic shock	Blood and blood products, limited crystalloids till blood is available
Metabolic alkalosis	0.9% saline
Septic shock	Balanced crystalloid, consider adding albumin, avoid HES
Traumatic brain injury	0.9% saline (avoid albumin)

(HES: hydroxyethyl starch)

BOX 1: Daily maintenance fluid requirement.

Normal daily fluid and electrolyte requirements:

- 25–30 mL/kg/day of water
- 1 mmol/kg/day of Na, K, and Cl
- 50–100 g of glucose

Conditions with increased requirement:

- Vomiting and nasogastric tube loss
- Biliary drainage loss
- High/low volume ileal stoma loss
- Diarrhea/excess colostomy loss
- Fever
- Pancreatic/jejunal fistula/stoma loss
- Urinary loss, e.g., post-AKI polyuria

(AKI: acute kidney injury)

SUMMARY

To conclude, fluids are administered to virtually all acutely ill patients. Choice of fluid should be individualized based on ongoing disease process, acid-base status, and electrolyte requirement. Thorough knowledge about IV fluids and their judicious use in the ED can improve patient outcomes.

TABLE 4: Examples of daily maintenance fluid prescription in an adult (70 kg).

Maintenance fluid	*Water*	*Sodium*	*Potassium*
2,000 mL D 5% + 500 mL NS + 50 mEq KCl	2,500 mL	76 mmol	50 mmol
2,500 mL (4%/0.18%) dextrose-saline + 50 mEq KCl	2,500 mL	76 mmol	50 mmol
2,500 mL isolyte M	2,500 mL	76 mmol	75 mmol

TABLE 5: Drops per minute reference guide.

Assessment of Volume Status and Hemodynamic Monitoring

44 CHAPTER

Sangeeta Chakraborty, Debashish Dhar, Devendra Richhariya

INTRODUCTION

Shock, by definition, is a condition of inadequate tissue perfusion; during resuscitation, the clinician's goal is to restore the patient's perfusion of organs and tissues. The importance of early goal-directed therapy and early intervention by emergency physicians for hypotensive patients has been shown in multiple studies, most classically by Rivers and colleagues for patients presenting in septic shock. One of the most important principles of Rivers' study was the use of targeted and aggressive fluid resuscitation to improve tissue perfusion increase cardiac filling and stroke volume (i.e., cardiac output). Fluid resuscitation is always an important part of the acute resuscitation. It is often less clear and also very difficult to determine before administering a fluid bolus, that patient who is currently hypotensive will actually respond to a fluid bolus. It is estimated in most of the studied studies, >40% of intensive care unit (ICU) patients receiving a fluid bolus did not show the desired increase in cardiac output and unnecessary and excessive fluid administration causes deleterious effects of fluid overload not only pulmonary edema but beyond that. Because of uncertainties of fluid therapy, outcome goals of fluid resuscitation are difficult to achieve. This chapter describes the various tools available for the emergency physician to answer various questions whether hemodynamically unstable patient responds to intravenous fluids, assessment of volume status, and hemodynamic monitoring. Methods for assessing the volume status are broadly categorized into static (traditional) and dynamic measurements (**Table 1**).

STATIC METHODS OF VOLUME ASSESSMENT AND ITS LIMITATIONS

Classic medical school teaching tells us to rely on the physical examination and vital signs to guide our resuscitation strategy, and this instruction extends into our clinical practice. However, when the objective findings are evaluated for their correlation with actual changes in perfusion and cardiac output, few of them perform well. One example is estimation of jugular venous pressure during the physical examination, which is used to evaluate abnormalities of the left-sided circulation. Not only is jugular venous pressure difficult to measure under some circumstances (e.g., when assessing an obese patient), but its true value can be confounded by numerous coexisting pathologies (e.g., valvular disease and pulmonary hypertension). Another commonly used marker, urine output, can fail to accurately indicate the success of resuscitative efforts because it can be difficult to distinguish oliguria secondary to circulatory dysfunction (prerenal azotemia) from intrinsic kidney injury (e.g., acute tubular necrosis) in the acute care setting. Even our most common and fundamental goal in resuscitation—improvement in the arterial pressure—does not necessarily correlate with improved cardiac output and, therefore, does not necessarily reflect improved perfusion.

Once the limitations of the physical examination were realized, advanced resuscitation techniques for patients in shock shifted to using cardiac filling pressures. When the left ventricle is underfilled, an increase in preload brings on a large increase in stroke volume, and the patient is said to be volume responsive. When the left ventricle is closer to maximum end-diastolic volume, the increase in stroke volume is minimal for the same increase in preload guide to fluid therapy. The use of filling pressures makes theoretic sense because, as indicated by physiology and the Frank-Starling curve (**Fig. 1**), ventricular pressures are directly proportional to ventricular volume until they reach a certain point at which this relationship is lost. Therefore, the goal during resuscitation is to administer intravenous fluids to optimally fill the left ventricle, which will increase the stroke volume, but not overfill it, which could result in deleterious side effects such as pulmonary edema. When these filling pressures are interpreted randomly, they are known as static measurements and are thought to be a direct reflection of the ventricular pressure and hence the volume of the cardiac chambers.

Central Venous Pressure

Central venous pressure (CVP) is the most popular of the static pressures and continues to be recommended in resuscitative

TABLE 1: Assessing of the volume status (static and dynamic measurement).

Static measurement	***Dynamic measurement***
• Mean arterial pressure	• Pulse pressure variation (PPV) or stroke volume variation (SVV)
• Central venous pressure	• IVC distensibility index (IVC DI)
• Pulmonary artery occlusion pressure	• End-expiratory occlusion test
• Mixed venous oxygen saturation	• Passive leg raise
• Mixed venous PCO_2	• *Limitations of dynamic indices*: *To predict accurate volume responsiveness by IVC DI, PPV, or SVV, methods the patient must be: Mechanical ventilated tidal volume of at least 8 mL/kg of ideal body weight, no spontaneous breaths of the patient, no cardiac arrhythmias*
• Arterial pH base excess and HCO_3	• *The passive leg raise (PLR) is the only dynamic index to date that has the ability to predict the response to fluids in a spontaneously breathing patient (no need to mechanically ventilate the patient*)
• Echocardiographic parameters: IVC size, LVEDP	
Hemodynamic monitors	
• Invasive monitors	Pulmonary artery catheters (PAC)
• Minimally (less) invasive monitors	• LiDCO, PiCCO (calibrated transpulmonary thermodilution) • Flotrac, LiDCO rapid (noncalibrated)
• Noninvasive monitors	• USCOM (ultrasonic cardiac output monitors) • NICOM (noninvasive cardiac output monitor) • Bioreactance • Bioimpedance

(IVC: inferior vena cava; LVEDP: left ventricular end-diastolic pressure)

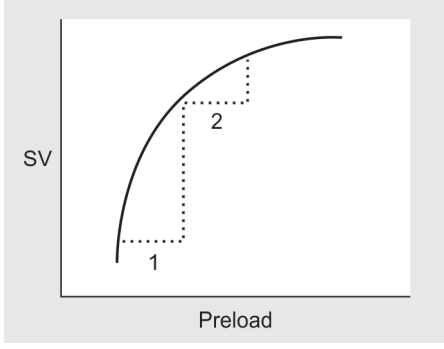

FIG. 1: Frank-Starling relationship of the heart. When the left ventricle is underfilled (1), an increase in preload brings on a large increase in stroke volume, and the patient is said to be volume responsive. When the left ventricle is closer to maximum end-diastolic volume (2), the increase in stroke volume is minimal for the same increase in preload.

protocols and guidelines. Despite these recommendations, the reliability of CVP for guiding fluid resuscitation is controversial because of variations in patients' physiologies (e.g., valvular pathology and right ventricular dysfunction) as well as persistent inaccuracy when it is used as a predictor of response to a volume bolus. An additional limitation to use of the CVP is that it requires insertion of a central venous catheter, which is invasive, and its placement is not readily possible in all emergency departments. Another example of a static measurement of volume status is the estimation of right atrial pressure, based on an ultrasound image of the absolute size of the inferior vena cava (IVC) and its measured respiratory variation. The IVC can be used to estimate right atrial pressures and, by indirect correlation, the CVP, which is the specified target in early goal-directed therapy. Ultrasound scan is an attractive hemodynamic monitor because it is noninvasive, rapid, and reproducible. Although there is debate as to its accuracy when predicting fluid responsiveness, it can be a useful measure when used as part of a comprehensive resuscitative protocol.

Mixed Central Venous Oxygen Saturation

The oxygen content (CaO_2) of the arterial blood coming out from left ventricle to aorta is determined by following formula:

$$CaO_2 = (1.34 \times Hb \times SaO_2) + (0.0003 \times PaO_2)$$

Where SaO_2 is the arterial oxygen saturation and PaO_2 is the partial pressure of oxygen in arterial blood. In optimum condition, the CaO_2 is about 20 mL/100 mL of arterial blood which is distributed to the different part of body. In steady state, about 25% of delivered oxygen is utilized by the different body tissues and deoxygenated blood is returned to right atrium and pulmonary artery. The saturation of this deoxygenated blood in pulmonary artery is termed mixed venous oxygen saturation (SvO_2). Nowadays, as pulmonary artery catheter (PAC) is not used commonly in ICU or ER, sampling of central venous catheter is done as surrogate of SvO_2 and is termed central venous oxygen saturation ($ScvO_2$). $ScvO_2/SvO_2$ represents the balance between the tissue demand and the tissue utilization of oxygen. The acceptable value of SvO_2 in resting state is 75–80%.

The $ScvO_2$ measures the saturation of blood in SvC unlike in SvO_2 which measures the mixed blood from both IVC and SVC In pulmonary artery. As the splanchnic oxygen extraction is normally lower than the brain; the oxygen saturation of $ScvO_2$ is 2–3% <SvO_2. Steady state $ScvO_2$ is 65–70%. $ScvO_2$ can be continuously measured and monitored during resuscitation by infrared oximetry based on mass spectrophotometry

using special proprietary central venous catheters available in market. There are various factors which alter $SvO_2/ScvO_2$ value (**Table 2**). Achieving $ScvO_2 > 70\%$ during septic shock resuscitation has been recommended as a part of early goal-directed therapy and has been associated with 16% increased survival when compared to control group. Later studies and evidences have, however, questioned this rationale and failed to find any significant improvement in the outcome.

Arterial Blood Pressure

Arterial blood pressure (ABP) is the pressure generated by the interaction of cardiac output with the arterial wall resistance. As the cardiac output is ejected from left ventricle, it travels downstream from aorta to different arterial branches, arterioles, and metarterioles perfusing different organs. Hence, ABP has been used traditionally as a marker of global tissue perfusion. During resuscitation in emergency room, usually we target mean ABP of > 65–70 mm Hg. In certain condition due to altered physiology and hemodynamic, different mean arterial pressure (MAP) is targeted (**Table 3**). Routinely, noninvasive blood pressure is measured in patients but in shock state they are unreliable; hence direct blood pressure measurement by placing indwelling arterial catheter in a peripheral artery is preferable during shock resuscitation. It provides beat-to-beat display of characteristic arterial pressure waveforms and values. The arterial catheter is commonly placed in radial or femoral artery. Femoral artery catheter is recommended when noninvasive cardiac output measurement is planned. The indwelling catheter is connected to monitor through tubing and transducer assembly. Transducer is the mainstay of the system and should be calibrated ("zeroing") to the ambient pressure at the ipsilateral midaxillary line fourth intercostal space. Transducer converts mechanical energy of the pulse wave into electrical waves which are transmitted to and displayed on the monitor. The waves must be interpreted with corresponding electrocardiogram (ECG) display.

Interpretations: *The arterial wave may be displayed underdamped (causes may be long tubing or high doses of vasopressors) or overdamped (causes may be bubbles, clot, or kinking of the tubing) or errors in system. This will display incorrect systolic/diastolic pressure value but mean pressure will be correct. The beat-to-beat variation in ABP plethysmography with breathing phases happens due to heart lung interaction. In a spontaneously breathing patient at end inspiration, there is decrease in left ventricular stroke volume which is displayed as decreased systolic blood pressure (SBP) while during positive pressure ventilation there is increased SBP value in plethysmograph at end inspiration. Any exacerbation of these variations in display usually indicates hypovolemic state and fluid challenge must be given.*

In monitors displaying dynamic parameters, it is possible to measure these variations and these are termed *systolic pressure variation (SPV) and pulse pressure variation (PPV). SPV variation of 15% and PPV variation of >12% again signify hypovolemia.*

TABLE 2: Common conditions altering mixed venous oxygen saturation.

Factors increasing $SvO_2/ScvO_2$	*Factors decreasing $SvO_2/ScvO_2$*
Increase tissue oxygen supply: • Vasodilatory shock • Hyperbaric oxygen therapy	*Decrease tissue oxygen supply*: • Cardiogenic shock • Hemorrhagic shock • Severe anemia
Decrease tissue oxygen utilization: • Anesthesia • Hypothermia • Cytopathic hypoxia	*Increase tissue oxygen utilization:* • Hyperthermia • Shivering • Exercise • Septic shock

($ScvO_2$: central venous oxygen saturation; SvO_2: venous oxygen saturation)

TABLE 3: Mean blood pressure (MAP) targets during resuscitation in special clinical conditions

Higher MAP target (85–90 mm Hg)	*Lower MAP target (55–60 mm Hg)*
Traumatic brain injury	Polytrauma (damage controlled resuscitation)
Cerebrovascular accident	Hemorrhagic shock
Chronic hypertension	
Hypertensive nephropathy	
Eclampsia	

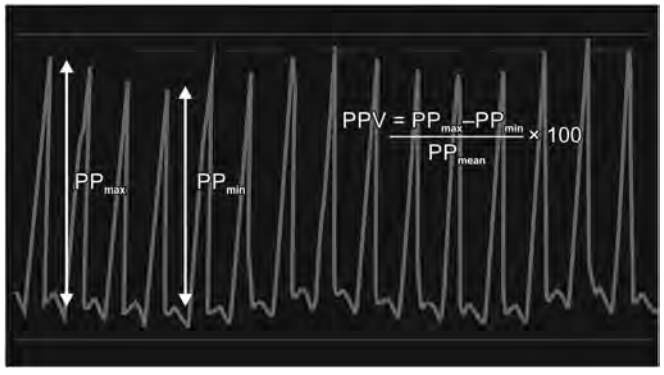
DYNAMIC METHODS OF VOLUME ASSESSMENT AND ITS LIMITATIONS

The counterpart to static measurement of volume status is dynamic measurement. Dynamic measurements differ from static measurements because they involve the monitoring of hemodynamic followed by an intervention (e.g., fluid bolus). Although dynamic measurements are better than static markers in predicting volume responsiveness, their routine use in the emergency department has two major limitations. First, dynamic measurements require the concurrent use of monitoring devices that can detect increases in stroke volume (e.g., ultrasound scan) during the assessment. Second, most dynamic assessments require that patients be intubated and mechanically ventilated. This method is chosen because mechanical ventilation increases intrathoracic pressure, producing a significant respirophasic variation in preload, which mimics a fluid bolus, with venous return being at a minimum at end-inspiration (highest intrathoracic pressure) and a maximum at end-expiration (lowest intrathoracic pressure). *Limitations of dynamic indices—to predict accurate volume responsiveness by IVC DI, PPV, or SVV, methods the patient must be mechanical-ventilated tidal volume of at least 8 mL/kg of ideal body weight, no spontaneous breaths of the patient, and there should be no cardiac arrhythmias. The passive leg raise (PLR) is the only dynamic index to date that has the ability to predict the response to fluids in a spontaneously breathing patient (no need to mechanically ventilate the patient).*

Pulse Pressure Variation and Stroke Volume Variation

Pulse pressure variation, a well-studied dynamic marker of cardiac output, measures the change in pulse pressure (PP) throughout a respiratory cycle on a mechanical ventilator

(**Fig. 2**). An arterial line is required to measure PPV, because systolic and diastolic measurements must be taken at specific points in the respiratory cycle. Once these measurements are recorded, the PPV can be calculated. Specialized monitors automatically perform both the measurements and the calculations in real time. SPV uses the same principal as PPV, except only the systolic pressures are measured at specific times in the respiratory cycle; therefore, it is not as reliable as PPV. PPV is a well-validated predictor of fluid responsiveness and can be applied in variety of clinical settings (emergency department, ICU, and operating room). A PPV > 12.5% suggests that a patient's cardiac output would increase when given a fluid bolus. Conversely, a PPV < 12.5% suggests that giving a fluid bolus would neither increase cardiac output nor improve hemodynamic status. The use of PPV for volume responsiveness in the emergency department has several limitations. One limitation is that this measurement reflects a patient's hemodynamic status at only one point in time, so PPV must be calculated several times during resuscitation, especially before administering a fluid bolus.



[PP_{max}: maximum pulse pressure; PP_{mean}: mean pulse pressure; PP_{min}: minimum pulse pressure (calculated by device)]

FIG. 2: Calculation of PPV using the tracing from an arterial catheter monitor.

Inferior Vena Cava Distensibility Index

The IVC distensibility index (IVC DI) is another commonly used dynamic assessment to determine fluid responsiveness. Ultrasound scan is used to assess the change in size of the IVC during a respiratory cycle in a mechanically ventilated patient. As was the case for PPV, positive intrathoracic pressure is essential to use this technique accurately. The benefit of IVC DI is that it is noninvasive (no arterial line is required) and is reproducible multiple times at the bedside. During the delivery of a mechanical breath, a patient's intrathoracic pressure increases, and venous return decreases, resulting in IVC dilation (an increase in the diameter of the vessel). When the mechanical breath is released, the intrathoracic pressure decreases, and the IVC returns to its normal diameter. The degree of IVC diameter change is measured with ultrasound scan and then the IVC DI is calculated (**Fig. 3**). Many findings suggest that IVC DI is a useful bedside tool for assessing the status of the intravascular volume for patients undergoing fluid resuscitation. There has been, however, variation in the agreed cut off values of the IVC DI across studies. Some studies found a cut off of 12%, but others proposed values as high as 36%. Limitations of measuring the IVC DI are similar to those described for PPV. There is also debate in the literature on what level of the IVC is the best site for measurement. The location of measurement (e.g., at the level of the hepatic or renal vein) can affect the recorded value of the IVC diameter.

End-expiratory Occlusion Test

The end-expiratory occlusion (EEO) test is a relatively new technique for dynamic assessment of fluid responsiveness in mechanically ventilated patients. The EEO test is executed by placing a 15-second expiratory hold on the ventilator (at the end of expiration). A prolonged state of increased preload is created by holding the positive pressure ventilation at it its lowest pressure, mimicking a fluid challenge. This test has the advantage of being able to assess fluid responsiveness even in the presence of arrhythmias, a notable difference from the techniques previously discussed. This technique requires concurrent measurement of stroke volume or cardiac output.

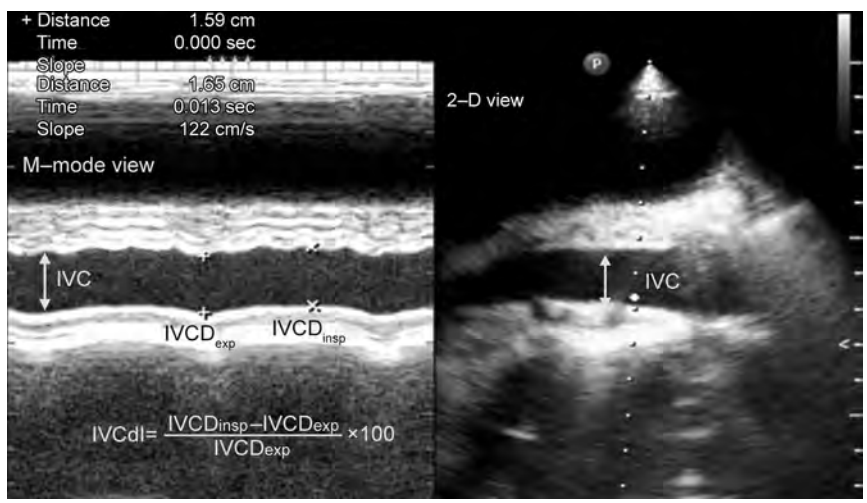


FIG. 3: Inferior vena cava (IVC) distensibility index. Calculation of IVC DI using M-mode ultrasound scan. $IVCD_{exp}$-IVC diameter at end-expiration; $IVCD_{insp}$-IVC diameter at end-inspiration.

FIG. 4: Passive leg raising maneuver. The process begins with the head of the bed and the patient's trunk elevated to approximately 45, at which time baseline parameters are recorded. The patient is then quickly laid back, with head and trunk flat and legs raised to 45, allowing the venous blood pooled in the legs to return to the heart quickly, creating an autologous transfusion. Parameters should be rerecorded 30–90 seconds after raising the legs to evaluate for volume responsiveness.

Although this is a notable limitation, several monitoring approaches have been reported, such as measuring cardiac output by thermodilution or waveform analysis. When such monitoring is available, if the stroke volume or cardiac output during the final 5 seconds of the expiratory hold is 5% higher than the premaneuver value, the patient will likely respond to the administration of a fluid bolus.

Passive Leg Raise

The dynamic techniques described above have one thing in common—the patient must be mechanically ventilated. Although these dynamic indices are fairly well validated, it is shown in **Figure 3** are IVC distensibility index. Calculation of IVC DI using M-mode ultrasound scan. IVC Dexp, (IVC diameter at end-expiration); IVC Dinsp, (IVC diameter at end-inspiration). Assessing volume status would be helpful to have a test that is valid for spontaneously breathing patients. *The passive leg raise (PLR) is the only dynamic index to date that has the ability to predict the response to fluids in a spontaneously breathing patient* (**Fig. 4**). The PLR technique mobilizes pooled venous blood in the lower extremities (~150–300 mL) to the central circulation as an autologous and reversible fluid bolus. In this way, extrinsic fluids are not necessary, and patients do not receive an unnecessary fluid bolus if they are not volume responsive. The PLR is performed by first measuring the baseline stroke volume or cardiac output, followed by remeasuring it 30–90 seconds after lifting the patient's lower extremities. A 10–15% change in stroke volume or cardiac output is an indicator that the patient will respond to exogenous fluid administration. Another benefit to this test is that it has been validated for patients with cardiac arrhythmias (e.g., atrial fibrillation). Similar to the EEO test, studies have used several monitoring systems, including bedside echocardiography, arterial waveform analysis, and bioreactance, to determine change in cardiac output or stroke volume.

DEVICES FOR HEMODYNAMIC MONITORING

The methods described in this chapter permit the clinician to deliver fluid boluses in a goal-directed manner. Unfortunately, many of these methods require the clinician to return to the bedside repeatedly to assess the patient's volume status. This requirement can be challenging and impractical in a busy emergency department. Devices that automatically monitor and display a patient's hemodynamic information are desirable because they allow the use of nurse-directed resuscitation protocols while the clinician leaves the bedside temporarily. Another benefit of such monitors is as an early warning system that alerts clinicians to changes in a patient's hemodynamic status. These devices display hemodynamic information such as stroke volume, cardiac output, and stroke volume variation (SVV). SVV is the amount of variation that occurs over a respiratory cycle in mechanically ventilated patients. It is similar in concept to PPV, except that a device is used to estimate the actual stroke volume rather than using the pulse pressure as a surrogate. Similar to PPV, SVV has been validated across multiple situations as a predictor of fluid responsiveness. An SVV measurement >11.5% suggests that giving a fluid bolus would be beneficial. Conversely, an SVV <11.5% suggests that a fluid bolus would not improve the patient's hemodynamic and might cause harm (e.g., pulmonary edema). Although PPV and SVV are very similar, PPV seems to slightly outperform SVV and requires the same conditions for validity as do PPV and IVC DI. *Two main categories of devices provide hemodynamic data—(1) invasive; and (2) noninvasive monitors* (**Table 1**). Each type has benefits and disadvantages, and neither is perfect. The choice of device depends on several factors.

INVASIVE HEMODYNAMIC MONITORS

Pulmonary Artery Catheter (PAC)

The PAC measures stroke volume and cardiac output by measuring the amount of time, it takes for a known quantity of fluid to traverse the right side of the heart. The longer it takes, the worse the stroke volume. One of the major criticisms of the PAC is its invasive nature, given that it must be inserted through the superior vena cava, into the right side of the heart, across the tricuspid and pulmonary valves, and into the pulmonary artery. Major complications associated with the PAC include pneumothorax, arterial puncture, and hematoma—complications associated with the placement of any central line. Complications specific to PAC include ventricular arrhythmias, ventricular rupture, and pulmonary artery rupture.

PiCCO and LiDCO systems

Two commercially available devices have monitoring principles similar to the PAC but are less (minimally) invasive—the PiCCO and LiDCO systems**.** These devices use an arterial catheter to perform pulse-contour analysis, which is a technique to determine hemodynamic parameters from an arterial waveform. Both devices are periodically calibrated to improve accuracy. Calibration is performed by injecting a fluid into a venous line (ice-cold saline for the PiCCO and lithium for LiDCO) and measuring the fluid in the arterial circulation after it traverses the heart.

The PiCCO system measures the degree of temperature elevation of the saline injected, and the LiDCO system measures the dilution of the lithium that was injected; these measurements are made via a sensor in an arterial line. Monitoring stroke volume and cardiac output with these monitors helps the clinician determine whether a hemodynamically unstable patient would benefit from a fluid bolus, because the response to fluid bolus can be measured. For example, an increase in either parameter by 10–15% after a fluid bolus suggests the patient was volume responsive as part of the hemodynamic resuscitation.

However, failure to increase the stroke volume or cardiac output by 10–15% after a fluid bolus suggests that the hemodynamically unstable patient would not improve with fluid administration and should perhaps receive vasopressors or an inotrope. The PiCCO device is considered a minimally invasive device because it requires the placement of a central venous catheter (the tip of which resides at the junction of the superior vena cava and the right atrium) and a femoral arterial line that will detect changes in saline temperature distally.

The limitations of the PiCCO device include decreased accuracy in patients with low-flow states (e.g., severe heart failure), valvular regurgitation, intracardiac shunts, and aortic aneurysms. The LiDCO device is somewhat less invasive than the PiCCO in that it requires placement of only a peripheral intravenous line and a radial arterial line (a central venous catheter can be used if it is already available). The major limitations to the accuracy of the LiDCO device are similar to those associated with the PiCCO device, including low flow states, valvular regurgitation, and intracardiac shunts.

A limitation specific to the LiDCO device is its use of lithium dye. Although this dye is safe for most patients, it should be avoided in certain situations, including patients who weigh <40 kg, pregnant patients, and those taking lithium as a medication. A third minimally invasive system is the FloTrac/Vigileo system. This system differs from the monitors discussed above in that it requires placement of only an arterial catheter.

The monitor displays hemodynamic data such as stroke volume, cardiac assessing volume status output, and SVV by analyzing arterial waveforms and pressures and integrating this information into a complex algorithm based on the patient's demographics (height, sex, and weight). This device does not require external calibration, and its manufacturer claims that the system is continuously fine tuning and autocalibrating each minute. Autocalibration is based on cadaveric studies, and its accuracy has been questioned. The device has also been found to be inaccurate in certain clinical conditions (e.g., in patients with rapidly changing cardiac output or high cardiac output states).

Several studies found these minimally invasive monitors to be accurate. No single device, however, has gained widespread acceptance in emergency medicine; one of the major reasons for this is their invasiveness, requiring at least an arterial line (and a central line in the case of the PiCCO). Despite their limitations, these devices provide clinicians with hemodynamic monitoring that is otherwise difficult to achieve with traditional methods.

NONINVASIVE HEMODYNAMIC MONITORS

Invasive catheters have the potential to create complications, such as discomfort during placement, infection, and bleeding, so a noninvasive hemodynamic monitor is an appealing concept in the emergency department. *Two examples of completely noninvasive monitors are the ultrasonic cardiac output monitor (USCOM) and the noninvasive cardiac output monitor (NICOM).*

USCOM

The USCOM is a small probe that can be applied intermittently to a patient's chest or suprasternal notch whenever hemodynamic information is needed. The device works by providing a continuous Doppler signal, which measures the velocity of blood flow in the aorta (parasternal view) or the pulmonary blood flow (suprasternal notch). This information is used in conjunction with the patient's height to calculate several hemodynamic parameters, including stroke volume and cardiac output. Beyond the noninvasive nature of this device, another advantage is that bedside nurses can obtain the information for use in resuscitative algorithms.

The USCOM seems to be a promising addition to the emergency department armamentarium, although there are *several limitations* to its general use. The device can easily be applied to a patient, but obtaining an adequate and accurate Doppler signal can be a challenge for novice users and altogether impossible in a percentage of certain populations (e.g., the elderly). Another limitation is that hemodynamic information is not obtained continuously but rather only when the device is applied; this means that crucial information might be missed in patients with a rapidly changing hemodynamic state. Another criticism of the USCOM is the assumption that two patients with the same height will have the same hemodynamic changes when faced with a similar stressor, which might not actually be true. A detailed discussion of this concept is beyond the scope of this chapter, but it is a valid limitation that should be considered.

NICOM: Bioreactance

The NICOM requires the placement of four adhesive electrodes on the patient's anterior thorax. These electrodes measure changes in the frequency of electrical currents as they cross the thorax, converting this information into relevant hemodynamic information, including stroke volume, cardiac output, and SVV. Newer versions of this device incorporate the use of a passive leg raise maneuver to determine volume responsiveness. This device has been found to correlate well with more invasive means of hemodynamic monitoring, such as the PAC. The greatest clinical benefit of this device is that it provides continuous hemodynamic monitoring noninvasively for critically ill patients. Rapidly changing hemodynamic is more likely to be detected with this monitor compared with monitors that use intermittent measurements. Additionally, little training is required to set up and use the device because the sensors are applied to the thorax and do not require constant manipulation, minimizing sampling errors between readings. More clinical trials are needed to determine whether this device improves patient outcomes, but it is a promising technology for continuous hemodynamic monitoring in the emergency department.

SUMMARY

Shock is a physiologic state associated with high morbidity and mortality rates. Emergency physicians have a major impact on patient survival. The clinician has several tools available to evaluate volume status. Each modality has its benefits and limitations but, to date, no one test can indicate with 100% accuracy which patients will be truly volume responsive. Although the search for the Holy Grail of a perfect intravascular monitor continues, we must remember the importance of early, aggressive, and goal-directed interventions for patients in shock. We, therefore, must be astute clinicians and integrate the multitude of variables available at the bedside to assist in our decision making; this is truly the art of medicine. Finally, there is no substitute for the most important intervention—the frequent presence of the physician at the patient's bedside.

CHAPTER

Arterial Blood Gas Analysis

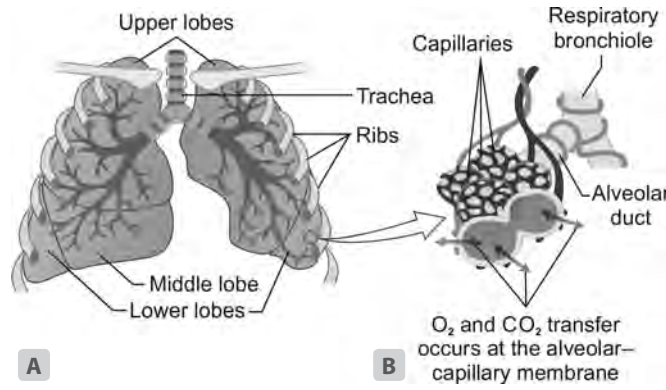
Devendra Richhariya, Bhawana Sharma

INTRODUCTION

Arterial blood gas (ABG) analysis is a common and useful tool in critically ill patient of emergency department. It gives information on oxygenation status and acid-base disorders. ABG measures the oxygen tension (PaO_2), oxyhemoglobin saturation (SaO_2), acidity (pH), carbon dioxide tension ($PaCO_2$), and bicarbonate (HCO_3) concentration in arterial blood. Some blood gas analyzers also measure the methemoglobin, carboxyhemoglobin, and hemoglobin levels. The newer available machines measure lactate and electrolytes too. ABG analysis provides immense information which helps in management of the critically ill patients. Correct interpretation is the key for usefulness of this diagnostic tool. A thorough understanding of acid–base balance is mandatory. There are three basic approach used to quantify acid-base status are, HCO_3 in relation to CO_2, standard base excess (SBE), and standard ion difference (SID). Important for the emergency physician to know the basics of pulmonary gas exchange and acid-base balance along with normal values of blood gases, indication contraindication and precaution while taking the arterial blood for evaluation.

BASICS OF PULMONARY GAS EXCHANGE

Pulmonary gas exchange is transfer of oxygen from atmosphere to blood and tissue (oxygenation) and carbon dioxide from blood to atmosphere. The gas exchange takes place between alveoli and capillaries as they are in close contact (alveolar-capillary membrane) and thus O_2 and CO_2 able to diffuse. ABG measures the effective gas exchange in form of partial pressure of gas (PaO_2/$PaCO_2$). Partial pressure is contribution of any gas within the gas mixture (air). When gas dissolves in blood, the amount dissolved depends on partial pressure (PaO_2-partial pressure of oxygen in arterial blood). Gas moves from higher partial pressure area to low partial pressure (so at alveolar-capillary membrane oxygen moves from alveoli to blood and carbon dioxide moves from capillary to alveoli until partial pressure is equal) (**Figs. 1A** and **B**). At sea level total pressure of gases in atmosphere is 760 mm of Hg and oxygen is 21% of all gases so partial pressure of oxygen (21% of total pressure) is 160 mm Hg. Carbon dioxide is very small fraction of air so partial pressure of carbon dioxide is negligible.



FIGS. 1A AND B: (A) Normal lung; (B) pulmonary gas exchange.

Carbon Dioxide Elimination

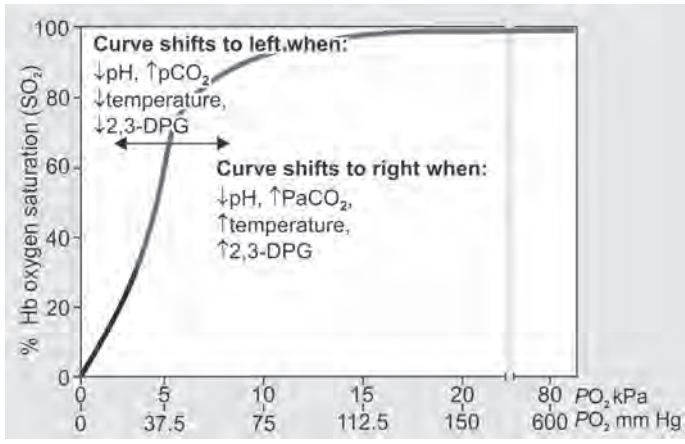
Carbon dioxide elimination (from blood stream to alveoli) is very efficient and uncomplicated and depends on *alveolar ventilation* (total air transported from alveoli to atmosphere). Ventilation is regulated by respiratory center situated in brain stem. Normally, lung is able to maintain normal $PaCO_2$ in high carbon dioxide producing situation such as sepsis. High $PaCO_2$ (hypercapnia) signifies reduced alveolar ventilation.

Hemoglobin Oxygen Saturation

Oxygenation is more complex than carbon dioxide elimination. Almost all oxygen molecules are attached to hemoglobin, so amount of oxygen in blood depends on hemoglobin concentration in blood and saturation of hemoglobin with oxygen (sO_2). PO_2 only measures unbound and free oxygen molecule. PO_2 is not a measure of the amount of O_2 in blood—ultimately, the SaO_2 and the Hb concentration determine the O_2 content of arterial blood.

Oxyhemoglobin Dissociation Curve

Oxygen in blood depends on hemoglobin concentration and sO_2. PO_2 is driving force for oxygen molecule to bind with hemoglobin. So, oxyhemoglobin dissociation curve shows sO_2 at any given PO_2 (generally we can say higher the PO_2—higher the sO_2). But curve is not linear, *flat part*



(2,3-DPG: 2,3-diphosphoglycerate)

FIG. 2: *Oxyhemoglobin dissociation curve*. The curve defines the relationship between PO_2 and the percentage saturation of hemoglobin with oxygen (sO_2). Note the sigmoid shape: It is relatively flat when PO_2 is >80 mm Hg (10.6 kPa) but steep when PO_2 falls below 60 mm Hg (8 kPa).

of the curve shows that PO_2 has little effect on sO_2 over this range. While the *steep part of curve* shows that even small change in PO_2 make significant change in sO_2 over this range (**Fig. 2**).

Alveolar Ventilation and PaO_2

With above discussion, we know PaO_2 regulates SaO_2. But SaO_2 is determined by three factors alveolar ventilation, ventilation perfusion V/Q match, and concentration of oxygen in inspired air (FiO_2).

- *Alveolar ventilation:* With oxygen moves rapidly from alveoli (PO_2) to blood, higher the PaO_2. Increase in alveolar ventilation causes more carbon dioxide elimination (high PO_2 presence) while decrease in alveolar ventilation signifies accumulation of CO_2 at expense of oxygen and fall of Po_2.
- *Ventilation perfusion V/Q mismatch:* In the presence of any lung disease, not all alveoli are well perfused by blood and not all blood flowing through lung gets well-ventilated alveoli. This issue is known as *ventilation perfusion V/Q mismatch.* So, if any amount of blood passing through the poorly ventilated part of lung due to collapse or consolidation, will get less oxygen and more CO_2 than normal and this is called *shunting.* In ventilation perfusion mismatch condition, low PaO_2 and low SaO_2 occur but $PaCO_2$ will not rise till overall alveolar ventilation is maintained.
- *FiO_2 and oxygenation:* Fraction of oxygen in inspired air (% of oxygen in room air is 21%). In any disease process, exact FiO_2 requirement can be fulfilled by supplemental oxygen by using appropriate delivery system.

DISORDERS OF GAS EXCHANGE

Hypoxia is a state in which tissue receives the inadequate oxygenation (cell is not getting enough oxygen). *Hypoxemia* is a state in which O_2 content of arterial blood is reduced (not enough oxygen in blood).

- *Type 1 respiratory impairment*: It is characterized by low PaO_2 and normal or low $PaCO_2$ (due to compensatory hyperventilation). V/Q mismatch is usual mechanism behind this. Pneumonia, acute asthma pulmonary embolism, acute respiratory distress syndrome, pneumothorax, fibrosing alveolitis pulmonary edema, and chronic obstructive pulmonary disease are common causes. High FiO_2 requirements, lactic acidosis and signs of organ dysfunctions (confusion drowsiness hypotension coma) are the markers of severity.
- *Type 2 respiratory impairment*: It is characterized by high $PaCO_2$ (hypercapnia) due to alveolar hypoventilations. Acute rise of $PaCO_2$ gives rise to accumulation of acid in blood. Chronic obstructive pulmonary disease, opiate/benzodiazepine toxicity, exhaustion, inhaled foreign body, flail chest injury, neuromuscular disorders, kyphoscoliosis, and obstructive sleep apnea are the common causes.
- *Hyperventilation*: It leads to $PaCO_2$ (hypocapnia) and resulting raised blood pH. Perioral/extremities tingling, light headedness, and syncope are the common symptoms. Anxiety (psychogenic), pain, hypoxemia, fever, salicylate alicylateecentral entralatee the common sy, and hepatic cirrhosis are the common causes.

BASICS OF ACID-BASE BALANCE

Concentration of free hydrogen ion H^+ in a solution (nmol/L) refers to acidity or alkalinity. H^+ concentration can be expressed as nmol/L or as pH (power of hydrogen). Solution with high hydrogen ion (low pH) acidic and low hydrogen ion (high pH) is alkaline. A negative logarithmic scale expresses the correlation of pH and H^+ concentration (**Table 1**). Normal pH of the human blood is 7.35–7.45 (<7.35 is acidemia and >7.45 is alkalemia). Any process which lowers of pH is acidosis and any process which increases the pH is alkalosis.

Maintaining the Acid-base Balance

- *How H^+ generates in our body*: Generation of energy, fats, and sugars after breakdown generates CO_2 and forms carbonic acid when CO_2 dissolved in blood. Protein

TABLE 1: Correlation of pH and H^+ concentration.

pH	*H^+ nEq/L*
7.70	20
7.60	25
7.50	32
7.40	40
7.30	50
7.20	63
7.10	79
7.00	100
6.90	126

- For H^+ concentration sequentially multiply 40 nEq/L with between pH of 7.4–7.8
- For H^+ concentration sequentially multiply 40 nEq/L with between pH of 6.8–7.4

metabolism produces hydrochloric acid sulfuric acid and other metabolic acids. H^+ must be removed from our body to maintain normal pH. Failure to maintain normal pH leads to inefficient cellular reaction and untimely death.

- *How H^+ removal from our body*: *By respiratory mechanism,* lungs are responsible for excretion CO_2. Our breathing is altered as the CO_2 production is altered. *By renal mechanism,* our kidneys are responsible for the excretion of metabolic acids. Kidneys excrete H^+ and absorb HCO^3. Respiratory and renal system work simultaneously to maintain the pH. If one system overburdened, another system automatically adjusts. If kidneys fail to excrete the H, ventilation increased to exhale more CO_2. *This is known as compensation.* Important to know that respiratory compensation happens in minute to hours while renal compensation takes days to develop.

DISTURBANCE OF ACID-BASE BALANCE

Normal values of gases in arterial blood (**Table 2**) and nomenclature related to acid-base disorder (**Table 3**) such as acidemia, alkalemia, acidosis, alkalosis, respiratory/metabolic, and simple/mixed disorder are important to know before analysis of ABGs. Common acid-base disorders and their cause are shown in **Tables 4** and **5**. Nomogram is the alternative way to know the disturbance in acid-base balance simple or mixed acid-base disorder (**Fig. 3**) (pH, H^+, and $PaCO_2$ is plotted, if values fall outside designated areas, indicate mixed acid-base disorder).

CONCEPTS IN ACID BASE DISORDERS AND FORMULAS

Concepts in acid-base disorders and formulas used in interpretation of arterial blood gas are given in **Boxes 1** to **4**.

STEPS IN THE INTERPRETATION OF ARTERIAL BLOOD GAS

After understanding the concepts and formulas used in interpretation of arterial blood gas, stepwise approach is used for evaluation of any arterial blood gas disorder **Box 5**.

TABLE 2: Normal values of gases in arterial blood.

	Normal range	*For calculation*
pH	7.34–7.45	7.4
pCO_2	35–45	40
HCO_3	22–26	24
PO_2	≥80	≥95

STRONG ION DIFFERENCE APPROACH VERSUS TRADITIONAL APPROACH

The Stewart or strong ion approach to acid-base disturbances has gained acceptance among many intensivists because of perceived weaknesses of the traditional approach in the evaluation of patients with critical illnesses. As per Stewart approach, dissociation (pH) is governed by laws of physical chemistry.

- *Law of conservation of mass*: Amount of substance in a solution remains constant unless added or removed or generated or destroyed by chemical reaction.
- *Law of conservation of electric charge*: Sum of all cations always equal sum of all anions.

TABLE 3: Nomenclature for acid-base disorders.

Acidemia	Fall in arterial pH
Alkalemia	Rise in arterial pH
Acidosis	A process that acidifies body fluids (increased H^+ concentration) and if unopposed leads to fall in pH. This can be caused by a fall in the serum bicarbonate (HCO_3) concentration and/or an elevation in pCO_2
Alkalosis	A process that alkalinizes body fluids (decreased H^+ concentration) and if unopposed leads to rise in pH. This can be caused by an elevation in the serum HCO_3 concentration and/or a fall in pCO_2
Metabolic disorder	*Primary change in HCO_3 (increased in alkalosis and reduced in acidosis)*
Respiratory disorder	*Primary change in H_2CO_3, i.e., CO_2 (increased in acidosis and reduced in alkalosis)*
Simple acid-base disorder	The presence of a single primary disorder with the appropriate respiratory or renal compensation
Mixed acid-base disorder	It means simultaneous presence of more than one acid-base disorder. Mixed acid-base disorders can be suspected from the patient's history, from a lesser- or greater-than-expected compensatory respiratory or renal response, and from analysis of the serum electrolytes and anion gap. *Always correlate with history*
Primary disorders not only change acid-base equilibrium directly, but also set in motion secondary compensatory changes in the other member of the pCO_2-HCO_3^- pair. It requires normal lungs and kidneys. Remember that compensation never returns the pH fully back to normal	

TABLE 4: Primary changes in acid-base disorder and compensatory response.

Disorder	*Primary disturbance*	*Compensatory Response*	*Mechanism involved in compensatory response*
Metabolic acidosis	Decrease in HCO_3	Decrease in pCO_2	Hyperventilation
Metabolic alkalosis	Increase in HCO_3	Increase in pCO_2	Hypoventilation
Respiratory acidosis	Increase in pCO_2	Increase in HCO_3	Increased H^+ secretion
Respiratory alkalosis	Decrease in pCO_2	Decrease in HCO_3	Decreased H^+ secretion

TABLE 5: Important causes of various acid-base disorders.

(AG) Metabolic acidosis	*(NAG) Metabolic acidosis*	*Respiratory acidosis*	*Metabolic alkalosis*	*Respiratory alkalosis*
MUDPILERS:	***HARDUPS:***	CNS depression (drugs/CVA)	***CLEVER PD:***	***CHAMPS:***
M = Methanol	H = Hyperalimentation	Nerve damage beyond CNS	C = Contraction	C = CNS disease meningitis, encephalitis, hemorrhage
U = Uremia	A = Acetazolamide	(High spinal cord injury phrenic palsy)	L = Licorice*	H = Hypoxia, hepatic failure and heart failure
D = DKA/Alcoholic ketosis	R = Renal tubular acidosis	Guillain–Barré syndrome	E = Endo: Conn's/ Cushing's/Bartter's*	A = Anxiety
P = Paraldehyde	D = Diarrhea	Airway obstruction	V = Vomiting, NG aspirate	M = Mech ventilators

E = Ethanol/Ethylene glycol	S = Spironolactone	Myopathy, electrolyte disturbances—hypokalemia and hypophosphatemia	P = Posthypercapnia	
R = Rhabdomyolysis/ Renal failure		Neuromuscular disorders—myasthenia gravis, Lambert–Eaton syndrome, aminoglycosides, and colistin	D = Diuretics	
S = Salicylates		Chest wall deformity—kyphoscoliosis, flail chest	* = Associated with high urine Cl levels	

(AG: anion gap; NAG: nonanion gap; DKA: diabetic ketoacidosis; CNS: central nervous system; CVA: cerebrovascular accident; NG: nasogastric)

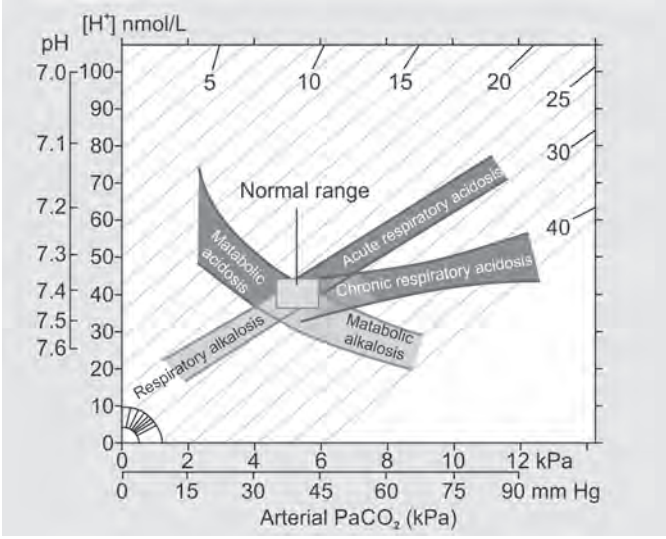

FIG. 3: Nomogram for assessment of acid-base disorder.

BOX 1: The Henderson–Hasselbalch equation.

It shows that the pH is determined by the ratio of the serum bicarbonate (HCO_3) concentration and the pCO_2.

pH = pK + log $(HCO_3)/(H_2CO_3)$
= Kidney/Lung
= [Metabolic/Respiratory]

- **$H^+ = 24 \times pCO_2/HCO_3$ (validity check)** ***Formula 1***

pH and pCO_2 Relationship in Respiratory Disorders:

- $\frac{\Delta H^+}{\Delta PaCO_2}$ **<0.3 – Chronic** ***Formula 2***

>0.8— acute and 0.3–0.8—acute on chronic

- *Law of mass action*: Dissociation equilibrium of all incompletely dissociated substance must be satisfied at all times. According to this approach, HCO_3^- is a dependent variable (**Fig. 4**).

Three mathematically *independent* determinant of blood pH is:

- Strong ion difference (SID)
  SID = $([Na^-] + [K^-] + [Ca^{2+}] + [Mg^{+2}]) - ([Cl^-]) = [HCO_3^-] + [A^-]$
  $SID_a = ([Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}]) - ([Cl^-])$
  $SID_e = [HCO_3^-] + [A^-]$
  Total charges contributed by all nonbicarbonate buffers, primarily albumin, phosphate, and, in whole blood, hemoglobin. *Normal SID is 40–42.*
- Total weak acid buffers (A TOT) = Total A^- and its weak acid $([A^-] + [HA])$
- PCO_2
  SIG = SIDa – SIDe. It Is due to unmeasured anions. It represents SBE.
  - *Metabolic acidosis*: Decrease in SID by addition of strong anions
  - *Metabolic alkalosis*: Increase in SID by additions of strong cations (with weak anions)

Stewart approach is much more cumbersome and may be more prone to error, given its dependence upon multiple measurements of different variables. When measurements obtained from automated blood chemistry devices are used to calculate the *strong ion gap (SIG),* the results can also vary substantially depending upon which device is used. Therefore, the traditional approach in the analysis of all acid-base disturbances is preferred. Moreover, if serum albumin concentration is considered in the traditional analysis of acid-base disturbances, Stewart approach is nonsuperior over the traditional Schwartz-Bartter approach to acid-base disturbances.

BOX 2: Analysis of compensation in acid-base disorders.

- **Metabolic compensation of respiratory disorder:**
  - *Respiratory acidosis:* ***Formula 3***

    ΔHCO_3 = change from 24; ΔpCO_2 = change from 40

    Acute: $\Delta HCO_3^- = 1/10\ (\Delta pCO_2)$ Chronic: $\Delta HCO_3^- = 4/10\ (\Delta pCO_2)$

    Add ΔHCO_3 to 24 (normal HCO_3). Match with HCO_3 on ABG. If two match it is simple respiratory disorder. If calculated HCO_3 is more or less than on ABG, there is primary metabolic alkalosis and metabolic acidosis respectively also
  - *Respiratory alkalosis:* ***Formula 4***

    Acute: $\Delta HCO_3^- = 2/10\ (\Delta pCO_2)$ Chronic: $\Delta HCO_3^- = 5/10\ (\Delta pCO_2)$

    Subtract ΔHCO_3 from 24 (normal HCO_3). Match with HCO_3 on ABG. Similar interpretation as above
- **Respiratory compensations for metabolic disorders:**
  - *Metabolic acidosis:* ***Formula 5***

    Expected $pCO_2 = [(1.5\ HCO_3) + 8] \pm 2$. (Match with ABG pCO_2)
  - *Metabolic alkalosis:* ***Formula 6***

    Expected $pCO_2 = [(0.7\ HCO_3) + 21] \pm 2$ (If ABG pCO_2 is more or less than calculated pCO_2, there is primary respiratory acidosis or alkalosis respectively also)

BOX 3: Anion gap concept.

Normal anion gap is 10 ± 2 mmol/L

- Anion gap = $Na^+ - (Cl^- + HCO_3^-)$ ***Formula 7***

The "normal" anion gap in patients with hypoalbuminemia is about 2.5 mEq/L lower for each 1 g/dL decrease in the plasma albumin concentration from normal

- Corrected AG = Calculated AG + 2.5 (albumin normal i.e., 4 – albumin measured) ***Formula 8***

Raised anion gap acidosis:

Anion gap raised in lactic acidosis (e.g., hypoxemia, ischemia, shock, and sepsis), ketoacidosis (diabetes, starvation, and alcohol excess), renal failure (accumulation of sulfate, phosphate, and urate), poisoning (aspirin, methanol, and ethylene glycol), and massive rhabdomyolysis

If the anion gap is raised, *calculate the osmolal gap* in case of compatible situations

- Osmolal gap = Measured osmolality − Calculated osmolality ***Formula 9***
- S Osm = 2(Na) + BUN/2.8 + Glucose/18 ***Formula 10***

Normal osmolal gap <15 mOsm/L Osmolar gap may be increased in methanol poisoning ethanol poisoning hyperlipidemia chronic renal failure and myeloma

Normal anion gap (hyperchloremic) acidosis:

Predominantly due to loss of HCO_3^-

Non anion gap (NAG) acidosis seen in renal tubular acidosis (types 1, 2, and 4), diarrhea (HCO_3^- loss), adrenal insufficiency, ammonium chloride ingestion, urinary diversion (e.g., ureterosigmoidostomy), and drugs (e.g., acetazolamide)

Check urine anion gap (UAG)—To get clue for site of loss; *renal versus gastrointestinal*

- UAG = (Urine Na^+ + Urine K^+) − Urine Cl^- ***Formula 11***

Negative UAG = (Urine Cl^- >> Urine Na^+ + Urine K^+) = suggestive of GI loss of HCO_3

Positive UAG = (Urine Cl^- < Urine Na^+ + Urine K^+) = suggestive of renal tubular acidosis

If metabolic alkalosis—check spot urinary chloride, urine Cl^- > 20 mEq/L or > 20 mEq/L

Assessment of oxygenation:

It is equally or even more important to assess oxygenation while interpreting the ABG. PaO_2 < 45 mm Hg: Severe, 45–59 mm Hg: Moderate, 60–79 mm Hg: Mild

Always check *PAO_2–PaO_2 gradient* (Where PAO_2 is pressure of alveolar oxygen and PaO_2 is pressure of arterial oxygenation)

Equation for the calculation of alveolar PO_2: (PAO_2)

- $PAO_2 = (760-47) \times FiO_2 - (pCO_2/0.8)$ ***Formula 12***

  $= 150—(pCO_2/0.8)$ or room air. Check on room air if possible

Where 760—barometric pressure at sea level, 47—water vapor pressure, 0.8—respiratory quotient

(A–a) O_2 gradient = PAO_2–PaO_2 (normal: 5–25 mm Hg)

BOX 4: Delta ratio.

Delta ratio (used to assess raised AG acidosis and also assess whether mixed acid-base disorder is present):
Delta ratio = Δ AG/Δ HCO_3 (Δ AG = measured anion gap-normal anion gap Δ HCO_3 = normal HCO_3—measured HCO_3)
Consider normal AG = 12 and normal HCO_3 = 24
Delta ratio = Measured anion gap—12/24—measured HCO_3
Delta ratio value and interpretation:
<0.4—normal anion gap metabolic acidosis
0.4–0.8—mixed-normal anion gap + high anion gap metabolic acidosis
0.8–2—pure high anion gap acidosis
>2—Mixed-high anion gap acidosis + metabolic alkalosis

BOX 5: Steps in interpretation of arterial blood gas.

- ***Perform validity check to assess the consistency of the ABG*:**
  $H^+ = 24 \times pCO_2/HCO_3$
  Calculate x H^+ from pH
  Match the two. If both correlate then ABG is valid
- ***Look at pH—< 7.40—acidosis; >7.40—alkalosis***
- ***If pH indicates acidosis, then look at $PaCO_2$ and HCO_3^-***
- ***If $PaCO_2$ is ↑, then it is primary respiratory acidosis*:**
  - To determine whether it is acute or chronic: $\Delta H+/\Delta PaCO_2$ <0.3—chronic >0.8—acute and 0.3–0.8—acute on chronic
  - Calculate compensation by the respective methods:
    - Acute: $[HCO_3^-]$ ↑ by 1 mEq/L for every 10 mm Hg ↑ in $PaCO_2$ above 40
    - Chronic: $[HCO_3^-]$ ↑ by 3.5 mEq/L for every 10 mm Hg ↑ in $PaCO_2$ above 4
- ***If $PaCO_2$ ↓ and HCO_3^- is also ↓→ primary metabolic acidosis*:**
  Calculate expected $PaCO_2$ as follows: $PaCO_2 = [1.5 \times HCO_3 + 8] \pm 2$ metabolic acidosis only
  If $PaCO_2$ < expected $PaCO_2$ → concomitant respiratory alkalosis
  If $PaCO_2$ > expected $PaCO_2$ → concomitant respiratory acidosis
- ***If HCO_3^- is ↓, then AG should be examined. Anion gap = Na^+ - (Cl^- + HCO_3^-) normal anion gap 12*:**
  - If AG is unchanged → then it is hyperchloremic metabolic acidosis
  - If AG is ↑→ then it is wide AG acidosis
  - If the anion gap is raised, calculate the osmolal gap also
    Osmolal gap = Measured osmolality − Calculated osmolality
    S Osm = 2 (Na) + BUN/2.8 + Glucose/18 (normal osmolal gap < 15 mOsm/L)
- ***Check Delta ratio Δ AG/Δ HCO_3^- Delta Ratio = Measured anion gap—12/24—Measured HCO_3***
  Delta ratio Value and interpretation <0.4, normal anion gap metabolic acidosis,
  0.4–0.8 mixed-normal anion gap + high anion gap metabolic acidosis
  0.8–2 pure high anion gap acidosis, >2—mixed-high anion gap acidosis + metabolic alkalosis
- ***If pH indicates alkalosis, then look at HCO_3^- and $PaCO_2$***
- ***If $PaCO_2$ is ↓→ then it is primary respiratory alkalosis*:**
  - Whether it is acute or chronic (with the same formula as above)
  - Calculate compensation by the respective methods:
    Acute: $[HCO_3^-]$ ↓ by 2 mEq/L for every 10 mm Hg ↓ in $PaCO_2$ below 40
    Chronic: $[HCO_3^-]$ ↓ by 5 mEq/L for every 10 mm Hg ↓ in $PaCO_2$ below 40
- ***If $PaCO_2$ ↑ and HCO_3^- also ↑→ then it is primary metabolic alkalosis***
  Calculate the expected $PaCO_2$
  $PaCO_2 = [0.7 \times HCO_3^- + 21] \pm 2$ Or 40 + (0.7 ΔHCO_3) → metabolic alkalosis only $PaCO_2$ < expected $PaCO_2$ → concomitant respiratory alkalosis. $PaCO_2$ > expected $PaCO_2$ → concomitant respiratory acidosis
- ***Check urinary chloride*:**
  - If urinary chloride < 20 → chloride responsive or ECV depletion
  - If urinary chloride > 20 → chloride resistant

Continued

Continued

- ***If pH is normal ABG may be normal or mixed disorder*:**
  - ↑$PaCO_2$ and ↓HCO_3^- → respiratory and metabolic acidosis
  - ↓$PaCO_2$ and ↑HCO_3^- → respiratory and metabolic alkalosis

Calculate % difference ($\Delta HCO_3^-/HCO_3^-$ and $\Delta PaCO_2/PaCO_2$) to see which is dominant disorder

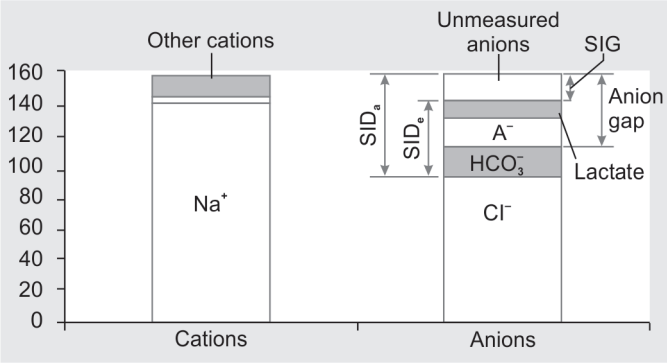

FIG. 4: Strong ion difference (SID) approach for assessment of acid-base disorder.

ARTERIAL BLOOD GAS SAMPLING TECHNIQUE

Before Sampling

The first thing the need (indications) for arterial sampling should be ascertained along with contraindications if any (**Table 6**). Oxygen saturation, oxygen therapy should be noted and discussed with the patient about the procedure and related complications such as bleeding, bruising, arterial thrombosis, infection, and pain. Then obtain consent to proceed. Prepare the heparinized syringe with cap, universal precautions. Look for the suitable artery for sampling by palpating the radial, brachial or femoral artery (**Fig. 5**). Radial artery of the nondominant arm should be preferred for routine sampling.

Sampling from Radial Artery

Allen test is performed to ascertain the adequate collateral circulation from ulnar artery (**Figs. 6A** to **C**). Position the patient's hand and insertion of needle is important for adequate sampling as shown in **Figure 7**. Clean the sampling site with an alcohol swab and obtain at least 3 mL of blood.

After Sampling

Sample site should be pressed for at least 5 minutes until bleeding has stopped. Presence of air bubbles may compromise the results so remove all the bubbles from the samples. Sample should be analyzed immediately else it should be stored in crushed ice (**Fig. 8**).

SUMMARY

Thus, analysis of ABG is an essential tool in management of critically ill patients. Always remember to assess oxygenation problem first. Next follow stepwise approach and correlate to clinical history while interpreting the ABG. ABG is a useful bedside tool in management of intensive care unit (ICU) patients.

TABLE 6: Indication and contraindications of arterial blood sampling.

Indications	• To assess derangement of oxygenation, its severity and cause • Assessment of acid-base disorder to identify primary disorder/disorders and plan its management • To check response to the interventions • Aids in adjustment of ventilator settings • For detection of abnormal hemoglobin (carboxy- and methemoglobin) and its severity
Contraindications	• An abnormal modified Allen test • Local infection or distorted anatomy at the puncture site • Severe peripheral vascular disease of the artery selected for sampling • Active Raynaud's syndrome

Selection of artery: Radial artery (preferred), femoral artery in case of shock if radial artery is not palpable (beware of coagulopathy). Avoid brachial artery sampling due to poor collateral circulation and risk of limb ischemia.

Precautions while taking sample: Avoid air bubbles. (Air contamination: spurious increase in PaO_2). Analyze within 30 min (Blood cells consume O_2, produce CO_2, and lower pH). If delay cool to 5°C immediately. Avoid excessive use of heparin (drop in $pCO_2 > PO_2$. pH usually remains unchanged).

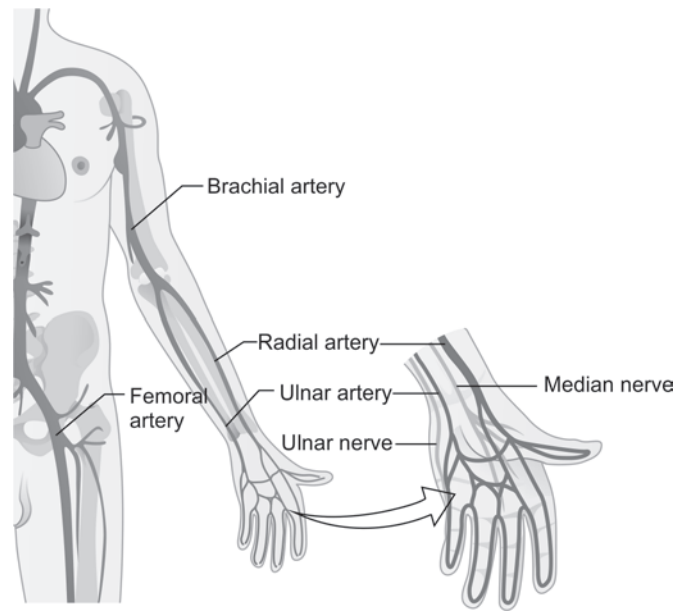

FIG. 5: Various arterial puncture sites.

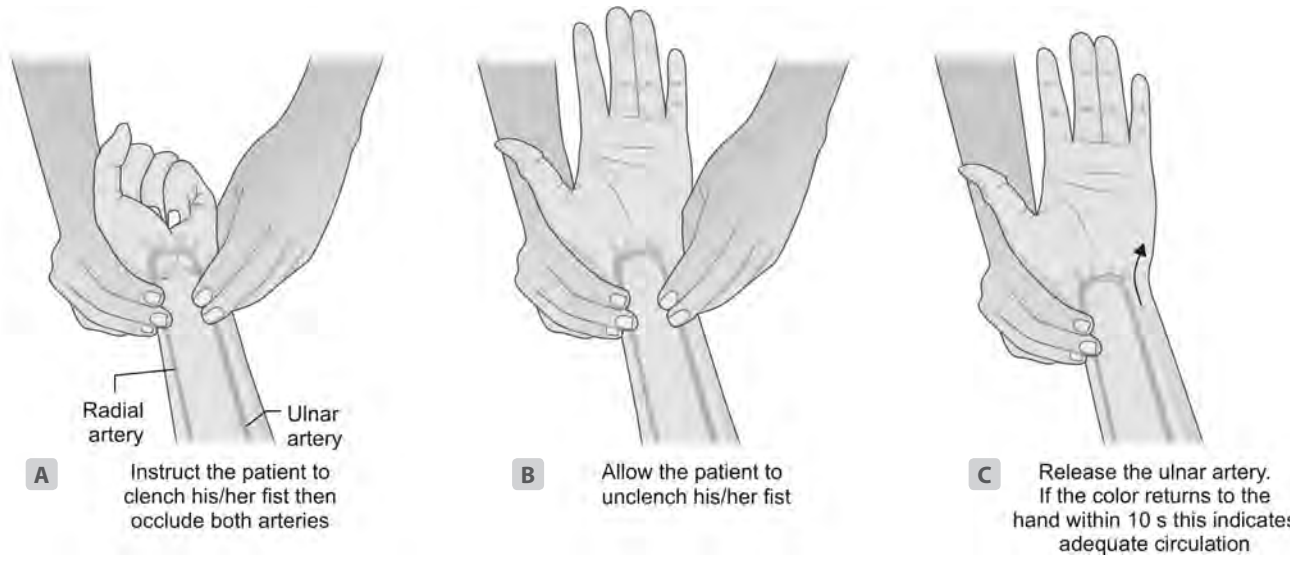

Radial artery
Ulnar artery
A
Instruct the patient to clench his/her fist then occlude both arteries
B
Allow the patient to unclench his/her fist
C
Release the ulnar artery. If the color returns to the hand within 10 s this indicates adequate circulation

46 CHAPTER

Electrolyte Imbalances

Ayşegül Bayır

INTRODUCTION

Electrolyte imbalances are common clinical problems that may occur in emergency departments, which may cause fatal rhythm problems and central nervous system complications and may result in cardiac arrest, if their differential diagnosis and proper treatment are not performed. Therefore, in life-threatening electrolyte disorders, treatment should be initiated before the results of the biochemistry laboratory are obtained. In this section, problems related to four electrolytes (sodium, potassium, calcium, and magnesium) that play an important role in the human body will be explained.

HYPERNATREMIA

It occurs when serum sodium level is measured over 145 mmol/L and a clinical picture related to this. Tonicity shows the activity of solutes that cannot easily penetrate the cell membrane and provides the transcellular distribution of water. It is the most effective anion that provides osmolality of extracellular fluid. Hypernatremia is accompanied by hypertonicity, decreased cell volume, and usually dehydration. If hypernatremia develops within 48 hours, it is called acute hypernatremia and if it develops over 48 hours, it is called chronic hypernatremia.

Pathophysiology

Extracellular and intracellular fluid osmolality is equal to each other. Water passes through the cell membrane comfortably. There is mainly sodium outside the cell and potassium ion inside the cell. Serum sodium concentration, as seen in the equation below, is closely related to the amount of potassium and water in the body.

Plasma osmolality: It is formulated as plasma osmolality: 2 (Na) mEq/L + serum glucose (mg/dL)/18 + BUN (mg/dL)/2.8 and its normal limit is 275–290 mOsm/kg. Plasma sodium and plasma osmolality are kept in balance by water intake and excretion.

$$\text{Na} = \text{total body (Na + K)/total body water}$$

Hypernatremia occurs either due to increased salt consumption, using hypertonic salt solutions, or loss of water from the body without electrolyte. When osmolality increases, arginine vasopressin (AVP) hormone and thirst are increased and balance is achieved. Intracellular fluid is drawn into the intravascular area due to increased osmolality. Dehydration develops in the cells that work as an osmoreceptor or tonicity receptor in the brain. These cells work like a mechanoreceptor and provide AVP release and thirst. This regulator system activates even when a large amount of salt is taken or fluid is lost and keeps serum sodium within normal limits. However, this physiological regulatory system may be insufficient for oral intake in people with impaired-mental status, advanced elderly or care patients, critical care intensive care patients who are hospitalized, children, and infants.

Etiology

Not replacing serious water losses without solutes. These losses can be caused by sweating, burns, losses through the gastrointestinal system (GIS) (vomiting, osmotic diarrhea, and loss of small intestine fluids), urinary losses, central diabetes insipidus (DI), nephrogenic DI, osmotic diuresis, and diseases (adipsic DI) that affect osmoreceptors in hypothalamus or the feeling of thirst. Intracellular water loss, excessive salt intake (or intentional or unintentional increased intake of oral salt), iatrogenic (hypertonic saline infusion, sodium bicarbonate therapy, intrauterine hypertonic saline administration for abortion induction), and some medications (lithium, phenytoin, and corticosteroids) can cause hypernatremia.

Clinical Findings

Advanced age, oral intake and/or impairment of consciousness, debility, physical disability, diuretic therapy, uncontrolled DI, hospitalization, and insufficient parent or nurse care at home are risk factors for hypernatremia.

In physical examination, hemodynamic status should be evaluated first and vital parameters should be monitored. Clinical findings are based on volume deficiency, hypertonicity, and dehydration in the cells in central nervous system. Neurological evaluation should be done very well. In patients with severe hypernatremia, brain hemorrhage due to tear may occur in the cerebral vessels. Hypotension, orthostatic hypotension, tachycardia, oliguria, dryness of the skin and mucous membranes, and turgor-tonus decrease occur due

to hypovolemia. In addition, lethargy, irritability, cloudiness, confusion, widespread weakness, myoclonic jerks, seizures, and coma are neurological signs and symptoms.

Diagnostic Tests and Differential Diagnosis

The diagnosis is made when the serum sodium level is above normal. Urine osmolality is an important test to differentiate the cause of hypernatremia. Plasma osmolality is determined. Serum and urine sodium, potassium, calcium, and magnesium levels are required. Kidney functions and blood glucose level are the other required tests. AVP level is also checked if necessary. The amount of 24-hour urine is important for diagnosis.

If urine sodium level is below 10 mEq/L, it supports volume deficiency. In hypovolemic patients, if urinary sodium is low but urine osmolality is high (usually above 600 mOsm/kg), it indicates extrarenal (GIS or skin) fluid loss. If urine osmolality is low (below 300 mOsm/kg) and urinary sodium is above 10 mEq/L, renal loss is considered. Basal AVP level and urine osmolality response to single dose AVP are examined for central and nephrogenic DI differential diagnosis.

Brain computed tomography (CT) and magnetic resonance imaging (MRI) may be requested to investigate central causes.

Treatment of Hypernatremia

The most important determinants in treatment are the acute or chronic distinction of hypernatremia, the severity of clinical findings, the level of volume deficiency, and the underlying causes. Treatment should be started immediately in patients with acute hypernatremia, severe central nervous system signs, or severe dehydration. In acute hypernatremia, serum sodium should be reduced to 2–3 mEq/L/h and not >12 mEq/L/day. In patients with asymptomatic or slightly symptomatic chronic hypernatremia, serum sodium is reduced to 0.5 mEq/h and 8–10 mEq/24 h. In patients with volume deficiency, volume replacement should first be done with isotonic sodium chloride. During the treatment, the patient is followed up with hourly neurological examination, serum and urine electrolyte measurements. The total amount of water in the body must first be known in order to calculate the amount of fluid to be given during treatment.

Total body water (TBW); is calculated with TBW = weight (kg) × correction factor formula. Correction factor is used as 0.6 for children, 0.5 for women, and 0.6 for men.

The amount of water to be given is determined by the formula below.

$$\text{Water deficit} = \text{Current TBW} \times (\text{Serum Na}/140) - 1$$

Generally, hypotonic (5% dextrose) fluids are used to lower serum sodium. Change in serum Na = (infusate Na – serum Na)/(TBW + 1) formula is used to find the amount of decrease in serum sodium each 1-liter intravenous (IV) fluid will provide. The sodium content of some solutions used in IV fluid treatment is shown in **Table 1**.

In patients with hypervolemic hypernatremia, hemodialysis treatment is planned for patients with loop diuretics and, if necessary, severe loading findings (congestive heart failure and acute pulmonary edema). As soon as life-threatening hypernatremia is treated, the underlying cause should also be treated. Attention should be paid when using glucose-containing fluids in diabetic patients.

Specific Precaution in the Treatment of Hypernatremia

- If hypernatremia has acute or life-threatening symptoms, treatment with hypotonic fluids should be initiated immediately.
- Treatment priority in patients with volume deficiency and with hypotensive, tachycardic, and shock is to support circulation with isotonic fluids.
- Chronic or asymptomatic hypernatremia should not be improved quickly; treatment should be given for the underlying cause.
- In acute hypernatremia, serum sodium should be reduced to 2–3 mEq/L/h and not >12 mEq/L/day.
- In patients with asymptomatic or mildly symptomatic chronic hypernatremia, serum sodium should be reduced by 0.5 mEq/h and no >8–10 mEq/24 h.

HYPONATREMIA

It is the condition that the serum sodium level is below 135 mEq/L. It is the most common electrolyte disorder. Hyponatremic patients are generally patients treated at home or in hospital due to their comorbidity (heart failure and renal failure). Hyponatremia is the most common electrolyte problem that occurred during the hospital follow-up and treatment of any disease. The incidence in hospitalized patients is 15–30%. Hyponatremia is divided into three according to serum sodium level.

1. *Mild hyponatremia*: Serum sodium level is 130–134 mEq/L.
2. *Moderate hyponatremia*: Serum sodium level is 129–125 mEq/L.
3. *Severe hyponatremia*: Serum sodium level is below 125 mEq/L.

It is also classified as hypovolemic, euvolemic, and hypervolemic hyponatremia according to its volume reserve. Once again, it is divided into hypotonic hyponatremia, isotonic hyponatremia, and hypertonic hyponatremia according to osmolality. According to the duration of hyponatremia

TABLE 1: Common fluids for fluid and electrolyte treatment.

Crystalloid fluid	*Osmolality mOsm*	*pH*	*Na^+ mEq/L*	*K^+ mEq/L*	*Cl^- mEq/L*	*Ca^{++} mEq/L*	*Glucose gr/L*	*Lactate mEq/L*

Lactated ringers	275	6.5	130	4	109	3	0	28

occurrence, it is called acute if it occurs in <48 hours, and chronic hyponatremia if it appears in >48 hours.

Etiology and Pathophysiology

Hyponatremia is caused by the kidney's inability to perform the water extraction function or excessive intake of water. Increased osmolality stimulates the thirst center in the hypothalamus. As a result, AVP, that is, antidiuretic hormone (ADH) is secreted from the posterior hypophysis. ADH reduces thirst increasing water reabsorption from collector tubules. Hyponatremia occurs if ADH secretion persists or if it is released inappropriately. Tissue perfusion decreases due to low cardiac output or arterial vasodilation in diseases such as heart failure and cirrhosis. As a result, ADH secretion is increased by stimulating the baroreceptors in the carotid sinus and arcus aorta, the renin-angiotensin system is activated and natriuretic peptides are secreted. Thus, water retention increases. ADH hormone, which is secreted in high amounts in inappropriate ADH syndrome, causes water retention and hyponatremia.

Clinical Findings

A decrease in serum osmolality leads to osmotic gradient with brain cells and causes water entry into brain cells. Accordingly, clinical signs and symptoms related to brain edema and central nervous system appear. Central nervous system findings appear suddenly especially in acute hyponatremia cases and come to the forefront. If it remain untreated, the mental state changes, seizures, coma and, death may occur. Treatment of hyponatremic patients presenting with central nervous system symptoms should be performed urgently with hypertonic saline.

Chronic hyponatremia is more common than acute hyponatremia. As serum sodium levels decrease over a longer period of time, brain cells produce idiogenic osmoles as their adaptation mechanism. Thus, the brain suffers less and clinical findings are less severe. Sometimes chronic hyponatremic patients may be asymptomatic. Nausea, vomiting, weakness, anorexia, imbalance, dizziness, confusion, forgetfulness, lethargy, and muscle cramps are other findings that may be seen in hyponatremia.

Diagnostic Tests and Differential Diagnosis

Anamnesis and physical examination are important guiding tools for determining the underlying cause. During the physical examination, the findings of hypovolemia are investigated. Hypotension, tachycardia, dryness of mucous membranes, and decreased turgor are evaluated.

Urinary sodium, serum, and urine osmolality together with serum sodium level are important tests for diagnosis. Urine osmolality is <100 mOsm in primary polydips. Urinary osmolality above 100 mOsm shows high ADH level. Serum osmolality is important for the differential diagnosis of real and pseudohyponatremia. Due to hyperlipidemia or hyperproteinemia (such as myeloma) in pseudohyponatremia, the protein or lipid ratio of plasma fluid drops from 97 to 80%. For this reason, serum sodium level is measured high. In this state, the patient's osmolality is normal.

Serum glucose, mannitol, glycine (used in some gynecological and urological processes), sucrose, and maltose levels are high in hypertonic hyponatremia. Renal functions, other serum electrolytes, serum lipid levels, and proteins are also requested for differential diagnosis of hyponatremia. As a further examination, thyroid hormones and suprarenal hormones may be requested. If urine sodium is above 20–40 mEq/L, inappropriate ADH release syndrome is considered. Urine sodium is below 25 mEq/L in hypovolemic hyponatremia. Serum uric acid level is found low in inappropriate ADH syndrome. Brain CT and chest radiography may be requested to investigate the underlying cause of inappropriate ADH syndrome.

Treatment of Hyponatremia

Immediately 100 mL 3% (513 mEq sodium) NaCl is administrated IV in 10 minutes in patients with acute severe central nervous system findings as there is high risk of herniation. If the clinical findings have not changed, infuse 2 more 100 mL. 3% NaCl intravenously. A total of three doses can be applied. Since the risk of herniation is low in moderate or mild symptomatic patients, 3% NaCl is infused at a rate of 0.5–2 mL/kg/h. Patients with chronic hyponatremia are at risk of osmotic demyelination syndrome (ODS), which can sometimes be irreversible. Patients who are in high-risk group especially for ODS are patients accompanied by alcoholism, chronic hepatic disease, cirrhosis, hypokalemia, and malnutrition.

In patients with low ODS risk, a maximum of 10–12 mEq/L increase should be achieved in 24 hours. In patients with a high risk of ODS, a maximum of 4–6 mEq/L improvement is achieved in 24 hours.

If chronic hyponatremia is severe, i.e., serum sodium is below 125 mEq/L or symptomatic (lethargy, confusion, and seizure), 3% NaCl is recommended for treatment as in acute hyponatremia. Initially, 3% NaCl is given to these patients to raise the basal sodium level to 4–6 mEq. If the urine/serum electrolyte ratio is below 0.5, water is restricted or vasopressin antagonists are given. If this ratio is above 1, salt tablets are added to the diet and loop diuretics are also given.

Serum sodium level should be closely monitored during treatment. To find the amount of fluid required to close the sodium deficit, and how much the liquid given in the treatment raises serum sodium: Na deficit = TBW × (desired Na – actual Na) can be used.

Each 1 mL/kg of 3% NaCl administered increases serum sodium by approximately 1 mEq/L. It is this calculation rather than others recommended to be followed by international guides.

Specific Precaution in Hyponatremia Treatment

- If patients with acute hyponatremia and severe central nervous system findings and herniation risk, their serum sodium level should be improved rapidly by giving 3% 100 mL NaCl IV three times.
- In moderate or mild symptomatic patients, serum sodium is corrected by infusing 3% NaCl at 0.5–2 mL/kg/h.
- The underlying cause should be treated in patients with chronic hyponatremia. Serum sodium should be corrected slowly due to the risk of ODS.
- In patients with hypotonic hyponatremia, sodium should be corrected up to 10 mEq in 24 hours and 18 mEq in 48 hours.

HYPERKALEMIA

Potassium is the major intracellular cation, predominantly in the cell. 98% of the potassium in the body is contained in the cell. While serum potassium level is 3.5–5 mEq/L, it is found in the cell at 140 mEq/L level. Na-K-ATPase pump provides sodium and potassium passage through the cell membrane. Potassium regulates excitability in all muscles including myocardium and nerves. Changes in serum potassium levels above or below normal levels can cause fatal rhythm problems, cardiac arrest, paralysis of the muscles, and respiratory arrest. Serum potassium level is determined by exogenous potassium intake, absorption, potassium exchange between extracellular fluid and cells, and the balance between and potassium excretion through urine.

Hyperkalemia is that serum potassium level is above 5 mEq/L. If serum potassium level is between 5 and 6 mEq/L, it is considered as mild, if it is between 6.1 and 7 mEq/L, moderate, and if it is above 7 mEq/L, it is considered as severe hyperkalemia.

Etiopathology of Hyperkalemia

Hyperkalemia occurs when potassium intake (diet containing high potassium low sodium) increases, supportive tablets containing potassium, IV fluids containing high potassium, or nutritional solutions are taken, and in cases such as saved (2–3-week-old) bank blood transfusion, cardioplegic solutions, metabolic acidosis, hypoaldosteronism, pseudohypoaldosteronism rhabdomyolysis, electrical trauma, hemolysis, hyperkalemic periodic paralysis, and decreased potassium excretion; kidney failure (GFR—if the glomerular filtration rate falls below 15–20 mL/kg, even if a high amount of potassium is not taken, potassium level may increase), renal tubular acidosis, drugs (potassium-sparing diuretics, ACE inhibitors, NSAI, penicillin G potassium, heparin, beta-blockers antifungals, and succinylcholine), and pseudohyperkalemia.

Clinical Symptoms Findings

Central nervous system and neuromuscular system findings are seen together. Muscle weakness, depression, muscle cramps, ascending paralysis in muscles, respiratory arrest, cardiac rhythm problems (extrasystoles, bradycardia, AV block, and ventricular tachycardia), and cardiac arrest can be seen. Changes in electrocardiography (ECG) support hyperkalemia.

Diagnostic Tests

Kidney functions (urea and creatinine), other electrolytes, pH, bicarbonate level (blood gases), whole blood test, urine potassium, and creatinine are the tests that can be requested. ECG should be drawn to all patients to assess cardiac exposure. ECG findings are generally correlated with serum potassium levels. However, the potassium level is not required to increase too high to see fatal rhythm problems. While serum potassium level in the early period is 5.5–6.5 mEq/L, prominent narrow-bottomed T wave spikes, short QT, and ST segment depression especially in precordial derivations are considered as ECG findings.

If the serum potassium level increases above 6.5 mEq/L (between 6.5 and 8 mEq/L), the P wave disappears, the PR interval is extended, and the QRS complex expands. If the serum potassium level increases above 8 mEq/L, the QRS complex expands completely and branch blocks, ventricular tachycardia, ventricular fibrillation, and asystole are observed.

Treatment of Hyperkalemia

The basis of the treatment is to ensure membrane stabilization especially in cardiac myocytes, to excrete potassium into the cell, to limit potassium intake and increase excretion (**Table 2**). Patients with severe hyperkalemia, potassium levels above 7 mEq/L, patients with cardiac rhythm problems in ECG are monitored by immediately opening the airway and vascular access. IV 10% calcium chloride 10 mL is infused with slow push (at 5–10 min). Thus, the effect of potassium on the myocardial cell membrane is eliminated. If the patient still has ECG findings and clinical findings have not improved, the same dose of calcium chloride can be given again. IV 50 mEq sodium bicarbonate is given in 5–10 minutes. This treatment allows potassium to be excreted into the cell. Insulin + glucose mixture (25 g glucose + 10 units of insulin) is infused in 15–20 min. Also 10–20 mg. Potassium is transferred into the cell by giving nebulized albuterol. Diuretics and potassium-sparing oxalate treatment are other treatment methods that can be applied. Hemodialysis should be done for the treatment of resistant hyperkalemia.

Insulin + glucose, sodium bicarbonate, and albuterol treatments are given to patients with moderate hyperkalemia, and hyperkalemic (6.1–7 mEq/L) but without cardiac findings.

In patients with mild hyperkalemia (5–6 mEq/L), furosemide IV 40–80 mg and potassium-sparing resins can be given in the form of oral or enema in 15–30 g of oxalate 50–100 mL with 20% sorbitol.

TABLE 2: Treatment of hyperkalemia and complications.

Drugs/ treatment	*Mechanism of action*	*Management of treatment*
Calcium	Membrane stabilization	As a cardiac antidote, only if ECG changes/ dysrhythmia and/or blood potassium level >7 mEq/L
Insulin + glucose	Moves potassium to intracellular space	Blood glucose level should be monitored closely
Sodium bicarbonate	Moves potassium to intracellular space	If hyperkalemia is accompanied with acidosis
B2 Agonist	Moves potassium to intracellular space	As a rescue treatment with insulin + glucose
Diuretics	Excretion of potassium by urine	If hyperkalemia is accompanied with hypervolemia
Ion exchange resins	Potassium ion exchange	Effects is seen 4 hours
Dialysis (hemodialysis or hemofiltration)	Remove excess potassium from blood	In renal failure and/or refractory hyperkalemia

Specific Precaution in the Treatment of Hyperkalemia

- Pseudohyperkalemia (excessive tightening of the tourniquet during blood collection, leukocytosis, or thrombocytosis) should be excluded.
- 10 mL of calcium chloride, which provides membrane stabilization immediately, should be given IV to the patients with severe hyperkalemia and rhythm problems in ECG.
- Other methods of lowering potassium are 25 g glucose + 10 units of insulin mixture, sodium bicarbonate, and nebulized albuterol treatments.
- Mild hyperkalemic patients are given loop diuretics and oxalate.
- Hemodialysis treatment should be carried out for resistant hyperkalemia.

HYPOKALEMIA

It is the clinical picture related to the serum potassium level below 3.5 mEq/dL. It is classified as mild hypokalemia if serum potassium level is 3–3.5 mEq/L, and life-threatening hypokalemia if below 2.5 mEq/L. Life-threatening hypokalemia causes fatal rhythm problems and is mortal.

Etiology of Hypokalemia

Redistribution from extracellular fluid into the cell, diarrhea, vomiting, diuretics, primary or secondary hyperaldosteronism, laxative use, renal tubular acidosis, hypomagnesemia, replacement with potassium-free fluids, hypercortisolism, and tube drainage are the main causes of hypokalemia.

Clinical Signs and Findings

Clinical findings occur due to the underlying cause rather than the hypokalemia itself. The symptoms are mainly related to the neuromuscular system and the cardiovascular system. Muscle weakness (usually seen if potassium is below 2.5 mEq/L), rhabdomyolysis, cramps, polyuria, and palpitations are observed. Respiratory failure and death may occur as a result of paralysis in the respiratory muscles. Nausea, vomiting, and anorexia occur as a result of being affected by GIS muscles. Some patients develop concomitant diarrhea, and some patients develop ileus.

Different rhythm problems occur in hypokalemic patients. Sinus bradycardia, paroxysmal atrial tachycardia, sinus bradycardia, premature ventricular or atrial beats, AV block, ventricular tachycardia, and ventricular fibrillation are findings that can be seen in ECG. In addition, ST segment depression, decrease in the amplitude of the T wave, and U wave at the end of the T wave are among other ECG findings.

Diagnostic Tests

Potassium in spot urine is the diagnostic test most commonly used. If urinary potassium is below 20 mEq/L, oral intake deficiency, loss through GIS, or potassium shift from the extracellular fluid into the cell is considered. If urine potassium is above 40 mEq/L, the loss of potassium with urine is considered to be high. Low sodium and high potassium levels in spot urine support the diagnosis of secondary hyperaldosteronism. Osmolality test must be requested. In addition, urine osmolality should be checked. Urine chlorine level and serum bicarbonate level, kidney functions are also among the tests to be requested. ECG should be done in all hypokalemic patients.

Treatment of Hypokalemia

The aim of the treatment is to prevent potassium loss, replacement of lost potassium, and prevention of recurrence of hypokalemia by treating the problem causing hypokalemia. Drugs (laxatives, diuretics, and ACE inhibitors) that cause potassium loss should be discontinued at the start of treatment. If diuretic therapy is required, potassium-sparing diuretics should be preferred.

Each 1 mEq/L decrease in serum potassium indicates an approximate deficiency of 200–400 mEq. Mild-to-moderate hypokalemia (2.5–3.5 mEq/L) is usually minimally symptomatic or asymptomatic. Replacing these patients with oral potassium tablets is sufficient. IV and more aggressive treatments are required in patients with cardiac rhythm problems or severe hypokalemic. Potassium can cause phlebitis during IV infusion. Maximum 20 mEq IV potassium replacement can be performed per hour. Both ECG and serum potassium levels monitoring should be done during replacement. Maximum IV 120 mEq replacement can be done daily.

Hypercalcemia

Calcium is an electrolyte which has an important role in the functioning of many processes such as enzymatic reaction in the cell, contraction in all muscles including the heart muscle, receptor activation, and coagulation. It is used as a cardiac antidote in hyperkalemia and hypermagnesemia, as it antagonizes potassium and magnesium in the cell membrane. Half of the calcium is bound to albumin in the extracellular fluid. The rest is the ionized active form. Calcium balance in the body is provided by parathormone and vitamin D. There is a close relationship between the total amount of calcium in the body and the serum albumin level. Every 1 g/dL increase in serum albumin increases the total calcium in the body by 0.8 mg/dL. In the case of hypoalbuminemia, ionized calcium levels may be normal, but in reality, the total amount of calcium is low. Hypercalcemia occurs when total serum calcium level is above 10.5 mEq/L or ionized calcium level is above 4.8 mg/dL.

Etiology of Hypercalcemia

Hyperparathyroidism (primary, secondary, and tertiary), malignancy (solid tumors or leukemia), thyrotoxicosis, immobilization, drugs (lithium, theophylline, thiazide group diuretics, estrogens, and antiestrogens), hypervitaminosis A, hypervitaminosis D, chronic renal failure milk-alkaline syndrome, pheochromocytoma, adrenal insufficiency, rhabdomyolysis, acute renal failure, familial hypocalciuric hypercalcemia, metaphyseal chondroplasia, and Paget's disease are the causes of hypercalcemia.

Clinical Findings

Symptoms begin to appear when the total calcium level in the body exceeds 12–15 mEq/L. The symptoms are; difficulty swallowing, constipation, peptic ulcer, and symptoms related to pancreatitis GIS. Generally, hypercalcemia has serious negative effects on the neuromuscular system, central nervous

system, and cardiovascular system. Fatigue, muscle weakness, exhaustion, depression, hallucination at higher blood levels, disorientation, loss of tonus, seizures, and coma may be seen. In severe hypercalcemia, signs of dehydration can be seen, as the kidneys' ability to concentrate urine is affected. Myocardial depression, decreased automaticity, refractory period shortening, and arrhythmias occur in the cardiovascular system. The QT interval is shortened, the PR interval and the QRS complex expand. Sodium, potassium, magnesium, and phosphate loss together with liquid and calcium in the urine are also seen.

Diagnostic Tests

First of all, remeasurement should be done to confirm hypercalcemia and corrected calcium level should be calculated to find whether there is an increase in total calcium level. Corrected calcium = serum calcium + 0.8 × (4 - serum albumin).

The degree of hypercalcemia is a key to identifying the underlying cause. Mild or borderline high calcium levels or long-term slightly high calcium levels support primary hyperparathyroidism. If the serum calcium level exceeds 13 mEq/L, the symptoms become evident. One of the main purposes in diagnosis is to determine whether hypercalcemia is caused by a parathyroid hormone (PTH) related problem.

Renal functions, blood levels of other electrolytes, PTH, and vitamin D levels should be requested. Serum phosphate level, serum chlorine level, and calcium levels in urine may be requested.

Treatment of Hypercalcemia

Patients with mild chronic hypercalcemia are asymptomatic or clinical findings are very few. Urgent treatment is not required in these patients (serum calcium level below 12 mEq/L). Drugs that increase the level of calcium (lithium treatment, thiazide group diuretics) and calcium-rich diet are prohibited to these patients. Abundant hydration is provided. Long-term inactivity is prevented.

Patients with moderate hypercalcemia (serum calcium 12–14 mEq/L), if not symptomatic, undergo the same treatment applied for mild hypercalcemia patients. Treatment of patient who are symptomatic, high serum calcium with neurologic symptoms are treated with intravenous saline, aggressive hydration and bisphosphonates.

Intravenous hydration is started immediately in patients with severe hypercalcemia (if corrected serum calcium level is 14 mEq/L or serum ionized calcium level above 10 mEq/L), whose serum calcium level is acutely elevated and with serious central nervous system findings (lethargy, stupor, and coma). Generally, IV isotonic sodium chloride is given at a rate of 200–300 mL/h, with 100–150 mL of urine output per hour. However, more aggressive fluid replacement can be performed in patients without cardiovascular and renal failure. These patients should be targeted to have an isotonic saline infusion at a rate of 500 mL/h and an hourly urine output of 300 mL. Loop diuretics can be given to patients with renal or heart failure together. Salmon calcitonin 4 U/kg IV, bisphosphonates (zoledronic acid 4 mg IV in 15 minutes, pamidronate 60–90 mg in 2 hours) can also be used to lower serum calcium. Bisphosphonates cannot be used in patients with severe renal impairment. Alternatively, denosumab can be given in these patients. In very extreme cases, 10–50 mg/kg ethylenediaminetetraacetic acid (EDTA) can be given as a chelator in 4 hours or PO4 50 mEq in 8 hours. Hemodialysis is the most effective form of treatment for all patients with resistant hypercalcemia, renal, and heart failure. Causal treatment should also be done simultaneously.

HYPOCALCEMIA

A serum calcium level below 8.5 mg/dL or serum ionized calcium level below 4.2 mg/dL is called hypocalcemia.

Etiology of Hypocalcemia

Hypoparathyroidism, pseudohypoparathyroidism, vitamin D metabolism disorder, thyroid surgery, magnesium metabolism disorders, renal failure, tumor lysis syndrome, burns, sepsis, pancreatitis, fluorine poisoning, phosphate infusion, some drugs (anticonvulsants, antifungals, loop diuretics, bisphosphonates, and isoniazid), citrated blood transfusion, and toxic shock syndrome can be considered as the cause.

Symptoms and Clinical Findings

Generally, symptoms begin when the serum ionized calcium level drops below 2.5 mg/dL. The main symptoms and signs include extremity and facial paresthesia, Chvostek and Trousseau sign, muscle cramps, hyperreflexia, stridor, bronchospasm, carpopedal spasm, tetany, personality disorder, memory and concentration difficulties, seizure, cloudiness, extrapyramidal findings, and congestive heart failure.

Electrocardiography findings include prolonged QT interval, QRS and ST changes mimicking ischemia, and ventricular arrhythmias.

Diagnostic Tests in Hypocalcemia

Serum albumin level, kidney functions, serum levels of other electrolytes, serum vitamin D level, PTH level, and serum phosphate level should be requested. All patients should have ECG. High serum alkaline phosphatase level is important for secondary hypoparathyroidism or severe vitamin D deficiency. High amylase level supports the diagnosis of pancreatitis as the underlying cause. Calcium level in urine should be checked. Low urinary calcium level indicates hypoparathyroidism and vitamin D deficiency.

Treatment of Hypocalcemia

Treatment of severe acute symptomatic hypocalcemia is urgent. If the patient has carpopedal spasm, tetany, convulsion, and QG prolongation in ECG or if it is not symptomatic and if the patient's corrected calcium level is below 7.5 mg/dL, IV calcium gluconate is given. The patient is given IV 10–20 mL of 10% calcium gluconate in 100 mL of 5% dextrose or isotonic sodium chloride in 10 minutes. Afterwards, IV infusion starts with 100 mL of 10% calcium gluconate in 1,000 mL of 5% dextrose or isotonic sodium chloride at a rate of 50 mL/h. The cardiac rhythm of the patient must be monitored during IV calcium infusion.

It is preferable to treat orally calcium in patients with moderately acute (corrected calcium level 7.5–8 mg/dL or ionized calcium level 1.9–2.1 mEq/L) or chronic hypocalcemia

patients. These patients are either asymptomatic or have mild symptoms, such as oral paresthesia. These patients are given oral elemental 1,500–2,000 mg calcium citrate or calcium carbonate in two doses daily. Meanwhile, if the patient's vitamin D level is low, treatment is started and hypomagnesemia is treated.

Specific Precaution in the Treatment of Hypercalcemia and Hypocalcemia

- In patients with severe hypercalcemia, IV isotonic sodium chloride is given at a rate of 200–300 mL/h, with 100–150 mL of urine output per hour.
- Loop diuretics are not recommended for patients without renal or heart failure.
- Salmon calcitonin and bisphosphonates can also be used to lower serum calcium.
- Hemodialysis is the most important form of treatment for all patients with resistant hypercalcemia, kidney, and heart failure.
- In severe acute symptomatic hypocalcemia, 10–20 mL of 10% calcium gluconate in 100 mL of 5% dextrose or isotonic sodium chloride is given IV immediately in 10 minutes.
- Patients with moderate acute hypercalcemia are given two doses of oral elemental 1,500–2,000 mg of calcium citrate or calcium carbonate daily.

HYPERMAGNESEMIA

The level of serum magnesia is above 2.2 mEq/L. Hypermagnesemia is not a common problem, if renal failure or high dose magnesium infusion is not performed. Generally, serum magnesium concentration rises slightly and is asymptomatic or minimally symptomatic. Significant clinical symptoms occur when serum magnesium level exceeds 4 mEq/L.

Etiology of Hypermagnesemia

The most common cause is renal failure. In addition, taking high doses of magnesium orally, long-term constipation and the use of enemas containing magnesium are the main reasons.

Clinical Signs and Findings

As a result of hypermagnesemia, symptoms and symptoms related to the neuromuscular system and cardiovascular system occur. Headache, dizziness, lethargy, somnolence, nausea, weakness or loss of deep tendon reflexes, hypotension, and bradycardia are symptoms that can be seen in mild and moderate hypermagnesemia. It can be fatal if the serum magnesium level rises above 10 mEq/L. Flask muscle paralysis, respiratory muscle paralysis, respiratory arrest, cardiac arrhythmia, and cardiac arrest are observed.

Treatment of Hypermagnesemia

Drugs containing magnesium should be discontinued. In severe hypermagnesemia, cardiovascular support may be required until the serum magnesium level is reduced to an optimal level. 5–10 mL 10% calcium chloride is given IV to patients with fatal cardiac rhythm problems. If necessary, the same dose can be repeated. The excretion of magnesium can be increased by giving loop diuretics together with isotonic sodium chloride IV to those with normal renal function. Dialysis therapy can be applied to patients with severe hypermagnesemia and/or those with kidney failure.

HYPOMAGNESEMIA

Serum magnesium level is below 1.3 mEq/L. It is an electrolyte imbalance that can be seen in 12% of hospitalized patients and 60–65% of intensive care patients. Symptomatic hypomagnesemia can often accompany some metabolic problems, such as hypokalemia and hypocalcemia.

Etiology of Hypomagnesemia

The most important reason is increased excretion from kidneys or GIS due to diarrhea. Diseases that impair absorption from GIS or reduced oral magnesium intake also lower serum magnesium levels. Thyroid dysfunction and drug interaction can also lower serum magnesium levels.

Clinical Symptoms and Findings of Hypomagnesemia

Signs and symptoms related to the neuromuscular system and cardiovascular system are at the forefront. Tremor, weakness, apathy, irritability, convulsion, tetany, and coma can be seen. In addition, atrial and ventricular arrhythmias related to the cardiovascular system can be observed.

Among the ECG findings, PR interval and enlargement of the QRS complex and T wave spikes can be seen.

Treatment of Hypomagnesemia

If there are signs of central nervous system (such as seizures) or cardiac findings in severe or symptomatic hypomagnesemia, IV 1–2 g magnesium sulfate is given in 5–60 minutes. If the patient comes with convulsions and there is concomitant hypocalcemia, calcium replacement should also be performed. If there are cardiac arrest and Torsades de pointes, 1–2 g magnesium sulfate should be given IV in 5–20 minutes during resuscitation.

Specific Precaution in the Treatment of Hypermagnesemia and Hypomagnesemia

- 5–10 mL 10% calcium chloride is given IV to patients with hypermagnesemia with fatal rhythm problems.
- Patients with severe hypermagnesemia undergo dialysis therapy.
- In severe or symptomatic hypomagnesaemia, 1–2 g magnesium sulfate should be given IV in 5–20 minutes in case of convulsions and cardiac arrest.

SUMMARY

Electrolytes play an important role in maintaining the homeostatic environment within the body. They help to regulate neurological and cardiac function, fluid balance, oxygen delivery, acid-base balance, and much more. Electrolyte abnormalities can develop due to increased intake or decreased removal of an electrolyte. The most common cause of electrolyte disturbances is kidney failure. Most

common electrolyte disorders involve sodium, potassium, and calcium. Others such as magnesium and phosphorus although important are relatively less common. Electrolytes basically help in maintaining voltages across cell membranes and also help in carrying nerve impulses to heart, nerves, and muscles. It is the function of kidneys to maintain the electrolyte concentration in blood constant. During illnesses such as diarrhea and vomiting, kidneys try to maintain electrolytes. Electrolyte imbalance is one of the common presentations in emergency department and emergency physician should have sound knowledge to manage.

47
CHAPTER

Sepsis

Ravi Jain, Yash Javeri

INTRODUCTION

The terminology of sepsis evolved from ancient Greek language, from the term "*sepo*" that literally means "*I rot*". Documentation related to this can be traced to ancient Greek texts dating back to 400 BC. Hippocrates, a physician and philosopher, viewed sepsis as dangerous biological decay that could potentially occur in the body. With evolving knowledge of modern medicine and understanding of sepsis, definition of sepsis has also evolved.

DEFINITION

First practical definition of sepsis came in 1992, when consensus conference considered basic pathophysiological facts and defined sepsis as "the systemic response to infection," as presented in this particular definition, it was clear that majority of harm is caused by body's own response and not the inciting event itself.

The definition further evolved and presently sepsis-3 in 2016, defines sepsis as a "*life-threatening organ dysfunction caused by dysregulated host response to infection.*" Whereas septic shock is recognized as, "*A subset of sepsis in which underlying circulatory and cellular metabolism abnormalities are profound enough to substantially increase mortality.*"

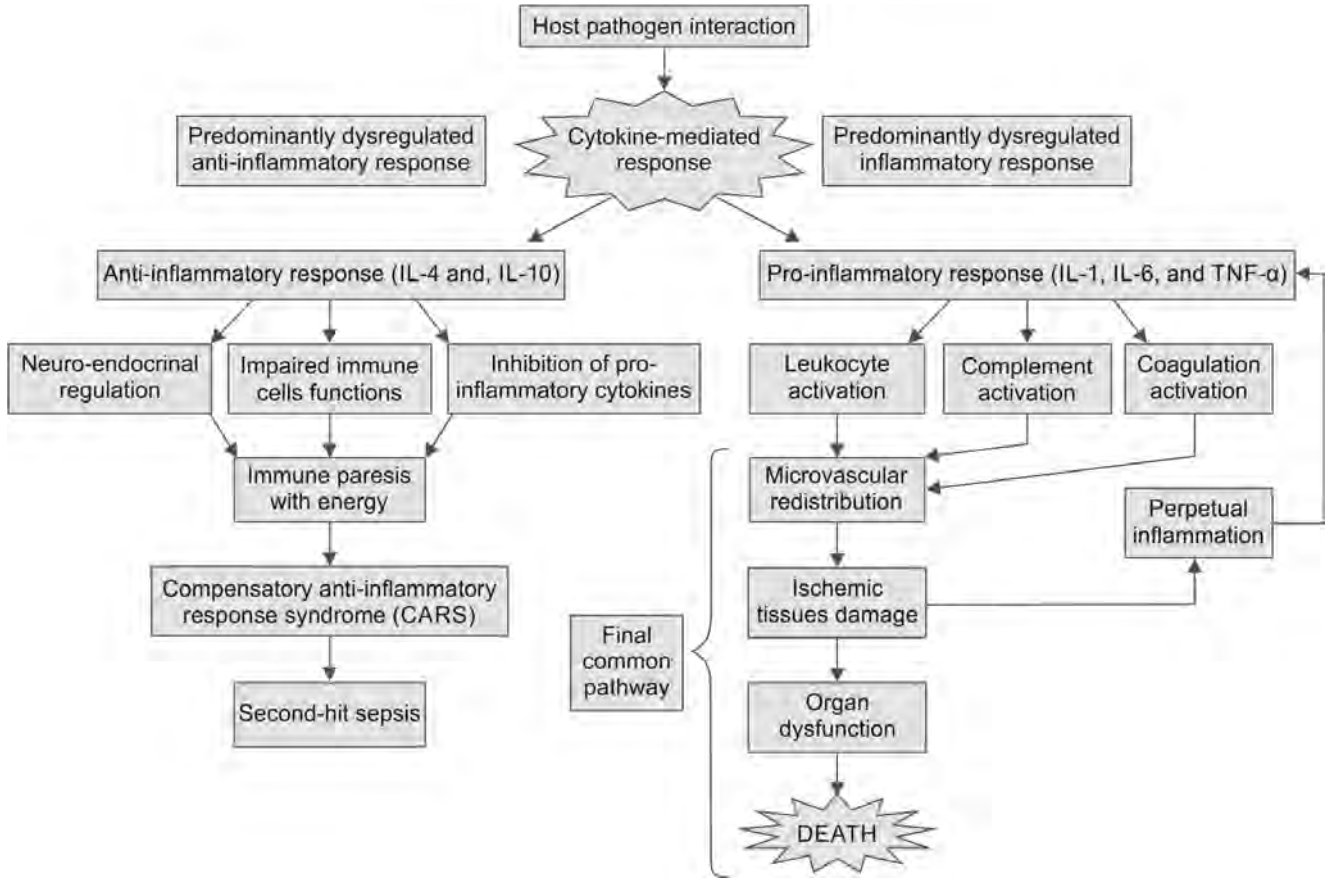
In present definition of sepsis, authors emphasized that previous distinction of sepsis, severe sepsis, and septic shock are no longer relevant. An infection without organ dysfunction or hypotension or evidence of hypoperfusion does not warrant similar aggressive response, and can simply be categorized as having an infection only and not "sepsis". Whereas previous "severe sepsis" is now termed as "sepsis". For standardization of organ dysfunction purpose, task force promotes use of quick sequential organ failure assessment (qSOFA) score in out of ICU settings and sequential organ failure assessment (SOFA) score for intensive care unit (ICU) settings. Further details of scoring system and comparison are provided ahead in chapter. By these definitions, it is clear that only infection is not the actual problem. But it is just a starting process and rest damaging work is done by the overwhelming response to infection by body's defense mechanism. Practically sepsis can be initiated from variety of organ system infections and by variety of organisms. Effective early treatment and control hold the key for successful management of sepsis and various aspects of general emergency room interventions have been proven to be very crucial for ultimate outcome.

EPIDEMIOLOGY

Sepsis is one of the leading top five causes of mortality globally, and is the most common cause of mortality in hospitals. Majority of sepsis cases come from community and about one-fifth of cases got readmitted in 30 days of discharge after sepsis. Cost of hospital stay with sepsis is almost double than any other illness. It is one of the leading cause of hospital readmissions and the costliest disease by cost burden and Disability-adjusted Life Year (DALY*) on society. This makes early identification of sepsis syndromes very important for reducing the disease mortality and morbidity burden and that in term reflect in DALYs.

PATHOPHYSIOLOGY

Sepsis pathogenesis is characterized by an inflammatory cascade. The cascade has humoral, cellular, complement, and cytokine components. **Flowchart 1** is a simple depiction of a complex host and pathogen interaction model that if remains unchecked, and dysregulated, ultimately leads to final common pathway of cell injury and death. The endothelial cell is the focal point of interactions between the inflammatory events and disordered hemostasis. Vascular bed-specific factors and endothelial cell injury can shift the balance between antithrombotic or prothrombotic state. The mediators ultimately lead to microvascular plugging and vasoconstriction. The resultant hypoperfusion/ischemia leads to acute organ dysfunction. Uninterrupted, a vicious cycle ensues that can end in death. Disease course is a result of several innate, immunological, and external factors. Disease progression in sepsis is highly heterogeneous and unpredictable. Sepsis is a dynamic disease with progress to sepsis or a septic shock. Organ failure is linked to mortality in sepsis.



FLOWCHART 1: Pathogenesis of sepsis—inflammatory cascade.

Infection Site and Microbiologic Considerations

Site of infection and type of microorganism are equally important factors for pathophysiology of sepsis. Pulmonary infections are the most common type of infection, followed by the abdomen and urinary tract infections. Site determination is not done in approximately 20–30% cases, and even when the site is strongly suspected a similar proportion has a sterile culture or microbiological isolates that are questionable. Occult sites such as pleural, peritoneal, and paranasal-sinus infections can easily be missed, even with the use of appropriate imaging. In fact, no imaging study can definitively rule out infection.

DIFFERENTIALS

There can be many other noninfectious conditions that can present with vasodilatory of distributive shock, some of them have been enlisted here, they have been discussed in different chapter elsewhere, and hence a detailed description is out of the scope of this text.

- Drug and transfusion-related reactions
- Anaphylactic shock
- Neurogenic shock
- Adrenal/thyroid insufficiency
- Toxicity (e.g., drugs)
- As a component of multiorgan dysfunction syndrome

SCREENING AND DIAGNOSIS OF SEPSIS

Step-1: Suspicion of Sepsis

Sepsis is a clinical syndrome, and first step toward establishing diagnosis of sepsis is to establish/suspect a source of infection that may be overt or occult. Various system infections present with some common general symptoms and then systemic manifestations of those infections. Most of the times systemic infections have typical case definition type presentation, but real challenge is when infections present with atypical or occult presentation. There may be many reasons for atypical/occult presentations such as uncontrolled diabetes, immune compromised status, etc. Simple screening tool for rule in/out sepsis in emergency department (**Table 1**).

Step-2: Categorization of Sepsis/Septic Shock

Sepsis-3 definition suggests clinical criteria to operationalize and rapidly categorize patients according to new definition. A *qSOFA score* (**Table 2**) of ≥2 points or a worsening **SOFA score** (**Table 3**) of ≥2 points is taken as marker of organ dysfunction and in event of suspected infection qualifies for sepsis. Among these two scores, qSOFA is of utility while triaging patients in emergency room as many data in SOFA score will not be available at first point of contact.

TABLE 1: Screening tool for rule in/out sepsis in emergency department.

This is a simplified tool that can be used to screen patients for sepsis in the ED or in critical care unit		
• Obtain proper history for any potential source of infection	Lung infections, kidney infections such as urinary tract infection, infection lingering in the abdomen, meningitis and endocarditis, skin and soft tissue infection, wound infection, catheter-related infections, and blood stream infections	YES/ NO
• Search for signs and symptoms that would indicate	Fever > 38.3°C or temperature < 36°C, altered mental status with a GCS < 15, Heart rate > 90 bpm (tachycardia), respiratory rate > 20 bpm (tachypnea) , leukocytosis or leukopenia (WBC count > 12,000 µ/L or <4,000 µ/L, respectively)	YES/ NO
• *If both the above are yes, suspicion of infection is present* • *Laboratory investigations that should be ordered are complete blood count with differential, blood lactate and cultures, and basic metabolic panel. Ultrasound abdomen, CT scan, chest X-ray, amylase, lipase, ABG, and procalcitonin should be obtained according to the signs and symptoms and according to physician discretion*		
• Whether organ dysfunction criteria present?	If suspicion of infection and organ dysfunction are present, the patient's condition is labeled as septic shock and should be entered into the protocol	YES/ NO

(ABG: arterial blood gas; CT: computed tomography; ED: emergency department; GCS: Glasgow Coma Scale)

TABLE 2: qSOFA score.

H	*H*ypotension: SBP ≤ 100 mm Hg
A	*A*ltered mental status (any GCS < 15)
T	*T*achypnea: Respiratory rate ≥ 22/min

Step-3: Approach to Diagnose Source and Establish Basic Physiology Status

Routine complete blood count, other organ functions testing should be done to find a baseline organ function or to establish a recent organ dysfunction. Early appropriate cultures and microbiological examinations should be sent as soon as possible as they are the cornerstone in sepsis management and result may alter even after first dose of antimicrobial therapy. These microbiological examinations help in tailor-made antimicrobial therapy later in the course of hospitalization. Imaging modalities such as ultrasonography, roentgenography, and advance imaging should be done as and when required to establish or rule out any specific systemic infection under question. There is apparently minimal role of biomarkers in sepsis diagnosis and emergency room management with one exception of lower respiratory tract infections. *A recent Cochrane review suggests using procalcitonin in suspected lower respiratory tract infection to establish role of antibiotics and bacterial infection.* Procalcitonin use is proven to reduce antibiotics use in such situation without having any significant harm.

MANAGEMENT

Sepsis management is essentially based on managing all three aspects of sepsis pathophysiology, i.e., (1) infection, (2) host response, (3) hemodynamic instability leading to organ dysfunction. For simple understanding of this concept a management scheme is described in **Flowchart 2** and divided in three subheadings.

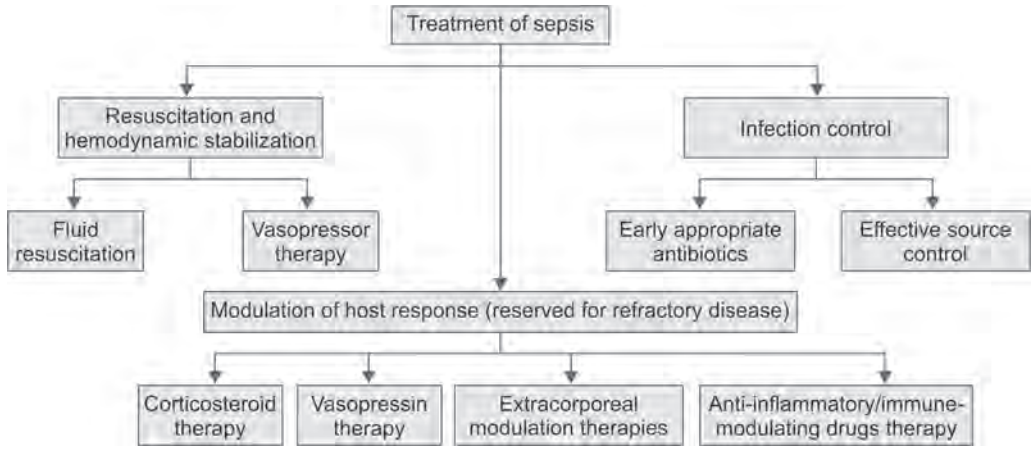
1. Resuscitation and hemodynamic stabilization
2. Infection control
3. Modulation of host response

Sepsis management starts right in the emergency room with triaging. *Surviving sepsis campaign (SSC) suggests 1-hour bundle* (**Table 4**) *for early sepsis management.* Following the care bundle protocol is vital in maintaining uniformity of care at emergency rooms. This care bundle has five key elements to be completed within first hour of "time zero" or "time of presentation."

TABLE 3: SOFA score.

Organ failure	***Variables***	***Score 0***	***Score 1***	***Score 2***	***Score 3***	***Score 4***
Respiratory	PaO_2/FiO_2	>400	<400	<300	<200 MV	<100 MV
Renal	Creatinine mg/dL	<1.2	1.2–1.9	2.0–3.4	3.5–4.9	>5.0
	UOP mL/day	>500 mL			<500 mL	
Cardiovascular All doses in µg/kg/min	Mean arterial pressure (mm Hg)	>70	<70			
	• Dopamine • Dobutamine			<5 Any dose	>5	>15
	Epinephrine				<0.1	>0.1
	Norepinephrine				<0.1	>0.1
Hepatic	Bilirubin (Mg/dL)	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	>12.0
Hematological	Platelets (10^9/L)	>150	<150	<100	<50	<20
CNS	GCS	15	13–14	10–12	6–9	<6

(CNS: central nervous system; GCS: Glasgow coma scale; MV: mechanical ventilation)



FLOWCHART 2: Sepsis management scheme.

TABLE 4: HOUR-1 bundle of surviving sepsis campaign.	
Bundle elements to be completed within first hour	Measure lactate level. Remeasure if initial lactate is >2 mmol/L
	Obtain blood cultures prior to administration of antibiotics best practice statement
	Administer broad-spectrum antibiotics strong recommendation
	Rapidly administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L
	Apply vasopressors if patient is hypotensive during or after fluid resuscitation to maintain MAP ≥ 65 mm Hg
"Time zero" or "time of presentation"	Time of triage at the first point of contact or, if patient is referred from another care location, represent the time when sepsis is first identified through chart review.

Resuscitation and Hemodynamic Stabilization

After identification of sepsis immediate commencement of resuscitation is the key priority. SSC guidelines suggest 30 mL/kg crystalloids should be given immediately. During resuscitation, additional fluids can be given by frequent assessment of hemodynamic status. Hemodynamic status assessment should be based on clinical examination and physiological variables such as heart rate, blood pressure, arterial oxygen saturation, respiratory rate, capillary refill time, urine output, etc., these can be supplemented by various invasive and noninvasive hemodynamic monitoring tools to improve accuracy. If any amount of uncertainty exists for differentials of shock, then cardiac function assessment can add to hemodynamic assessment.

Dynamic variables, such as inferior vena cava (IVC) collapsibility, echocardiographic evaluation, passive leg raising (PLR) with continuous monitoring for changes in cardiac output (CO) or stroke volume (SV) [assessed by arterial pulse contour analysis (PCA), transpulmonary thermodilution (TPTD) technology, aortic flow velocity, or echocardiography methods], "mini bolus" of intravenous fluid, trend evaluation of central venous pressure (CVP) with fluid resuscitation, pulse pressure, and SV variation (PPV or SVV) evaluation in mechanically ventilated patients with normal heart rhythm, are always better to predict fluid tolerance and responsiveness than *static variables* such as single CVP, SV, CO, systolic blood pressure, and cardiac ejection fraction measurements. During resuscitation a mean arterial pressure (MAP) of 65 mm Hg can be targeted in patients requiring vasopressors support. If hyperlactatemia is present and there is no plausible explanations for it (liver disease, drug-induced like metformin, thiamine deficiency, etc.), then resuscitation can be targeted to normalize lactate levels.

Infection Control

Infection control is the cornerstone therapy for sepsis. *Important contents have been included in HOUR-1 bundle itself, like obtain blood cultures and administer early and appropriate empirical broad-spectrum antibiotics.* There is now good amount of evidence and literature supporting that delaying antimicrobial therapy by each hour leads to substantially increased chances of failure. *Choice of initial antibiotics* depends on the various historical aspects, case definition, imaging-based focus of infection, and information of local antibiogram. This initial therapy needs modification once the source and culprit organism is identified, and more targeted antibiotics should be continued (**Table 5**).

Apart from antibiotics therapy whenever medically and logistically feasible an identified and controllable source of infection should be removed. These include minor imaging-guided drainage procedures to surgeries for source control and removal of suspected vascular or other catheters.

Modulation of Host Response

These therapies include, inclusion if intravenous cortico-steroid therapy (injection hydrocortisone 200 mg/day in continuous infusion or divided doses) for septic shock refractory to fluid resuscitation and vasopressor support, immunoglobulin therapies, extracorporeal blood purification therapies (cytokine or endotoxin adsorption therapy), addition of immune supplementary feeding (Ω3 fatty acid/glutamine supplementation), addition of trace elements (e.g., selenium, etc.), investigational anti-inflammatory agents (e.g., ulinastatin), antioxidant vitamins (vitamin C and thiamin), etc. This list can be exhaustive, however, apart from steroid therapy, evidences in favor of any other are lacking and should always be started under expert supervision. Due to the

TABLE 5: Common infections and empirical treatment regimen.

Condition	*Suspected organisms*	*Empiric regimen*	*Remarks*
Cholera	*V. cholerae*	• Doxycycline 300 mg oral stat • Azithromycin oral in children (20 mg/kg) and pregnant women (1 g)	• Rehydration (oral/IV) is essential • Antibiotics are adjunctive therapy
Enteric fever	*S. typhi, S. paratyphi A*	Inpatients: Ceftriaxone 2 g IV BD for 2 weeks +/-Azithromycin 500 mg BD for 7 days	• Majority of strains are fluoroquinolones resistant • IV therapy can be changed to oral cefixime when patient is afebrile to finish total duration of 14 days
Biliary tract infections (cholangitis, cholecystitis)	Enterobacteriaceae *(E. coli, Klebsiella* species)	• Ceftriaxone 2 g IV OD or • Piperacillin-tazobactam 4.5 g IV 8 hourly or • Cefoperazone-sulbactam 3 g IV 12 hourly • For 7–10 days	• Surgical or endoscopic intervention to be considered if there is biliary obstruction • High prevalence of ESBL producing • *E. coli*, *Klebsiella* species strains. De-escalate therapy once antibiotic susceptibility is known
Spontaneous bacterial peritonitis	Enterobacteriaceae (*E. coli, Klebsiella* species*)*	• Cefotaxime 1–2 g IV TDS or • Piperacillin-tazobactam 4.5 g IV 8 hourly or • Cefoperazone-sulbactam 3 g IV 12 h	De-escalate to ertapenem 1 g IV OD for 5–7 days once the patient improves
Secondary peritonitis, Intra-abdominal abscess/GI perforation	Enterobacteriaceae (*E. coli, Klebsiella* species), *Bacteroides* (colonic perforation), Anaerobes	• Piperacillin-tazobactam 4.5 g IV 8 hourly or • Cefoperazone-sulbactam 3 g IV 12 hourly in severe infections • In very sick patients, if required, addition of cover for yeast (fluconazole IV 800 mg loading dose day 1, followed by 400 mg)	• *Source control is important to reduce bacterial load* • If excellent source control for 5–7 days; otherwise 2–3 weeks suggested
Pancreatitis Mild-moderate	Sterile	No antibiotics	
Post-necrotizing pancreatitis: infected pseudocyst; pancreatic abscess	*Enterobacteriaceae, Enterococci, S. aureus, S. epidermidis, anaerobes, Candida* species	• Piperacillin-tazobactam 4.5 g IV 8 hourly empirically or • Cefoperazone-sulbactam 3 g IV 8 hourly in severe infections • In very sick patients, if required, addition of cover for yeast (fluconazole IV 800 mg loading dose day 1, followed by 400 mg 2nd day onward) and for *Enterococcus* (vancomycin/teicoplanin) may be contemplated • For 7–10 days	Duration of treatment is based on source control and clinical improvement
Liver abscess	Polymicobial	Amoxicillin-clavulanate/third-generation cephalosporin + Metronidazole 500 mg IVTID/800 mg oral TID for 2 weeks	Ultrasound-guided drainage indicated in large abscesses, signs of imminent rupture and no response to medical treatment
Acute bacterial meningitis	*S. pneumoniae, H. influenzae, Neisseria meningitidis*	• Ceftriaxone • 2 g IV 12 hourly/cefotaxime • 2 g IV 4–6 hourly • 10–14 days treatment	• Antibiotics should be started as soon as the possibility of bacterial meningitis becomes evident, ideally within 30 minutes. Do not wait for CT scan or LP results • No need to add vancomycin as primary agent, as ceftriaxone-resistant *Pneumococcus* is not common in India • *Listeria* is also rare in India and so ampicillin is also not indicated • Adjust therapy once pathogen and susceptibilities are known

Continued

Continued

Condition	Suspected organisms	Empiric regimen	Remarks
Meningitis—Postneurosurgery or Penetrating head trauma	*Staphylococcus epidermidis, Staphylococcus aureus, Propionibacterium acnes, Pseudomonas aeruginosa, Acinetobacter baumannii*	• Meropenem 2 g IV 8 hourly and • Vancomycin 15 mg/kg IV 8 hourly for 14 days	May need intraventricular therapy in severe cases
Brain abscess, Subdural empyema	Streptococci, Bacteroides, Enterobacteriaceae, *S. aureus*	• Ceftriaxone 2 g IV 12 hourly or • Cefotaxime 2 g IV 4–6 hourly and • Metronidazole 1 g IV 12 hourly • Duration of treatment to be decided by clinical and radiological response, minimum 2 months required	• Exclude TB, *Nocardia*, *Aspergillus*, and *Mucor* • If abscess <2.5 cm and patient neurologically stable, await response to antibiotics. Otherwise, consider aspiration/surgical drainage and modify antibiotics as per sensitivity of aspirated/drained secretions
Cellulitis	*Streptococcus pyogenes* (common), *S. aureus*	• Amoxicillin-clavulanate 1.2 g IV TDS/625 mg oral TDS or • Ceftriaxone 2 g IV OD +/– Clindamycin 600–900 mg IV TDS	Treat for 5–7 days
Necrotizing fasciitis	*Streptococcus pyogenes, S. aureus*, anaerobes, Enterobacteriaceae (polymicrobial)	• Piperacillin-tazobactam 4.5 g IV 6 hourly or cefoperazone-sulbactam 3 g IV 12 hourly and • Clindamycin 600–900 mg IV 8 hourly • Duration depends on the progress	Early surgical intervention crucial
Community-acquired Pneumonia	*S. pneumoniae*, *H. influenzae*, *Legionella*, *E.coli*, *Klebsiella* species, *S. aureus*	Mild-to-moderate cases: • Amoxycillin—500 mg–1 g TDS oral • If IV indicated, amoxycillin-clavulanate 1.2 g IV TDS or ceftriaxone 2 g IV OD For severe cases: • Amoxycillin-clavulanate 1.2 g IV TDS or Ceftriaxone 2 g IV OD • Duration 5–8 days	• If MRSA is a concern, add linezolid 600 mg IV/oral BD • If atypical pneumonia suspected, doxycycline 100 mg BD or • Azithromycin 500 mg oral/IV OD
Lung abscess, Empyema	*S. pneumoniae*, *E. coli*, *Klebsiella* species, *Pseudomonas aeruginosa*, *S. aureus*, anaerobes	• Piperacillin-tazobactam 4.5 g IV 6 hourly or • Cefoperazone-sulbactam 3 g IV 12 hourly	3–4 weeks treatment required
Acute uncomplicated cystitis	*E. coli*, *Staphylococcus saprophyticus* (in sexually active young women), *Klebsiella pneumoniae*	• Nitrofurantoin 100 mg BD for 7 days or • Cotrimoxazole 960 mg BD for 3 *Legionella* 5 days or • Ciprofloxacin 500 mg BD for 3 *Legionella* 5 days	Get urine cultures before antibiotics and modify therapy based on sensitivities
Acute uncomplicated pyelonephritis	*E.coli*, *Staphylococcus saprophyticus* (in sexually active young women), *Klebsiella pneumoniae, Proteus mirabilis*	• Amikacin 1 g OD IM/IV or • Gentamicin 7 mg/kg/day OD (Monitor renal function closely and rationalize according to culture report) • Complete total duration of 14 days	Urine culture and susceptibilities need to be collected before starting antimicrobial treatment to guide treatment

Continued

Continued

Condition	Suspected organisms	Empiric regimen	Remarks
Septic abortion	Bacteroides, *Prevotella bivius,* Group B, Group A *Streptococcus*, *Enterobacteriaceae*, *C. trachomatis, Clostridium perfringens*	• Ampicillin 500 mg QID + metronidazole 500 mg IV TDS if patient has not taken any prior antibiotic (start antibiotic after sending cultures) • If patient has been partially treated with antibiotics, send blood cultures and start piperacillin-tazobactam or cefoperazone-sulbactam till the sensitivity report is available	
Acute osteomyelitis OR Septic arthritis	• *S. aureus, Streptococcus pyogenes* • *Enterobacteriaceae*	• Ceftriaxone 2 g IV OD Followed by oral therapy by: • Cloxacillin 500 mg q 8 hourly or • Cephalexin 500 mg q 6 hourly	• Treat based on culture of blood/synovial fluid/bone biopsy • Orthopedic consultation is essential for surgical debridement • Duration: 4–6 weeks (From initiation or last major debridement)
For burns wound that is clinically or microbiologically not infected			• *Prophylactic parenteral antibiotics in burns are NOT indicated* • Topical antibiotics to be given after debridement
For burns wound that are clinically or microbiologically infected	*Strep pyogenes, Enterobacter* species, *S. aureus, S. epidermidis*, *Pseudomonas*, fungi (rare)	*Burn wound sepsis*: • Piperacillin-tazobactam or cefoperazone-sulbactam or with or without: Vancomycin/teicoplanin (if there is suspicion for MRSA) • Antifungal therapy: When extensive burns and patient not responding to antibiotics ○ If hemodynamically stable: Fluconazole ○ If hemodynamically unstable: Echinocandin *Burn wound cellulitis*: • Cefazolin or • Clindamycin or • Vancomycin if there is suspicion for MRSA • With and without (for burns involving the lower extremity or feet or burns in patients with diabetes) • Piperacillin-tazobactam or • Cefoperazone-sulbactam	• Antibiotic choices are dependent on the antibiogram of the individual institution • Surgical debridement as necessary • Amphotericin B is toxic to all burn patient as renal system compromised, hence Caspofungin may be used
Febrile neutropenia	*Suspected gram negative infections*	Hemodynamically stable patient: • Start IV ceftazidime Hemodynamically unstable: • Start BL-BLI agent (cefoperazone-sulbactam/piperacillin-tazobactam) OR • Carbapenem (meropenem/imipenem/doripenem) +/– • Glycopeptides antibiotics	• No need to add glycopeptide in the initial regimen, except in specific situations where MRSA infection is suspected • Re-assess after 48 hours for effectiveness of therapy • Modify therapy based on c/s results
The choices of antibiotics are not to be followed strictly as they depend on local epidemiology and antibiogram			

focused nature of this text, detailed discussion of modulation of host response becomes out of the scope for discussion in this text. One can find detailed evidence-based discussion in SSC guidelines for management of sepsis and septic shock.

OTHER SUPPORTIVE THERAPIES

Ventilation

Principles of ventilation initiation remain same as for any other condition in emergency or critical care unit. It is strongly recommended to maintain lung protective ventilation in cases of sepsis-induced acute respiratory distress syndrome (ARDS) using a target tidal volume of 6 mL/kg predicted body weight (PBW) and using an upper limit goal for plateau pressures of 30 cmH_2O over higher plateau pressures. When in ICU and patient diagnosed with ARDS early proning, should also be considered to improve survival chances.

Sedation and Analgesia

After ICU admission and stabilization of initial hemodynamics, suitability for weaning from ventilation should be assessed at regular interval for this daily spontaneous awakening and breathing trials (SAT and SBT) are highly recommended.

Glycemic Control

Critical care experts follow a standardized approach for management of glycemic control and variability with protocols. Usually for this strategy, short-acting insulin infusions are given targeting a blood sugar level of <180 mg%. Intravenous insulin administration, in comparison to subcutaneous injection has significant advantages of reliable response and absorption in cases of septic shock and low perfusion states. This is later converted to usually followed sliding scales and subcutaneous administration after stabilization.

Venous Thromboembolism Prophylaxis

Surviving sepsis campaign guidelines recommend adding pharmacological venous thromboembolism (VTE) prophylaxis [with low molecular weight heparin (LMWH) preferably than unfractionated heparin (UFH)] in absence of contraindication. They further also suggest to add mechanical VTE prophylaxis, if any contraindication to LMWH exists.

Stress Ulcer Prophylaxis

Surviving sepsis campaign guideline recommends, adding stress ulcer prophylaxis for risk of upper gastrointestinal bleeding in sepsis and septic shock with proton pump inhibitor (PPI) drugs preferably. However, nowadays studies proved that any hemodynamically stable patient on enteral feeds has low risk of GI bleeding as feeding has protective role and hence PPIs are not given to these patient subgroups.

Nutrition

Early enteral feeding is encouraged in patients with sepsis and septic shock. Even in hemodynamically unstable patients, with high vasopressor requirements at least trophic/hypocaloric feeding (targeting <70% of target nutrition goal in first 48 h) is recommended. This aggressive enteral feeding approach has several protective effects such as reduced inflammatory response, maintenance of gut integrity, prevention of gut permeability to microbiota, modulation of metabolic responses, and improving insulin resistance. Prepared standard formula feeding is usually sufficient in satisfying needs of almost all the patients. Any specific additives such as microelements, immune supplementary feeding (Ω3 fatty acid/glutamine supplementation), antioxidant vitamins (vitamin C and thiamine) are not supported yet by SSC guidelines and have investigational role only.

DISPOSITION

After gauzing the response to emergency room, therapies decision should be made about the location of care. The patients should be admitted after the goals of care and prognosis is discussed with family and patient. These discussions should always be documented and incorporated in medical records for future references. Goals of care should be communicated and handed over to the critical care team so that it can be met and addressed as early as possible as and no later than 72 hours. To improve family satisfaction, a comprehensive management plan has been outlined in **Flowchart 3** for emergency department management of sepsis.

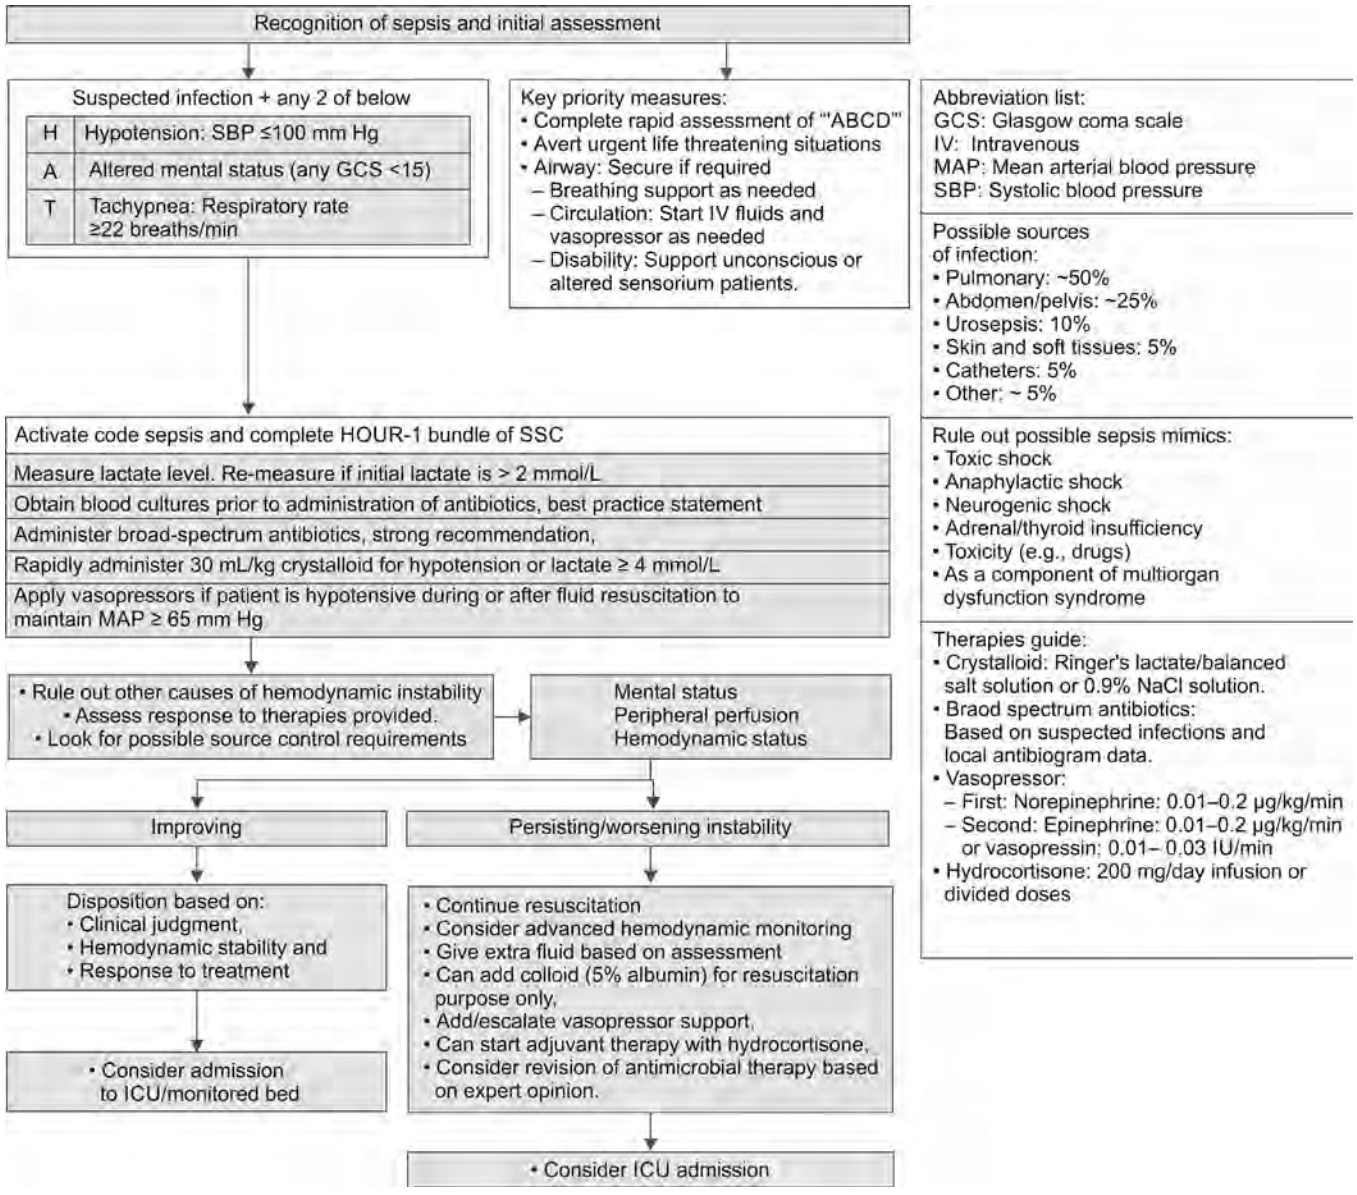
CODE SEPSIS

Sepsis has been identified as a major health problem and one of the leading causes of morbidity and mortality worldwide. There has been limited adherence to the sepsis care bundles. Hence now an emerging concept of *"Code Sepsis"* is adopted in many emergency rooms, to streamline the response and rapid deployment of specialized medical service. Code concept revolves around earliest completion of HOUR-1 bundle and meeting the targets of resuscitation. This exercise improves compliance to SSC care bundle and has been proven to reduce mortality related to sepsis.

SUMMARY

Sepsis is a life-threatening condition, which arises from host response to infection. Early identification and intervention is the key for successful management of sepsis. Emergency room management and promptness makes a lot of difference in overall out comes. Using "code sepsis" to assess and follow-up adherence to HOUR-1 bundle can become vital in comprehensive implementation of quality care, which may ultimately lead to improved outcomes.

Unprecedented scenario of COVID-19 pandemic has led to a very dynamic and fluid condition for safe and effective management of suspected or confirmed COVID-19 patients. Up to date information of progression of epidemic and communications with local governing authorities is the key to make institutional strategies for management. Presented flow and management protocol will need dynamic changes as future progression of epidemic and evidences evolve and emerge.



Recognition of sepsis and initial assessment
Suspected infection + any 2 of below
H Hypotension: SBP ≤100 mm Hg
A Altered mental status (any GCS <15)
T Tachypnea: Respiratory rate ≥22 breaths/min
Key priority measures:
• Complete rapid assessment of "'ABCD"'
• Avert urgent life threatening situations
• Airway: Secure if required
– Breathing support as needed
– Circulation: Start IV fluids and vasopressor as needed
– Disability: Support unconscious or altered sensorium patients.
Abbreviation list:
GCS: Glasgow coma scale
IV: Intravenous
MAP: Mean arterial blood pressure
SBP: Systolic blood pressure
Possible sources of infection:
• Pulmonary: ~50%
• Abdomen/pelvis: ~25%
• Urosepsis: 10%
• Skin and soft tissues: 5%
• Catheters: 5%
• Other: ~ 5%
Activate code sepsis and complete HOUR-1 bundle of SSC
Measure lactate level. Re-measure if initial lactate is > 2 mmol/L
Obtain blood cultures prior to administration of antibiotics, best practice statement
Administer broad-spectrum antibiotics, strong recommendation,
Rapidly administer 30 mL/kg crystalloid for hypotension or lactate ≥ 4 mmol/L
Apply vasopressors if patient is hypotensive during or after fluid resuscitation to maintain MAP ≥ 65 mm Hg
Rule out possible sepsis mimics:
• Toxic shock
• Anaphylactic shock
• Neurogenic shock
• Adrenal/thyroid insufficiency
• Toxicity (e.g., drugs)
• As a component of multiorgan dysfunction syndrome
• Rule out other causes of hemodynamic instability
• Assess response to therapies provided.
• Look for possible source control requirements
Mental status
Peripheral perfusion
Hemodynamic status
Therapies guide:
• Crystalloid: Ringer's lactate/balanced salt solution or 0.9% NaCl solution.
• Braod spectrum antibiotics: Based on suspected infections and local antibiogram data.
• Vasopressor:
– First: Norepinephrine: 0.01–0.2 µg/kg/min
– Second: Epinephrine: 0.01–0.2 µg/kg/min or vasopressin: 0.01– 0.03 IU/min
• Hydrocortisone: 200 mg/day infusion or divided doses
Improving
Persisting/worsening instability
Disposition based on:
• Clinical judgment,
• Hemodynamic stability and
• Response to treatment
• Continue resuscitation
• Consider advanced hemodynamic monitoring
• Give extra fluid based on assessment
• Can add colloid (5% albumin) for resuscitation purpose only,
• Add/escalate vasopressor support,
• Can start adjuvant therapy with hydrocortisone,
• Consider revision of antimicrobial therapy based on expert opinion.
• Consider admission to ICU/monitored bed
• Consider ICU admission

CHAPTER

Overview of Shock

Khusrav Bajan, Devendra Richhariya

INTRODUCTION

The word "shock" is derived from French word "choc" coined by French surgeon Henri LeDran. In 1827, an English surgeon, George Guthrie, first used the word "shock" in association with a physiological response to injury. Shock is best defined as a physiologic state of circulatory failure, resulting in insufficient tissue perfusion and oxygenation.

The diagnosis of shock is based on *hemodynamic parameters, clinical findings, and abnormal laboratory values.* Typically, hemodynamic parameters include systolic blood pressure < 90 mm Hg, mean blood pressure < 60 mm Hg; clinical findings include altered mentation, decreased urine output, etc., and abnormal laboratory values include elevated serum lactate and metabolic acidosis. *The skin, the kidneys, and the brain* provide us with three types of ***"windows"*** through which we can visualize the effects of impaired tissue perfusion (**Fig. 1**).

Etiopathophysiology of Shock

Shock state can result from four potential pathophysiological mechanisms (**Figs. 2A** to **D**)

1. *Hypovolemia*: Due to internal or external body fluid losses.
2. *Cardiogenic factors*: Myocardial infarction, myocarditis, etc.
3. *Obstruction*: Pulmonary embolism, cardiac tamponade, and tension pneumothorax
4. *Distributive*: Septic shock and anaphylactic shock

To understand these mechanisms, we need to revise basic physiologic equation of cardiac output. The blood pressure is product of cardiac output and systemic vascular resistance and CO is product of stroke volume and heart rate, thus:

$$BP = CO \times SVR \text{ and } BP = (SV \times HR) \times SVR$$

In this equation, BP represents contractility, SV represents preload, and SVR represents afterload. Hence, the forces which determine cardiac output are preload, contractility, and afterload and pathophysiological mechanisms of shock affect one of these factors, for example, in hypovolemic shock, there is reduced preload; in cardiogenic, shock there is decrease in cardiac contractility; in obstructive shock, there is increase in afterload; and in distributive shock (**Flowchart 1**), there is decrease in SVR and CO is high, although CO may be low due to myocardial depression.

We need to discuss the concept of oxygen delivery to tissues to better understand the concept of shock. Oxygen delivery to the tissues depends on cardiac output, hemoglobin concentration of blood, and the saturation of hemoglobin with oxygen,

$$DO_2 = CO \times CaO_2 = CO \times (1.34 \times Hb \times SaO_2) \times 10$$
$$VO_2 = CO \times 13.4 \times Hb \times (SaO_2 - SvO_2)$$

Where, DO_2—oxygen delivery, CO—cardiac output, CaO_2—oxygen content of blood, VO_2—oxygen consumption, Hb—hemoglobin concentration, SaO_2—% saturation of hemoglobin, SvO_2—% saturation of mixed venous blood.

Oxygen delivery to tissues is reduced in hypovolemic, obstructive, and cardiogenic shock, as a result of anemia, hypoxemia, and low cardiac output (**Table 1**). In hypovolemic shock, reduction in CO is due to decrease in preload. In obstructive shock, venous return to left ventricle is

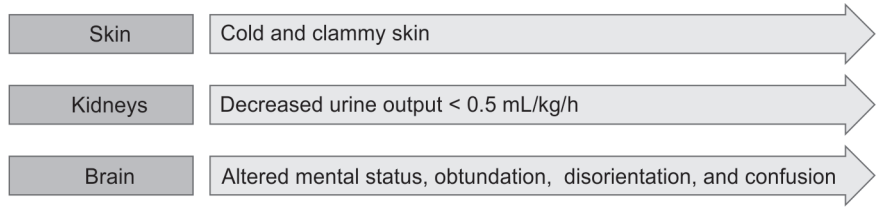

FIG. 1: Signs of hypoperfusion.

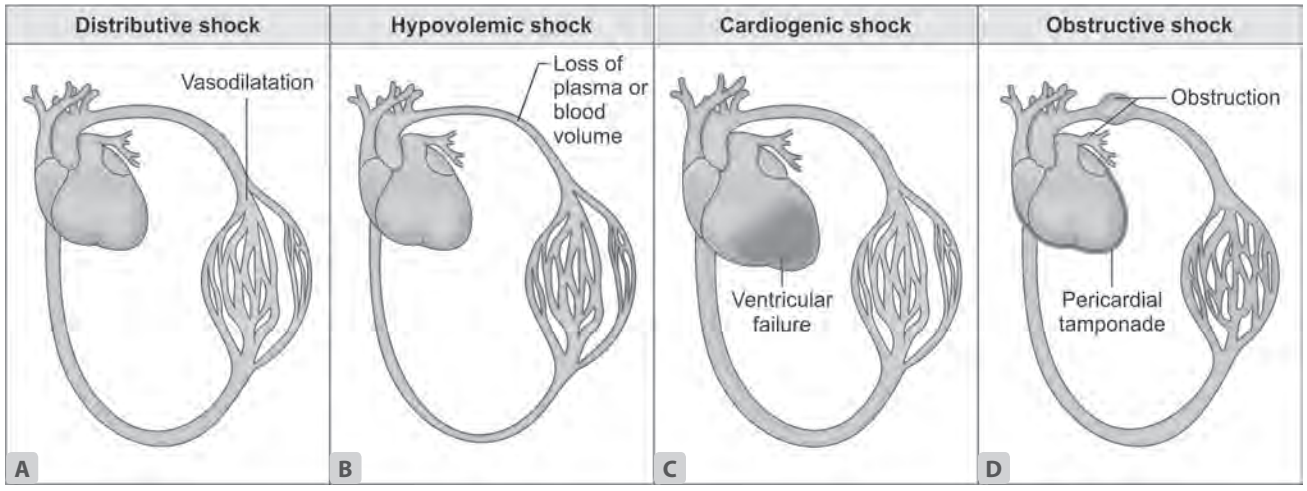
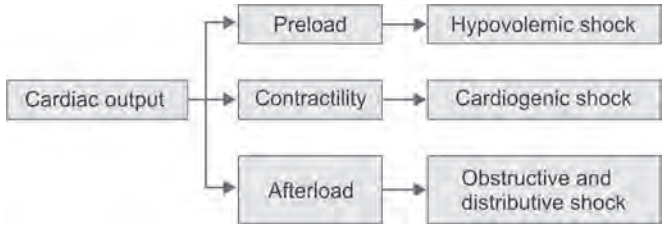


FIGS. 2A TO D: Pathophysiologic mechanism of shock.



FLOWCHART 1: Basic pathophysiological mechanisms.

TABLE 1: Pathophysiologic type of shock and their causes.

Types of shock	*Causes*
Hypovolemic	Hemorrhagic, trauma, and dehydration
Cardiogenic	Myocardial infarction, cardiomyopathy, valvular disease, and arrhythmias
Obstructive	Pulmonary embolism, tamponade, and tension pneumothorax
Distributive	Sepsis and anaphylaxis

reduced, whilst, in cardiogenic shock, impaired contractility predominates. In septic shock, there is profound inflammatory response, which leads to vasodilation, increased cardiac output despite impaired myocardial contractility and relative hypovolemia. There are abnormalities in perfusion at microcirculatory level resulting in locally reduced DO_2 despite global supranormal values. In addition, sepsis-induced myocardial dysfunction prevents oxygen utilization at cellular level.

CLINICAL PRESENTATION

Early signs include orthostatic hypotension, mild tachycardia, diaphoresis, and late signs are hypotension, significant tachycardia, tachypnea, and altered mental status. There may be signs of vasoconstriction (narrow pulse pressure and cool extremities) or vasodilation (wide pulse pressure and warm extremities) depending on type of shock. The following **Table 2** is showing clinical features of various type of shock. If Swan–Ganz catheter placement for invasive hemodynamic monitoring is used, then hemodynamic variables of type of shock can be identified (**Table 3**). Initial assessment of patient with features of shock is summarized in **Flowchart 2**.

TABLE 2: Clinical presentation of shock.

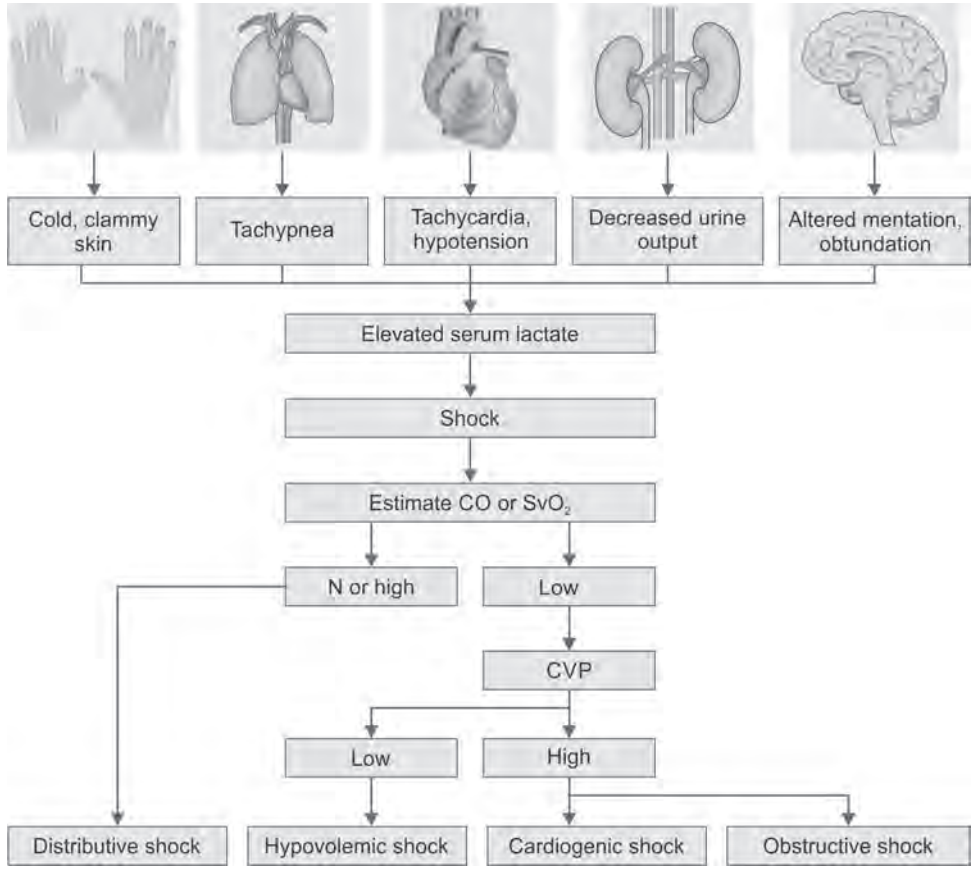
	Cardiogenic	*Hypovolemic*	*Distributive*
Pulse pressure	Decreased	Decreased	Increased
Diastolic pressure	Decreased	Decreased	Markedly decreased
Extremities	Cool	Cool	Warm
Nail bed blood return	Slow	Slow	Rapid
JVP	Raised	Low	Low
Respiratory crepts	+++	–	–
S3, S4 gallop	+++	–	–
Chest X-ray	Cardiomegaly, pulmonary edema	Diminished cardiac size	Normal or with pneumonia
Site of infection	–	–	+++
Other significant systemic manifestations are altered mentation, decreased urine output (<0.5 mL/kg/h).			

TABLE 3: Hemodynamic variables for shock.

Type of shock	*Cardiac index*	*SVR*	*PVR*	*SvO_2*	*Wedge Pressure*
Cardiogenic	↓	↑	N	↓	↑
Hypovolemic	↓	↑	N	↓	↓
Distributive	N - ↑	↓	N	N - ↑	N - ↓
Obstructive	↑	N - ↑	↑	N - ↓	N - ↓

USE OF ULTRASOUND IN EVALUATION AND DIAGNOSIS OF SHOCK

Ultrasound (USG) evaluation of shock has revolutionized the care in emergency department/intensive care unit (ED/ICU).



FLOWCHART 2: Algorithm for initial assessment of shock.

TABLE 4: Different probes available commonly for shock evaluation.

Type of USG probe	*Area of examination*
1–5 MHz; phased array	Heart (echocardiography)
2–5 MHz; curvilinear	Abdomen
6–13 MHz; linear	Blood vessels; thorax

It is a noninvasive, convenient, prompt, repeatable bedside evaluation technique of shock resuscitation. Various protocols (e.g., RUSH, E-FAST, FALLS, etc.,) for quick assessment and to provide point-of-care management of shock has been described.

USG in Diagnosis of Shock

Appropriate probes to be selected for optimum bedside USG resolution of different organs (**Table 4**). Prior clinical history and examination are mandatory and the USG examination is planned accordingly. The common USG findings suggestive of different types of shock are given in (**Table 5**). USG is used for immediate screening and stabilization pending specific appropriate management. The findings of USG will vary with preexisting comorbidities and duration of shock. Hence, individualized interpretation and clinical corroboration are essential.

MANAGEMENT OF SHOCK

Management of shock may be considered in terms of general measures that are applicable to all shock patients and specific measures as per the type of shock.

General Measures

Airway, breathing, circulation and O_2, IV, monitor are simple basic rules.

- *Airway/breathing*: Every shock patient should be given supplemental oxygen through face mask with the aim of improving arterial oxygen saturation and oxygen delivery to tissues. In cases of major hemodynamic instability, intubation and mechanical ventilation should be considered so as to reduce oxygen consumption by respiratory muscles and reduce work of breathing. Intubation at an early stage also facilitates insertion of invasive lines for hemodynamic monitoring and vasoactive drug administration, which is otherwise difficult and may be risky in confused and agitated patient.
- *Circulation*: The primary aim is restoration of adequate tissue perfusion and IV fluid administration is the initial treatment in all types of shock and if fluid therapy is not sufficient then vasopressors and inotropes need to be added. The initial fluid resuscitation is done through two large bores (16 or 18 G) IV cannulae. If needed then insertion of invasive lines should be considered for

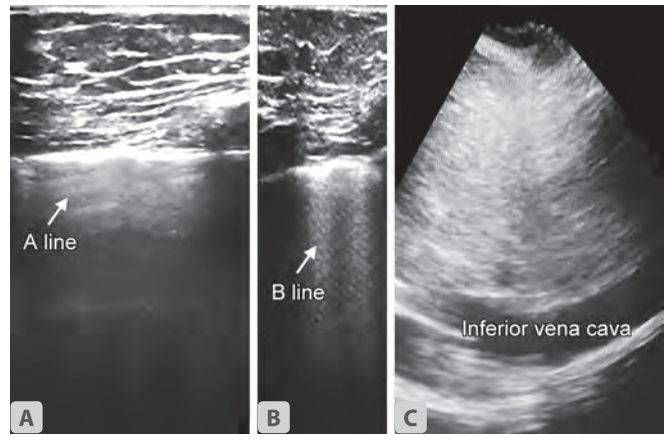
TABLE 5: Common USG findings of different types of shock.

Type of shock	*Common suggestive USG findings*
Hypovolemic Shock (e.g., trauma, aortic dissection, GI loss, etc.)	• Hypercontractile heart with systolic collapse (kissing) of the chambers • Collapsed IVC and IJV • Hyperechoic free fluid in pleural and abdominal cavities • Major abdominal organ/vessel injury
Obstructive shock (e.g., pulmonary embolism, cardiac tamponade, tension pneumothorax, etc.)	• Dilatation of right heart chambers with shifting of intravascular septum with maintained left contractility • Pericardial fluid collection • Dilated IJV and IVC • Absent lung sliding
Cardiogenic shock (e.g., acute MI, stress cardiomyopathy, etc.)	• Hypocontractile dilated heart chambers • Regional wall motion abnormalities • Dilated IJV and IVC • B lines (comet) in lungs
Distributive shock (e.g., septic shock, anaphylactic shock, etc.)	• Unremarkable USG echocardiography may be normal or hyper-/hypocontractile ventricles • IJV/IVC caliber to guide fluid resuscitation • Fluid collection in pleural cavity or abdominal cavity may suggest source of sepsis • Consolidation/abscess/fluid collection as source of sepsis

(GI: gastrointestinal; IVC: inferior vena cava; IJV: internal jugular vein; MI: myocardial infarction)

better hemodynamic monitoring and vasoactive drug administration.

- *Fluid therapy and use of USG in fluid resuscitation*: Optimizing cardiac preload and restoring circulating volume are the basic aspects of correcting tissue hypoxia, increasing cardiac output, and reestablishing perfusion in shock patients. Even patients with cardiogenic shock may benefit from initial fluid resuscitation, since acute edema may result in decrease in effective intravascular volume. The replacement fluid should be chosen so as to replace the type of fluid lost, for example, in hemorrhagic shock, patient clearly requires blood. Crystalloids, colloids, and blood are the usual replacement fluids. The fluid resuscitation should be optimized as per the hemodynamic, urine output, and ongoing losses. Once the type of shock has been known, the USG evaluation may be used to plan fluid resuscitation specific management. Optimized fluid therapy during resuscitation is the best practice. Repeated lung USG, echocardiography and measurement of inferior vena cava/internal jugular vein caliber may optimize resuscitative fluid therapy (**Figs. 3A** to **C**). All such parameters must be measured repeatedly and interpreted in combination with other hemodynamic and clinical features (**Table 6**).



(USG: ultrasound)

FIGS. 3A TO C: USG-guided fluid resuscitation in a shock patient. (A) Lung USG depicting A lines initially. (B and C) Appearance of B line in lung and noncollapsible inferior vena cava after fluid resuscitation.

TABLE 6: USG findings for fluid therapy guidance during resuscitation.

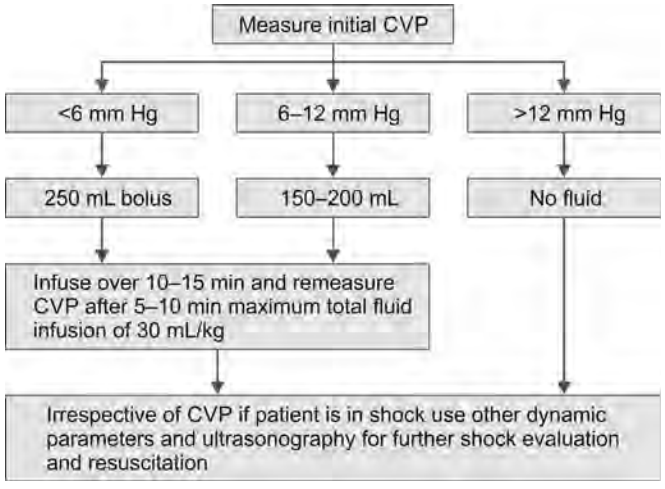
USG parameters	*Findings to continue fluid therapy*	*Findings to restrict fluid therapy*
Lung USG	• A Line present • B line <5	• A line difficult to delineate • Increased B line >5 (**Figs. 3A** and **B**)
IVC caliber	• Size <1.5 cm; collapsibility >50% • IVC collapsibility index >18%	• Size >2.5 cm; no respiratory variation, collapsibility <50% • IVC collapsibility index <12% (**Fig. 3C**)
Echocardiography	• Improved ventricular contractility and ejection fraction • Cardiac output increase	Decreased contractility and ventricular dilatation

(IVC: inferior vena cava; USG: ultrasound)

Resuscitation Guided by CVP, MAP, and $ScvO_2$

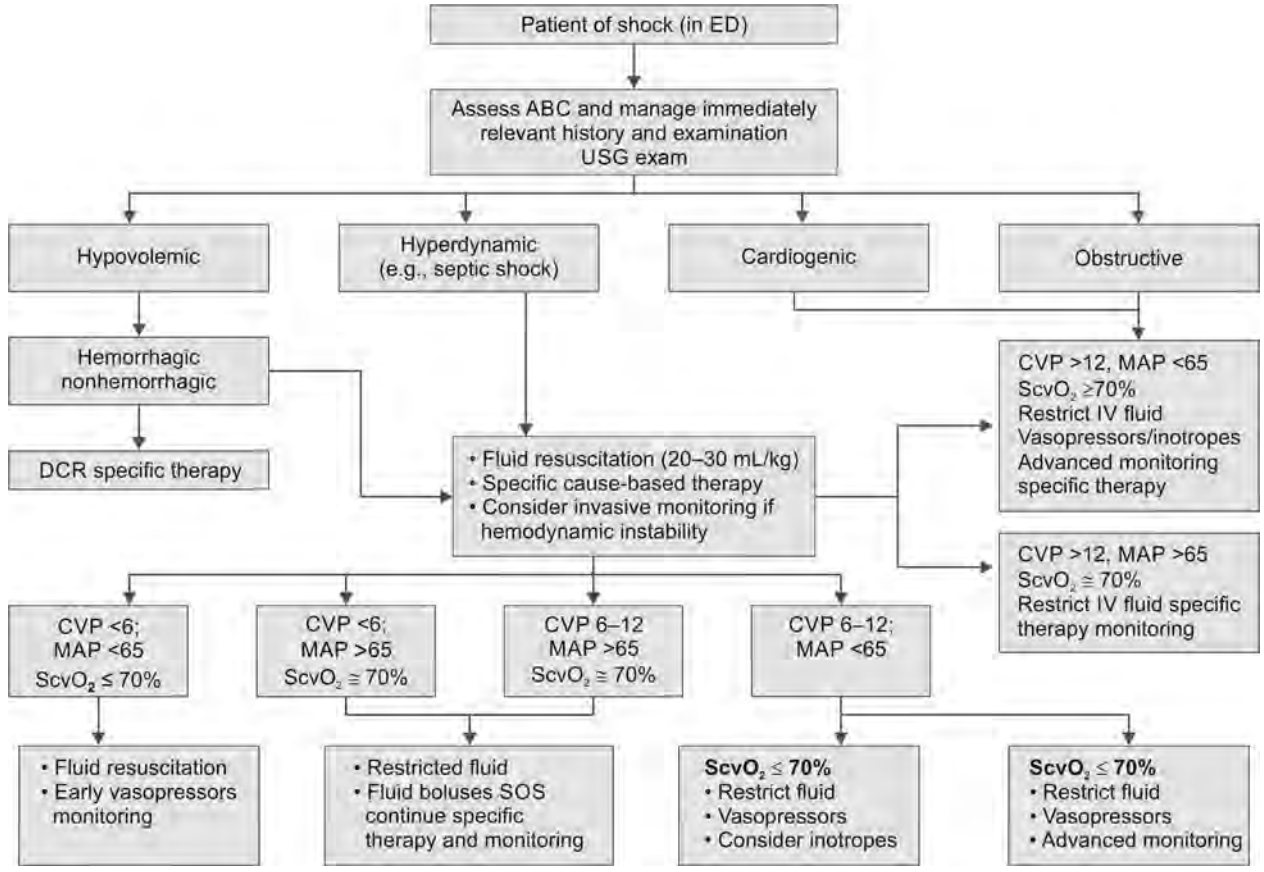
The central venous pressure (CVP) represents "preload" and is used as a surrogate of left ventricular end diastolic volume which determines cardiac output. Thus, venous return to the right atrium ("preload") is maintained if CVP is maintained within normal range. The target CVP during shock resuscitation is 6–12 mm Hg. No single CVP value is adequate and trend during fluid resuscitation is important. Low CVP usually signifies hypovolemia. Higher CVP during resuscitation is ominous and is associated with poor outcome in critically ill. Despite limitations, CVP is a convenient way to assess and monitor initial fluid therapy during resuscitation and has been used widely (**Flowchart 3**). Mini repeated fluid boluses (200–250 mL) of crystalloids may be infused in adults

over 10–15 minutes and CVP measured after 5–10 minutes to guide fluid resuscitation. Mean arterial pressure (MAP) continuous central venous oximetry ($ScvO_2$) parameter should also be taken in to account for resuscitation (**Flowchart 4**). If target CVP is not achieved in shock resuscitation after acute infusion of about 20–30 mL/kg of fluid then other dynamic parameters must be used to plan further fluid therapy and management of shock.



FLOWCHART 3: Fluid resuscitation guided by CVP alone.

Vasoactive drugs: Vasopressors are indicated in cases of persistent hypotension despite fluid resuscitation. It is reasonable to use vasopressor temporarily, while fluid resuscitation is ongoing in cases of major hemodynamic instability. *Noradrenaline is the first choice*; it has predominantly α-adrenergic properties and its modest β-adrenergic effects help to maintain cardiac output. Other vasopressors are adrenaline and dopamine. In randomized controlled trials, dopamine had no advantage over noradrenaline as first-line vasopressor and was found to be more arrhythmogenic. Adrenaline has predominantly β-adrenergic action at low doses, with α-adrenergic effects becoming more prominent in high doses. It is also more arrhythmogenic, decreases splanchnic circulation, and increases lactate levels. Trial has not shown beneficial effects of adrenaline over noradrenaline. Vasopressin deficiency can develop in patients with hyperkinetic forms of distributive shock and administration of low dose vasopressin can lead to substantial increase in blood pressure. *Amongst inotropes, dobutamine is the agent of choice,* it has predominantly β actions. Other agents are phosphodiesterase III inhibitors, such as milrinone and newer agent such as levosimendan, which acts primarily by binding to cardiac troponin C and increasing the calcium sensitivity of cardiac myocytes.



(CVP: central venous pressure; MAP: mean arterial pressure; $ScvO_2$: continuous central venous oximetry)

FLOWCHART 4: Resuscitation of shock guided by CVP, ABP and $ScvO_2$ (USG and other dynamic parameters may also be incorporated simultaneously).

SPECIFIC MEASURES

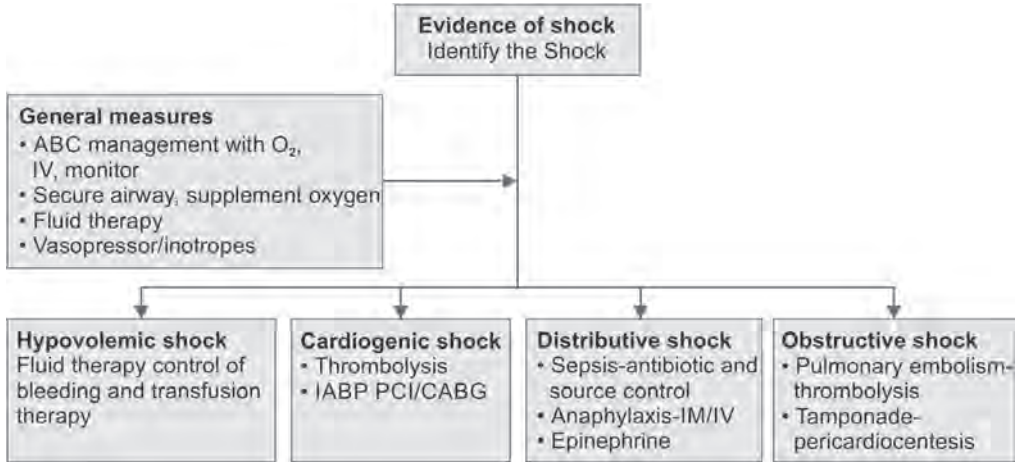
- *Hypovolemic shock*: Fluid administration is the first intervention, but in some trauma patients, it can be delayed until bleeding is controlled. Hemorrhagic shock warrants to identify the source of bleeding and appropriate control by surgical, radiological, or endoscopic intervention. Hypovolemic shock due to intra-abdominal pathologies such as perforation and obstruction also need surgery.
- *Cardiogenic shock*: If evidence of acute myocardial infarction with cardiogenic shock, then along with ventilator and inotropic supports intra-aortic balloon counterpulsation (IABP) is of great help. With IABP support, immediate reperfusion therapy in the form of either thrombolysis (if catheterization laboratory is not available) or immediate cardiac catheterization followed by percutaneous coronary intervention or emergency coronary artery bypass surgery should be done.
- *Distributive shock*: The management of septic shock consists of early goal-directed therapy and administration of antibiotics within 1 hour after sending cultures. Source of sepsis should be sought for with appropriate source control.
- *Obstructive shock*: The main causes are pulmonary embolism and cardiac tamponade. In case of pulmonary embolism, thrombolysis or embolectomy is the options, while in cardiac tamponade, urgent pericardiocentesis will lead to relief of symptoms.
- *Use of USG in specific management of shock*: USG is valuable and may be lifesaving to use for specific management and procedures during shock (**Table 7**). USG can be used for emergency relieve of tamponade, tension pneumothorax, abdominal compartment syndrome, etc. USG will improve the safety of vascular access during emergency.

SUMMARY

Shock is a medical emergency and resuscitation should begin immediately with simultaneous investigations to achieve good outcome. Correction of tissue hypoxia and restoration of adequate perfusion are of prime importance. It is very necessary to determine the type of shock to implement specific measures and correct the cause. The patient should be optimized with prompt resuscitation in emergency room to achieve reasonable hemodynamic stability before shifting to operation room, radiology, or ICU (**Flowchart 5**).

TABLE 7: Specific uses of USG in shock management.

Diagnostic	Tapping of pleural/abdominal fluid collection
Therapeutic	• Pericardiocentesis for tamponade • Thoracentesis for pneumothorax, hemothorax • Abscess drainage
Vascular access	• Central venous catheterization • Arterial line insertion • Dialysis catheter insertion



(CABG: coronary artery bypass graft; IABP: intra-aortic balloon pump; PCI: percutaneous coronary intervention)

FLOWCHART 5: Summary evaluation and management of shock.

49 CHAPTER

Vasopressors and Inotropes in Resuscitation

Manish Mehta

INTRODUCTION

Emergency physician and acute care providers are managing very complex patient population with serious comorbid conditions, and they often require vasopressors inotropes and chronotropes for preservation of vital organ perfusion during acute and severe illness. Although the usage of these drugs is disease specific and therapy is tailored to individual patient. Various physiologic parameters such as fluids status and cardiovascular reserve may also affect patient's response to these drugs. In few patients, the requirement of these drugs is high to achieve the treatment goals. Emergency physicians must be well aware with the use of these drugs as they produce different hemodynamic effect. *Vasopressors* produce peripheral vasoconstrictions increase in systemic vascular resistance (SVR) and mean arterial pressure (MAP). *Inotropes* are used to raise the cardiac contractility, cardiac output, and MAP. *Chronotropes* are used to increase the heart rate.

PHYSIOLOGY: RECEPTORS AND MECHANISMS OF ACTION

The main categories of adrenergic receptors relevant to vasopressor activity are the alpha-1, beta-1 and beta-2 adrenergic receptors, as well as the dopamine receptors. Various receptors and their mechanism of action are described in **Table 1**.

- *Alpha-adrenergic*: Alpha-1 adrenergic receptors, mostly located in vascular walls and also in heart, activation of these receptors induces significant vasoconstriction and also duration of contraction without increasing chronotropy.
- *Beta-adrenergic*: Beta-1 adrenergic receptors are situated in the heart and activation of these receptors causes increases in cardiac contractility, cardiac output, and MAP (inotropic) and chronotropic effect with minimal vasoconstriction. Beta-2 adrenergic receptors activation in blood vessels causes vasodilation.

TABLE 1: Receptor activity and clinical effects.

	Receptor activity				
Drug	***Alpha-1***	***Beta-1***	***Beta-2***	***Dopaminergic***	***Predominant clinical effects***
Phenylephrine	+++	0	0	0	SVR↑↑, CO↔/↑
Norepinephrine	+++	++	0	0	SVR↑↑, CO↔/↑
Epinephrine	+++	+++	++	0	CO↑↑, SVR↓ (low dose) SVR/↑ (higher dose)
Dopamine (μg/kg/min)*					
0.5–2	0	+	0	++	CO
5–10	+	++	0	++	CO↑, SVR↑
10–20	++	++	0	++	SVR↑↑
Dobutamine	0/+	+++	++	0	CO↑, SVR↓
Isoproterenol	0	+++	+++	0	CO↑, SVR↓

+++: Very strong effect; ++: Moderate effect; +: Weak effect; 0: No effect.

*Doses between 2 and 5 μg/kg/min have variable effects.

(CO: cardiac output; SVR: systemic vascular resistance)

- *Dopamine*: Dopamine receptors are situated in the renal, splanchnic (mesenteric), coronary, and cerebral vascular beds; stimulation of these receptors leads to vasodilation. A second subtype of dopamine receptors causes vasoconstriction by inducing norepinephrine release.
- *Calcium sensitizers*: Some agents increase the sensitivity of the myocardial contractile apparatus to calcium, causing an increase in myofilament tension development and myocardial contractility (e.g., pimobendan and levosimendan). These agents have additional pharmacological properties, such as phosphodiesterase inhibition, which increase inotropy and vasodilation.
- *Angiotensin*: Angiotensin receptors (AT1 and AT2) are G-coupled protein receptors with angiotensin II as their ligand. Angiotensin II is a vasoconstrictor that is a part of the renin-aldosterone-angiotensin system (RAAS). When receptors are stimulated, cytosolic calcium concentration increases to mediate vasoconstrictive effects as well as aldosterone and vasopressin secretion.

COMMON PHARMACOLOGICAL AGENTS

Adrenergic Agents

Adrenergic agents such as phenylephrine, norepinephrine, dopamine, and dobutamine are the most commonly used vasopressor and inotropic agents in critically ill patients (**Table 2**).

- *Norepinephrine*: Norepinephrine acts as strong alpha-1 and modest beta-1 adrenergic receptors, thus producing potent vasoconstriction and causes modest increase in cardiac output. So the final effect is increase in systolic and diastolic blood pressure, pulse pressure with modest effect on cardiac output. Minimal chronotropic effect is also noticed. A reflex bradycardia usually occurs in response to the increased MAP, such that the mild chronotropic effect is cancelled out and the heart rate remains unchanged or even decreases slightly. Norepinephrine is the preferred vasopressor for the treatment of septic shock.
- *Phenylephrine*: Phenylephrine exhibits alpha-adrenergic agonist activity and therefore results in vasoconstriction with minimal cardiac inotropy or chronotropy. MAP is augmented by raising SVR. It can be given as bolus to correct sudden and severe hypotension.
  Phenylephrine is reserved for patients in whom norepinephrine is contraindicated due to arrhythmias or who have failed other therapies because it may decrease stroke volume.
- *Epinephrine*: Epinephrine (adrenalin) has potent beta-1 adrenergic receptor activity and moderate beta-2 and alpha-1 adrenergic receptor effects thus vasoconstriction bronchodilation and positive inotropy are final outcome. At high infusion rate, it causes increase in coronary blood flow as myocytes are stimulated to release the local vasodilators. Patient on epinephrine is on high risk for arrhythmia

TABLE 2: Common vasopressors and inotropes.

Agent	*Initial dose*	*Maintenance dose*	*Maximum dose*	*Characteristics and role*
Vasopressors (alpha-1 adrenergic)				
Norepinephrine	• 8–12 µg/min (0.1–0.15 µg/kg/min) • A lower initial dose of 5 µg/min may be used, e.g., in older adults	2–4 µg/min (0.025–0.05 µg/kg/min)	35–100 µg/min (0.5–0.75 µg/kg/min; up to 3.3 µg/kg/min has been needed rarely)	• Initial vasopressor of choice in septic, cardiogenic, and hypovolemic shock • Must be diluted, e.g., a usual concentration is 4 mg in 250 mL of D5W or NS (16 µg/mL)
Epinephrine (adrenaline)	1 µg/min (0.014 µg/kg/min)	1–10 µg/min (0.014–0.14 µg/kg/min)	10–35 µg/min (0.14–0.5 µg/kg/min)	• Initial vasopressor of choice in anaphylactic shock • Typically an add on agent to norepinephrine in septic shock • Increases heart rate; may induce tachyarrhythmias and ischemia • Must be diluted; e.g., a usual concentration is 1 mg in 250 mL D5W (4 µg/mL)
Phenylephrine	100–180 µg/min (0.5–2 µg/kg/min)	20–80 µg/min (0.25–1.1 µg/kg/min)	80–360 µg/min (1.1–6 µg/kg/min)	• Pure alpha-adrenergic vasoconstrictor • Initial vasopressor when tachyarrhythmias preclude use of norepinephrine • May decrease stroke volume and cardiac output in patients with cardiac dysfunction • May be given as bolus dose of 50–100 µg to support blood pressure during rapid sequence intubation • Must be diluted; e.g., a usual concentration is 10 mg in 250 mL D5W OR NS (40 µg/mL)

Continued

Continued

Agent	*Initial dose*	*Maintenance dose*	*Maximum dose*	*Characteristics and role*
Dopamine	2–5 µg/kg/min	5–20 µg/kg/min	20–>50 µg/kg/min	• An alternative to norepinephrine in septic shock in highly selected patients (e.g., with compromised systolic function or absolute or relative bradycardia and low risk of tachyarrhythmias) • More adverse effects (e.g., tachycardia, arrhythmias particularly at doses >20 µg/kg/min) and less effective than norepinephrine for reversing hypotension in septic shock • Lower doses (e.g., 1–3 µg/kg/min) should not be used for renal protective effect and can cause hypotension during weaning • Must be diluted; e.g., a usual concentration is 400 mg in 250 mL D5W (1.6 mg/mL)
Antidiuretic hormone				
Vasopressin	0.01–0.03 units/min	0.03–0.04 units/min	• 0.04–0.07 units/min • Dose >0.04 units/min can cause cardiac ischemia and should be reserved for salvage therapy)	• Add on to norepinephrine to raise blood pressure. Not to be used as first-line vasopressor • Pure vasoconstrictor; may decrease stroke volume and cardiac output in myocardial dysfunction or precipitate ischemia in coronary artery disease • Must be diluted, e.g., a usual concentration is 25 units in 250 mL D5W OR NS (0.1 units/mL)
Inotrope (beta-1 adrenergic)				
Dobutamine	0.5–1 µg/kg/min	2–20 µg/kg/min	20–40 µg/kg/min; doses >20 µg/kg/min are not recommended in heart failure and should be reserved for salvage therapy	• Initial agent of choice in cardiogenic shock with low cardiac output and maintained blood pressure • Add-on to norepinephrine for cardiac output augmentation in septic shock with myocardial dysfunction • Increases cardiac contractility and rate; may cause hypotension and tachyarrhythmias • Must be diluted; a usual concentration is 250 mg in 500 mL D5W OR NS (0.5 mg/mL)
Inotrope (nonadrenergic, PDE3 inhibitor)				
Milrinone		0.125–0.75 µg/kg/min		• Alternative for short-term cardiac output augmentation to maintain organ perfusion in cardiogenic shock refractory to other agents • Increases cardiac contractility and heart rate at high doses; may cause peripheral vasodilation ,hypotension, and/or ventricular arrhythmias • Renally cleared; dose adjustment in renal impairment needed • Must be diluted; e.g., a usual concentration is 40 mg in 200 mL D5W (200 µg/mL)

(D5W: 5% dextrose water; MAP: mean arterial pressure; NS: 0.9% saline)

and splanchnic vasoconstriction in comparison to norepinephrine, dopamine, and vasopressin. Epinephrine is used for treatment of anaphylaxis, as a second-line agent after norepinephrine in septic shock, and for management of hypotension following coronary artery bypass surgery.

- *Dopamine*: Dopamine has a variety of effects depending upon the dose range administered and response is patient specific:
  - At doses of 1–2 μg/kg/min, dopamine acts predominantly on dopamine-1 receptors in the renal, mesenteric, cerebral, and coronary beds, resulting in selective vasodilation.
  - At doses of 5–10 μg/kg/min, dopamine also stimulates beta-1 adrenergic receptors and increases cardiac output, predominantly by increasing stroke volume with variable effects on heart rate.
  - At doses >10 μg/kg/min, the predominant effect of dopamine is to stimulate alpha-adrenergic receptors and produce vasoconstriction with an increased SVR. The usual dose range for dopamine is 2–20 μg/kg/min.
- *Dobutamine*: Dobutamine is an inotrope that causes vasodilation. It increases myocardial oxygen consumption such as isoproterenol. Dobutamine is useful in severe, medically refractory heart failure and cardiogenic shock. Dobutamine is also useful in pharmacological cardiac stress testing.
- *Isoproterenol*: Isoproterenol also is an inotropic and chronotropic agent rather than a vasopressor. The drug high affinity for beta-2 adrenergic receptor causes vasodilation and a decrease in MAP. Therefore, it is useful in hypotension due to bradycardia.

Noradrenergic Agents

A number of agents produce vasoconstriction or inotropy through nonadrenergic mechanisms, including phosphodiesterase (PDA) inhibitors and nitric oxide synthase inhibitors, calcium sensitizers, or angiotensin II.

- *Phosphodiesterase (PDE) inhibitors*: PDE inhibitor such as inamrinone (formerly known as amrinone) which is replaced by the second-generation milrinone improves cardiac output and reduces the SVR (inotrope and vasodilatory actions). Milrinone is used to treat patients with impaired cardiac function and medically refractory heart failure. It cannot be used in hypotensive patients due to its vasodilatory properties. Milrinone can be used in pulmonary vascular hypertension patients as it decreases the pulmonary vascular resistance.
- *Calcium sensitizers*: Levosimendan increases ventricular contractility, improves the cardiac output, arteriolar, and venous dilatation. It also improves the glomerular filtration rate in acute decompensated heart failure (ADHF) and also cardioprotective in ischemic situation.

Vasopressin

In response to hypotension pain nausea hypoxia and increased plasma osmolality, vasopressin [antidiuretic hormone (ADH)] is released from posterior pituitary. Vasopressin is also released from heart if any cardiac muscle stress or from adrenal glands also in response to increase in catecholamine secretion.

Vasopressin causes increase in SVR but minimal effect on cardiac output due to reflexive increase in systemic vagal tone. It is primarily used as a second-line agent in vasodilatory shock, particularly septic shock, or anaphylaxis that is unresponsive to epinephrine.

Vasopressin (ADH) is used in the management of diabetes insipidus and esophageal variceal bleeding. Adverse effects of vasopressin include hyponatremia and pulmonary vasoconstriction.

CLINICAL APPLICATION OF VASOPRESSORS AND INOTROPES IN SHOCK RESUSCITATION

Vasopressors and inotropes are used in various clinical situations described below and summarized in **Table 3**.

Septic shock management starts with source control, volume assessment correction of hypovolemia timely, and appropriate antibiotics, vasopressors are also required to maintain perfusion. Norepinephrine is the drug of choice in shock related to sepsis. Perfusion markers should be assessed regularly such as urine output, mental status, skin perfusion, and serum lactate levels. If resuscitation goals are not met then vasopressin should be started in low dose (0.04 U/min) is safe and effective. If patient has myocardial dysfunction (elevated cardiac filling pressor, low cardiac output, and signs of low perfusion in spite of fluid and vasopressor therapy) then dobutamine can be added. Dopamine can only be added in patient with low risk for arrhythmias.

Cardiogenic shock following the acute coronary syndrome, revascularization is the definitive treatment in this condition with temporary measures such as intra-aortic balloon pump (IABP) and ventricular assist device. Severe hypotension is supported by vasopressors, systolic blood pressor <70 staring the norepinephrine is the best strategies (with low-dose dopamine or/and dobutamine).

Inotropic support is required in ADHF to lower the end-diastolic pressure. Hypotensive patient of ADHF benefited with the dobutamine and milrinone. Inotropes are only recommended if patient has elevated left heart filling pressure or severely impaired cardiac index.

In postcardiac arrest patient in which MAP 70–90 is recommended, norepinephrine is reasonable choice over the dopamine.

Neurogenic shock after spinal trauma is presented by vasodilation, hypotension, and bradycardia. To maintain the MAP 85 or above, dopamine and norepinephrine are the reasonable choice to stimulate $\alpha 1$ and $\beta 1$ receptor activity if cervical injury is present and phenylephrine is the choice if lower thoracic injury is present.

Anaphylaxis is the condition where patient present with acute onset skin and mucosal involvement along with hypotension and respiratory distress after exposure to allergens. Epinephrine is the drug of choice 0.01 mg/kg of: 1,000 solution, maximum 0.5 mg intramuscular can be administered.

FUNDAMENTAL CONCEPTS FOR USE AND PRACTICAL ISSUES

Use of vasopressor and inotropes in resuscitation is based on three fundamental concepts:

1. *One drug many receptor concepts*: Any given vasopressors and inotropes exhibit multiple effects as they act on multiple receptors.

TABLE 3: Clinical applications of vasopressors and inotropes in shock resuscitation.

Type of shock	*First-line therapy*	*Second-line therapy*
Sepsis and shock	• Norepinephrine infusion at 0.1–1 mg/kg/min • Low-dose vasopressin 0.04 U/min	• Dopamine infusion at 5–15 mg/kg/min • Epinephrine infusion at 0.02 mg/kg/min
Cardiogenic shock with LVF	• SBP <70, norepinephrine infusion at 0.1–1 mg/kg/min (0.5–30 mg/min) SBP 70–90, dopamine infusion at 15 mg/kg/min • SBP >90, dobutamine infusion at 2–20 mg/kg/min	Milrinone, 50 mg/kg loading dose, then 5–10 mg/kg/min (not recommended post-MI)
Cardiogenic shock with pulmonary embolism	Dobutamine infusion at 5 mg/kg/min, norepinephrine infusion at 0.1–1 mg/kg/min	Phenylephrine infusion at 10–20 mg/kg/min
Neurogenic shock	Dopamine infusion at 5–15 mg/kg/min	Norepinephrine infusion at 0.1–1 mg/kg/min, phenylephrine infusion at 10–20 mg/kg/min
Anaphylactic shock	Epinephrine, 1 mL of 1:10,000 solution (100 mg), can be given as a slow IV push, then as a 0.02 mg/kg/min infusion (5–15 mg/min)	Norepinephrine infusion at 0.1–1 mg/kg/min (0.5–30 mg/min)
Hemorrhagic shock	Volume resuscitation	Dopamine infusion at 5–15 mg/kg/min as an adjunct
Drug overdose and shock	Norepinephrine infusion 0.1-1 µg/kg/min	• Phenylephrine infusion at 10–20 mg/kg/min • Glucagon given as a 5-mg IV bolus, then 1–5 mg/h infusion • calcium gluconate, 0.6 mL/kg bolus, then a 0.6–1.5 mL/kg/h infusion • Insulin started at 0.1 units/kg/h IV and titrated to a goal of 1 unit/kg/h

(LVF: left ventricular failure; SBP: systolic blood pressure)

2. *Dose responsive curve concept*: Many drugs action is based on "dose responsive curve" and drug like dopamine effect is dose dependent
3. *Direct and reflex action concept*: Norepinephrine-induced beta-1 adrenergic stimulation alone would normally cause tachycardia. However, the elevated MAP from norepinephrine alpha-adrenergic receptor-induced vasoconstriction results in reflex decrease in heart rate.

- *Volume resuscitation*: Coexistent hypovolemia should be corrected before starting the vasopressor in order to maximally effective.
- *Selection of vasopressor*: Choice of drug should be based on underlying etiology of shock. Then need to be titrated on the bases of signs of perfusion and urine output. If one agent is ineffective, the second drug may be added.
- *Rout of administration*: To facilitate the rapid delivery of the drug to the heart for systemic distribution, vasopressors and inotropes should be infused by placing the central venous catheter. Risk of peripheral extravasation of drug will also be eliminated. Vasopressors and inotropes can be given by appropriately placed peripheral cannulas till the time central line is placed.
- *Tachyphylaxis*: Drug must be titrated regularly, to avoid tachyphylaxis phenomenon as responsiveness of the drug reduced over the time.

COMPLICATIONS

Hypoperfusion

Excessive vasoconstriction with inadequate perfusion commonly occurs in setting of inadequate cardiac output or inadequate volume resuscitation. Perfusion of extremities, mesenteric organ and kidneys are also affected due to hypotension and vasopressors.

Initially skin color at the tips of the fingers and/or toes changes, which may progress to black color of digits, frank necrosis which require autoamputation of the digits. Renal insufficiency, oliguria, and acute limb ischemia may develop in patients with underlying peripheral artery disease.

Inadequate mesenteric perfusion increases the risk of gastritis, shock liver, intestinal ischemia, or translocation of gut flora with resultant bacteremia. Despite these concerns, maintenance of MAP with vasopressors appears more effective in maintaining renal and mesenteric blood flow than allowing MAP to drop, and maintenance of MAP with vasopressors may be life-saving despite evidence of localized hypoperfusion.

Dysrhythmias

Stimulation of beta-1 adrenergic receptors exerts powerful chronotropic effects. This causes the risk of sinus tachycardia (most common), atrial fibrillation, reentrant atrioventricular node tachycardia, or ventricular tachyarrhythmias.

Myocardial Ischemia

The chronotropic and inotropic effects of beta-adrenergic receptor stimulation can increase myocardial oxygen consumption. While there is usually coronary vasodilation in response to vasopressors, perfusion may still be inadequate to accommodate the increased myocardial oxygen demand. Daily ECG on patients treated with vasopressors or inotropes may screen for occult ischemia, and excessive tachycardia

should be avoided because of impaired diastolic filling of coronary arteries.

Local Effects

Peripheral extravasation of vasopressors into surrounding connective tissue can lead to excessive local vasoconstriction with subsequent skin necrosis. To avoid this complication, vasopressors should be administered via a central vein catheter whenever possible. If infiltration occurs, local treatment with phentolamine (5–10 mg in 10 mL of normal saline) injected subcutaneously can minimize local vasoconstriction.

Hyperglycemia

Hyperglycemia may occur due to inhibition of insulin secretion. The magnitude of hyperglycemia generally is minor and is more pronounced with norepinephrine and epinephrine than dopamine. Monitoring of blood glucose while on vasopressin can prevent complications of untreated hyperglycemia.

SUMMARY AND RECOMMENDATIONS

- Vasopressors are a powerful class of drugs that induce vasoconstriction and elevate MAP.
- Alpha-1 adrenergic receptors induce vasoconstriction, while beta-1 induces inotropy plus chronotropy, and beta-2 receptors induce vasodilation. One subtype of dopamine receptor induces norepinephrine release with subsequent vasoconstriction, although many dopamine receptors induce vasodilation. Some agents increase the sensitivity of the myocardial contractile apparatus to calcium while others cause direct vasoconstriction via angiotensin II receptor stimulation.
- Vasopressors are indicated for a MAP <60 mm Hg, or a decrease of systolic blood pressure that exceeds 30 mm Hg from baseline, when either condition results in end-organ dysfunction due to hypoperfusion.
- Hypovolemia should be corrected prior to the institution of vasopressor therapy for maximum efficacy. Patients should be reevaluated frequently once vasopressor therapy has been initiated. Common issues that arise include tachyphylaxis, which may require dose titration, and additional hemodynamic insults, which should be recognized and managed.
- Choice of an initial agent should be based upon the suspected underlying etiology of shock (e.g., dobutamine for cardiogenic shock without significant hypotension, norepinephrine for septic and cardiogenic shock with hypotension, and epinephrine for anaphylactic shock).
- Complications of vasopressor therapy include hypoperfusion (particularly affecting the extremities, mesentery or kidneys), dysrhythmias, myocardial ischemia, peripheral extravasation with skin necrosis, and hyperglycemia.

50 CHAPTER

Perfusion Endpoint in Resuscitation of Shock

Nisreen Hamza Maghraby, Zainab Musa Al Alawi

INTRODUCTION

Shock is a life-threatening condition of circulatory failure, causing inadequate oxygen delivery (DO_2) to meet cellular metabolic needs and oxygen consumption requirements, producing cellular, and tissue hypoxia. This results in metabolic acidosis, inflammation, coagulopathy, and then multiorgan failure (MOF) and death. There are five types of shock, each of them presents differently—(1) distributive, (2) cardiogenic, (3) obstructive, (4) neurogenic, and (5) hypovolemic (**Fig. 1**). Generally, shock has four stages based on physiologic parameters, including (1) heart rate, (2) blood pressure, (3) mental status, and (4) urine output. However, their utility in the initial assessment of shock has been questioned and these parameters alone are insufficient to define adequate management and resuscitation. So, well-defined endpoints in resuscitation are needed. Resuscitations primary goal is to restore adequate tissue DO_2 to match the metabolic demand at the level of the tissue. This is mostly accomplished through restoring volume to improve preload and cardiac output (CO), but sometimes medications and optimization of hemoglobin are required. Macrocirculatory endpoints, such as blood pressure and CO, should be the initial focus of resuscitation. Even though restoration of hemodynamic indices does not guarantee tissue-level DO_2 and significant abnormalities at cellular level may continue to exist. Therefore, microcirculatory and metabolic endpoints should be considered to guide further interventions. This chapter will be reviewing the *macro- and micro circulation endpoints* (**Table 1**) in addition to clinical assessment of perfusion.

MACROCIRCULATORY ENDPOINT

In the emergency department (ED), when starting to resuscitate, target macrocirculatory endpoints first, because they can be measured quickly at the bedside. Aims to address intravascular volume status, mean arterial pressure (MAP) and CO. Early recognition of abnormalities with these endpoints and optimizing resuscitation accordingly often prevents early cardiovascular collapse.

TABLE 1: Determinants of perfusion endpoint in resuscitation.

Macrocirculatory endpoints	• Mean arterial pressure • Cardiac output
Microcirculatory endpoints	• Lactate • Mixed and venous oxygen saturation • Central venous-arterial CO_2 gradient
Clinical assessment of perfusion	• Capillary filling time • Urine output

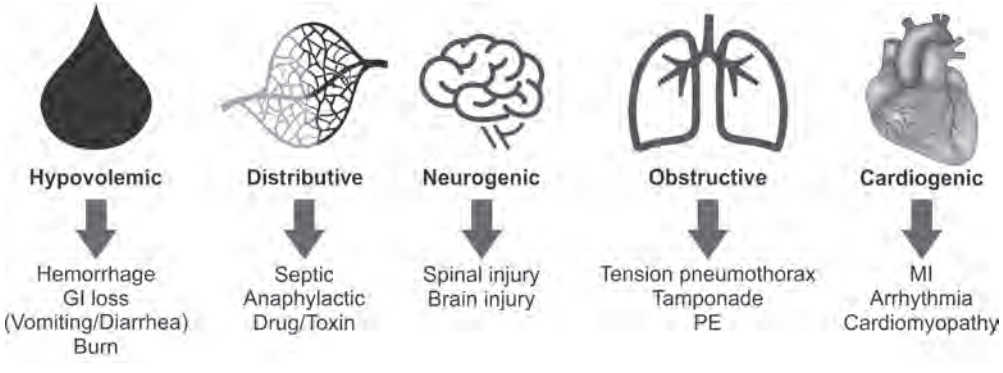

FIG. 1: Types of shock.

Mean Arterial Pressure

Mean arterial pressure, defined as: "MAP ¼ diastolic pressure 1/3 (systolic pressure–diastolic pressure)", is a common endpoint used to guide resuscitation worldwide. It is available between brackets under the blood pressure on most monitors and interpretable. MAP might not be a reliable parameter to follow during fluid resuscitation because of issues that are not uncommon with blood pressure cuffs (too large, too small, and wrong position) and no formal MAP goal that exists yet. Although initially during resuscitation a MAP > 65 and a MAP > 85 in patient with high ICP as head trauma patients are rough goals. In addition, it does not provide information regarding oxygenation at cellular level. During resuscitation in emergency room usually we target mean arterial blood pressure (ABP) of>65–70 mm Hg. In certain condition due to altered physiology and hemodynamic different MAP is targeted (**Table 2**).

Sepsis

The surviving sepsis campaign defines sepsis-related hypotension as a systolic blood pressure of <100 mm Hg, a 40 mm Hg decreases from baseline, or a MAP of <70 mm Hg. A MAP ≥ 60 mm Hg is believed to be needed to maintain adequate tissue perfusion. A MAP ≥65 mm Hg is recommended in patients with severe sepsis and septic shock by the Surviving Sepsis Campaign Guidelines Committee. Current guidelines recommendation to stabilize septic patient is to start with empiric crystalloid fluid bolus of 30 mL/kg to increase the intravascular filling pressure and CO. For fluid refractory hypotension, vasopressor therapy should be initiated. Despite normalization of MAP after proper management, lactic acidosis may persist (cryptic sepsis shock). So, more endpoints to guide septic shock resuscitation are needed.

Hemorrhagic Shock

Resuscitation initially should focus on hemorrhage control combined with rapid perfusion restore by volume reexpansion. In trauma patient without head injury, damage control resuscitation is a commonly implanted strategy that tolerates moderate hypotension to prevent excessive hemorrhage and the need for fluid administration until definitive hemorrhage control is provided. In such condition, resuscitation with balanced blood product administration, either a 1:1:1 ratio or whole blood over intravenous crystalloid therapy, is preferred. Current guidelines recommended a target systolic blood pressure of 80–90 mm Hg until major bleeding has been managed with no definitive evidence to support a specific MAP-based strategy.

TABLE 2: Mean blood pressure (MAP) targets during resuscitation in special clinical conditions.

Higher MAP target (85–90 mm Hg)	***Lower MAP target (55–60 mm Hg)***
Traumatic brain injury	Polytrauma (damage-controlled resuscitation)
Cerebrovascular accident	Hemorrhagic shock
Chronic hypertension	
Hypertensive nephropathy	
Eclampsia	

Cardiac Output

Cardiac output is defined as heart rate times the stroke volume. Normal CO is 4–8 L/min. CO is an important endpoint because it is frequently impaired in all types of shock and has been associated with poor outcomes in patients with cardiogenic shock, sepsis, and trauma, it also predicts fluid responsiveness. CO can be measured at the bedside through a variety of invasive like pulmonary artery catheter and noninvasive measures like bedside echocardiogram that are available in almost all EDs. Inotropic support should be considered in shocked patient with low CO who has adequate intravascular volume with evidence of poor perfusion. Dobutamine is often the inotrope of choice in most ED setting, but it must be used with caution because these agents can cause significant hypotension. Accordingly, most patients in cardiogenic shock need to start on vasopressor therapy first to avoid developing further hypotension secondary to inotropes. Echocardiography as endpoints remains poorly defined and there is limited data to guide standard practice in resuscitation, in addition it does not provide continuous data during resuscitation.

Point-of-care Ultrasound

Assessing intravascular volume status is a macro endpoint that can be evaluate easily at the bedside. The rapid ultrasound in shock (RUSH) protocol is used to evaluate critical patients in shock, to help further classify the type of shock they have. It evaluates via a series of scans the pump (heart), the tank [inferior vena cava (IVC)] and the pipes (aorta). The issue with bedside US is that its operator dependent, if you do not have the proper training and qualification to do it, you might end up with the wrong interpretations that miss leads further management. For more information on the RUSH protocol, please refer to the designated chapter.

MICROCIRCULATORY ENDPOINT

In many shock states, there is a loss of hemodynamic consistency where an improvement in systemic hemodynamics occurs without similar improvement in microcirculatory blood flow and end organ perfusion. Commonly available laboratory markers such as lactate, mixed venous oxygen saturation (SvO_2)/central venous oxygen saturation ($ScvO_2$), and central venous-to-arterial carbon dioxide gap ($PvaCO_2$) are helping to assess the end organ perfusion status.

Lactate

Lactate is a marker of anaerobic metabolism secondary to regional hypoxia and impairment in delivery of oxygen. Normal levels in resting healthy individuals 0.5–2 mml/L. It is easily drawn and measured in arterial or venous blood gas. It is well established that initial lactate correlates with clinical outcome and time to correction of increased lactate is associated with increased mortality rate. Despite reassuring hemodynamic vital signs, the patient with cryptic septic shock when lactate elevation > 4 mm/L has mortality risk similar to those presented with hypotension and should receive careful resuscitation. Data suggest that lactate may provide a useful resuscitation endpoint; however, specific lactate goals have not been defined yet. Alternate etiology of lactate elevation such as medications, adrenergic surge, and delayed clearance can cause hyperlactatemia as in hepatic and renal injury,

so correlating with the clinical presentation is very important, especially if elevated lactate is the only abnormality.

Mixed and Central Venous Oxygen Saturation

The oxygen content (CaO_2) of the arterial blood coming out from left ventricle to aorta is determined by following formula: $CaO_2 = (1.34 \times Hb \times SaO_2) + (0.0003 \times PaO_2)$ where SaO_2 is the arterial oxygen saturation and PaO_2 is the partial pressure of oxygen in arterial blood. In optimum condition, the CaO_2 is about 20 mL/100 mL of arterial blood which is distributed to the different part of body. In steady state, about 25% of delivered oxygen is utilized by the different body tissues and deoxygenated blood is returned to right atrium and pulmonary artery. *The saturation of this deoxygenated blood in pulmonary artery is termed SvO_2*. Nowadays, as pulmonary artery catheter is not used commonly in intensive care unit (ICU) or in ED sampling of central venous catheter is done as surrogate of SvO_2 and is termed $ScvO_2$. $ScvO_2/SvO_2$ represents the balance between the tissue demand and the tissue utilization of oxygen. The acceptable value of SvO_2 in resting state is 75–80%. The $ScvO_2$ measures the saturation of blood in superior vena cava (SVC) unlike in SvO_2 which measures the mixed blood from both IVC and SVC In pulmonary artery. As the splanchnic oxygen extraction is normally lower than the brain; the oxygen saturation of $ScvO_2$ is 2–3% lesser than SvO_2. Steady state $ScvO_2$ is 65–70%. $ScvO_2$ can be continuously measured and monitored during resuscitation by infrared oximetry based on mass spectrophotometry using special proprietary central venous catheters available in market. There are various factors which alter $SvO_2/ScvO_2$ value (**Table 3**). Achieving $ScvO_2$ >70% during septic shock, resuscitation has been recommended as a part of early goal directed therapy and has been associated with 16% increased survival when compared to control group.

Mixed venous oxygenation saturation and $ScvO_2$ are representative of oxygenation extraction by tissue. SvO_2 is measured using a pulmonary artery catheter, and most accurately gives total body oxygenation extraction because it is a true mixed venous sample. $ScvO_2$ is measured with a central line catheter, it is often higher than SvO_2, since it is only measuring regional oxygen extraction for the upper part of the body. The normal range for $ScvO_2$ is 65–75%. $ScvO_2$ of <60% has been associated with major adverse cardiac events in patients with acute decompensated heart failure requiring inotropes and shown to be predictive of poor outcomes. Unfortunately, normal and supranormal values do not guarantee adequate tissue oxygenation. If the $ScvO_2$ levels of >90% suggest poor oxygen utilization. Diseased tissue may not be able to extract oxygen, so venous return may have high O_2 content despite persistent cellular hypoxia, or significant microcirculatory shunting which is associated with a high mortality. Studies have shown benefit in cardiac, trauma, and sepsis patients when used as endpoints of resuscitation, but, it has not been shown to independently predict survival rate. Unfortunately, no benefit has been seen in studies comparing lactate and $ScvO_2$-based resuscitation protocols. SvO_2 and $ScvO_2$ are not commonly used in the ED during early resuscitation.

TABLE 3: Common conditions altering mixed venous oxygen saturation.

Factors increasing $SVO_2/ScvO_2$	***Factors decreasing $SVO_2/ScvO_2$***
Increase tissue oxygen supply: • Vasodilatory shock • Hyperbaric oxygen therapy	*Decrease tissue oxygen supply*: • Cardiogenic shock • Hemorrhagic shock • Severe anemia
Decrease tissue oxygen utilization	***Increase tissue oxygen utilization***
• Anesthesia • Hypothermia • Cytopathic hypoxia	• Hyperthermia • Shivering • Exercise • Septic shock

Central Venous-arterial CO_2 Gradient

The inability of a normal or high $ScvO_2$ to determine adequate organ perfusion has led clinicians to look for other markers of regional tissue hypoxia and metabolic abnormalities especially in septic shock. The venous-to-arterial carbon dioxide gradient has been considered as an alternative test to determine if the patient has achieved adequate CO along with adequate microcirculatory flow and perfusion. It is calculated by subtracting the arterial pCO_2 from the central venous pCO_2 ($ScvO_2$). In multiple studies, a $PcvaCO_2$ gap that is <6 mm Hg, has been found to be associated with a higher cardiac index, better lactate clearance, and improved microcirculatory perfusion. In an opposite manner, a Pcv-aCO_2 gap that is >6 mm Hg can reliably reflect critical hypoperfusion and the need for further resuscitation.

CLINICAL ASSESSMENT OF PERFUSION

In patient with shock, tissue microvascular hypoperfusion can be evaluated at bedside using indicators of skin perfusion, measuring capillary refill time and urine output that are both easily applicable method in many circumstances, cost-effective and it has been used for predicting unfavorable outcomes in critically ill adult patient.

Capillary Refill Time

Capillary refill time is defined as a marker of peripheral perfusion that worsens during circulatory failure. It is the duration of time needed for the patient fingertip to regain color after direct pressure is applied and maintained over 10 seconds to cause blanching. A normal CRT in a healthy patient is <3.5 seconds. Failure to normalize at 6 hours of resuscitation is predictive of worsening shock and values >5 seconds despite hemodynamic optimization suggest a significant risk of progressive organ failure. That indicate further resuscitation is required.

Urine Output

Urine output often is used as a marker of acute kidney injury but also to guide fluid resuscitation in critically ill patients. Although decrease of urine output may be associated to a decrease of glomerular filtration rate due to decreased of renal blood flow or renal perfusion pressure. Consider Foley catheter placement for accurate measurement (normal values: >0.5 mL/kg/h). During the resuscitation phase of

shock, interventions to improve urine output should focus on intravascular fluid optimization, achieving microcirculatory goals, and avoiding unnecessary nephrotoxic agents.

Approach to a Patient in Shock

Standard history and physical examination are crucial to be obtained on every sick patient in the ED as an initial assessment. Then, after a patent airway and adequate oxygenation are ensured, it is important to establish access to the circulation. Peripheral large bore intravenous lines are the first options for venous access. If the peripheral access is difficult, central venous catheterization provides a reliable means of fluid resuscitation. In addition, cannulation of the intraosseous (IO) as a temporizing method is a fast and easy access for the unstable patients presenting without intravascular access. Empiric fluid administration typically is the first line of therapy in all hypotensive patients. Patients presented with hemorrhagic shock are an exception as large volumes of crystalloids will further dilute hemoglobin, platelet, and clotting factors that worsen the general condition of the patient. Instead, blood product should be used. After immediate priorities such as airway and respiratory compromise have been addressed and managed, a rapid assessment of endpoints of resuscitation is required to provide valuable information to guide further resuscitation and volume administration. Start assessment of endpoints of resuscitation by targeting macrocirculatory endpoints at the bedside to address intravascular volume status using point of care ultrasound and MAP. Then, microcirculatory endpoints need to be evaluated using clinical assessment of capillary refill time and urine output. In addition to requesting other laboratory markers (lactate, SvO_2/$ScvO_2$), and $PvaCO_2$) to ensure adequate systemic DO_2 and end organ perfusion.

SUMMARY

Resuscitation is the process of treating shock to restore normal physiology. There are multiple different ways to monitor resuscitation efforts in these patients, no one method is superior. Rather, a combination of approaches must be used based on patient condition, individual, and institutional protocols. Patient in shock frequently present to the ED and the emergency physician must recognize the shock state early and aggressively start resuscitation, using well-defined endpoints. Resuscitation efforts should focus on correction of macro circulatory endpoints such as MAP and point of care US with specific goals dependent on the type of shock and individual patient response. Afterward, microcirculatory endpoints such as peripheral lactate, SvO_2 or $ScvO_2$, and $PvaCO_2$ should guide resuscitation optimization. Finally, clinical endpoints such as capillary refill time and urine output provide valuable information at the bedside and should continue to be part of the resuscitation plan for monitoring and to assist in guiding proper interventions.

Extracorporeal Membrane Oxygenation

51 CHAPTER

Basar Cander

INTRODUCTION

Extracorporeal membrane oxygenation (ECMO) is a modified cardiopulmonary bypass form providing artificial respiration and/or mechanical circulatory support in critically ill patients in intensive care units (ICUs). It is a mechanical cardiopulmonary form that can provide prolonged life support in patients unresponsive to conventional management. Conventional cardiopulmonary bypass devices provide support for patients undergoing surgery for minutes to hours, while ECMO provides support for days to weeks for patients with respiratory, cardiac, or combined cardiopulmonary failure. Indications for ECMO have been extended for longer use in ICUs and for both heart and lung transplants and lung resections in unstable patients. Venovenous ECMO (VV-ECMO) typically provides support for patients with isolated respiratory failure, while venoarterial ECMO (VA-ECMO) is used in both cardiac and cardiopulmonary failure.

As of 2016, >78,000 ECMO was implanted with >19,000 being in adult patients. There was a 433% increase in ECMO cases between 2006 and 2011 in the United States of America. Successful ECMO applications in diseases such as H1N1 influenza, advancements in ECMO technology, and published randomized clinical trials have contributed to this increase.

This chapter begins with historical development of ECMO and continues with description of the technical aspect of ECMO. The indications, contraindications, and complications of ECMO are included. In addition, ECMO practices in special patient groups such as children, the elderly, pregnant women, and obese are discussed. Finally, ECMO practices in COVID-19 that is a current global pandemic are explained and future projections for ECMO are evaluated.

HISTORICAL DEVELOPMENT OF EXTRACORPOREAL MEMBRANE OXYGENATION

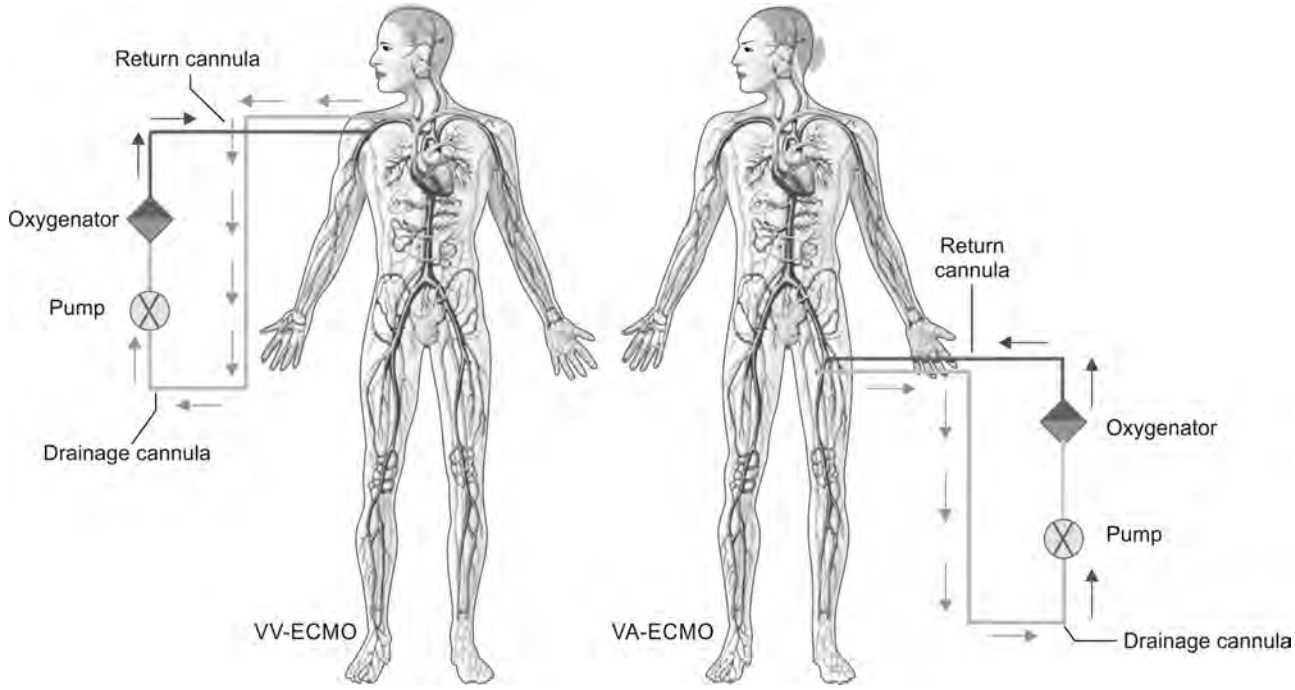
In 1944, Kolff et al. noticed that the blood was oxygenated as it passed through the cellophane chambers of the artificial kidney they developed. This concept was then applied by Gibbon who used artificial oxygenation and perfusion support for the first successful heart surgery in 1953. Direct exposure of the blood to gas in the heart-lung machine of Gibbon caused significant hematologic damage and this limited the use of this machine for only 2–3 hours. In 1969, Dorson et al. used a membrane oxygenation for cardiopulmonary bypass in infants. Whereas in adults, prolonged ECMO support was used for the first time in 1972 for severe respiratory failure. The interest in ECMO has decreased after it was demonstrated that this method is not superior over conventional ventilator support in 1990s, but the use of ECMO flourished again after CESAR study (2009), which randomized patients with severe respiratory failure treated with extracorporeal support between an expert high-case-volume center and a nonspecialized center, and showed a higher improvement in the rates of mortality and severe disability 6 months later in the expert center.

EXTRACORPOREAL MEMBRANE OXYGENATION TECHNIQUES

There are currently two main ECMO modes. VV-ECMO is indicated for severe, but potentially reversible respiratory failure. VA-ECMO provides hemodynamic support and is used for cardiac and/or pulmonary failure. Typical schematic illustration of VV-ECMO and VA-ECMO is shown in **Figure 1**.

Venovenous Extracorporeal Membrane Oxygenation

In VV-ECMO, the blood is drained from the vena cava or right atrium and returned to the right atrium. Alternatively, the drainage cannula is inserted into the jugular vein and the blood is returned to the cannula in the femoral vein. The use of double lumen enables blood drainage and returns functions from the same venous access, providing a greater patient mobility. With this ECMO type not hemodynamic support, but only respiratory support is provided and is used in patients with acute respiratory failure. Satisfying results of the CESAR trial and the successful use of ECMO in severe acute respiratory distress syndrome (ARDS) cases during 2009 influenza pandemic have increased popularity of VV-ECMO in acute respiratory failure.



(VA-ECMO: venoarterial extracorporeal membrane oxygenation; VV-ECMO: venovenous extracorporeal membrane oxygenation)

FIG. 1: Typical schematic illustration of VV-ECMO and VA-ECMO supports. ***(For color version, see plate 3)***

Venoarterial Extracorporeal Membrane Oxygenation

The main function of VA-ECMO is oxygen and carbon dioxide gas exchange as well as providing hemodynamic support. In VA-ECMO, the blood is drained from the right atrium and returned to the arterial system through the femoral, axillary, or carotid artery by bypassing the heart and lungs. The characteristics of VA-ECMO are exclusion of pulmonary circulation. VA-ECMO can be classified as central or peripheral according to the cannulated vessels. VA-ECMO is used in patients with cardiogenic shock or cardiac arrest. The improvement potential of oxygenation is less with VV-ECMO compared to VA-ECMO. However, this ECMO mode decreases right ventricular strain with pulmonary pressures through a similar mechanism.

EXTRACORPOREAL MEMBRANE OXYGENATION COMPONENTS

A typical ECMO circuit consists of a blood pump, membrane oxygenator, conduit tubing, heat exchanger, drainage, and return cannulas. ECMO circuit drains the blood from the venous system and returns the newly oxygenated blood in the membrane to the patient. The main difference between VV-ECMO and VA-ECMO circuits is cannula types and insertion sites.

Pump

The function of the blood pump is to pump blood of the patients to the oxygenator membrane, generating flow in the system. ECMO pump collects the blood from the body via an access site. The pump is usually positioned in the drainage cannula line between patient and membrane oxygenator. The blood flows from the centrifugal pump of the device toward the oxygenator component. ECMO pump is controlled by a console and runs with rotation per minute in order to provide blood flow through the patient's system. Presently, there are two pump types: (1) Roller, and (2) Centrifugal pumps. Roller pump generates a unidirectional and continuous blood flow through the progressive compressions of the segments of the drainage cannula tubing system. Whereas, a centrifugal pump provides a unidirectional and continuous blood flow through the magnetic field generated by the rotation of an axis coupled with a disk. Centrifugal pumps have been associated with less hemolysis compared to roller pumps, and therefore the use of these pumps in adults is increasing.

Oxygenator

Oxygenator contains a fibrous material, which has the ability to provide oxygen and remove carbon dioxide. Oxygenator serves as an artificial lung that exchanges oxygen (to blood) and carbon dioxide (from blood) instead of the native lungs of the patient. Gas diffusion occurs between the patient's blood and fresh blood flow through the oxygenator membrane, providing oxygenation of the venous blood and removal of carbon dioxide. The composition of fresh blood flow is determined by adjusting the inspired oxygen fraction (FiO_2) in the gas mixer. When the blood passes through both main components of the system, it returns to the body from another access site. In recent years, new generation oxygenators that eliminate disadvantages of the old ones have been developed. In these polymethylpentene oxygenators, the need for red blood cell and platelet transfusion is reduced, gas exchange is improved and the durability is better than the previous oxygenators.

WEANING

Weaning from ECMO support is conditioned by the recovery of organ dysfunction and the resolution of indication for

ECMO support. Weaning from VV-ECMO due to acute hypoxic or hypercapnic respiratory failure can be initiated when the patient can satisfactorily maintain gas exchange with acceptable mechanical ventilation parameters. Whereas weaning from VA-ECMO depends on the improvement of cardiac function. Predictors indicating recovery of cardiac functions include maintenance of continuous arterial pulse pressure at least for 24 hours, echocardiography showing improvement of systolic function [left ventricular ejection fraction (EF) ≥ 20%] and adequate arterial oxygenation.

INDICATIONS

Venovenous-ECMO is mostly used in patients with moderately decreased cardiac functions, and is the technique of choice in patients with hypoxemic respiratory failure and hypercapnic respiratory failure. VA-ECMO form is indicated in patients with heart failure that may or may not require pulmonary support.

Venovenous Extracorporeal Membrane Oxygenation Indications

Venovenous-ECMO indications are classically divided into two as hypoxemic respiratory failure and hypercapnic respiratory failure. According to ELSO; the main three indications for VV-ECMO are: (1) Bacterial pneumonia, (2) Viral pneumonia, and (3) Postoperative or trauma-related ARDS.

Venoarterial Extracorporeal Membrane Oxygenation Indications

Venoarterial-ECMO is indicated in the case of cardiogenic shock in which the patient has low cardiac output and tissue hypoperfusion despite hemodynamic optimization using volume replacement, inotrope, vasopressor, vasodilator agents, and/or intra-aortic balloon pump. According to ELSO; the main four indications for VA-ECMO are: (1) Cardiogenic shock, (2) Cardiomyopathy, (3) Congenital heart disease, and (4) Myocarditis. VV-ECMO and VA-ECMO indications are given in **Table 1**.

TABLE 1: Indications for VV-ECMO and VA-ECMO.

VA-ECMO	*VV-ECMO*
Cardiogenic shock	ARDS respiratory failure
Acute coronary syndrome	Primary graft dysfunction after lung transplant
Myocarditis	Pulmonary embolism
Post-cardiac arrest	Traumatic lung damage
Pulmonary hypertension	
Cardiomyopathy	
Primary graft dysfunction after heart transplant	
Traumatic cardiac injury	

(VA-ECMO: venoarterial extracorporeal membrane oxygenation; VV-ECMO: venovenous extracorporeal membrane oxygenation)

CONTRAINDICATIONS

According to the ELSO consensus, there is no absolute contraindication for the use of ECMO, but risks and benefits of ECMO support should be individually evaluated for each patient. However, there is some situation where ECMO benefits can be questioned and considered contraindication. These may include uncontrolled active hemorrhage, incurable cancer, and irreversible central nervous system dysfunction. VV-ECMO and VA-ECMO contraindications are given in **Table 2**.

COMPLICATIONS

The risk for potential complications is high due to the nature of ECMO. The common complications of ECMO include hemorrhage and embolic events; infection, sepsis, and multiple organ failure; pressure injury from impaired skin integrity due to immobility of the patient and organ or tissue malperfusion. The most common complication during ECMO is hemorrhage, ranging between 10% and 30%.

In addition, technical complications are frequently encountered in patients managed with ECMO support. In a retrospective analysis of 265 adult ARDS patients treated with ECMO, reinsertion of ECMO system was needed in 31% of the patients due to technical problems (worsened gas exchange, device-induced coagulation disorders, and suspicion of infection in ECMO circuit). In the same study, the most common technical complications were reported as the formation of progressive clot in the oxygenator membrane

TABLE 2: Contraindications for VV-ECMO and VA-ECMO.

	VA-ECMO	*VV-ECMO*
Relative	Organ dysfunction	Mechanical ventilation in high setting
	Advanced age	Advanced age
	Prolonged mechanical ventilation	Prolonged mechanical ventilation
	Obesity	Obesity
	Peripheral vascular disease	Peripheral vascular disease
Absolute	No chance of organ recovery and not appropriate candidate for transplant	No chance of organ recovery and not appropriate candidate for transplant
	Multiple organ failure	Multiple organ failure
	Prolonged CPR	Malignancy (advanced or metastatic)
	Malignancy (advanced or metastatic)	Severe brain damage
	Severe brain damage	
	Severe aortic regurgitation	

(CPR: cardiopulmonary resuscitation; VA-ECMO: venoarterial extracorporeal membrane oxygenation; VV-ECMO: venovenous extracorporeal membrane oxygenation)

(51%), sudden clot formation in the oxygenator membrane or blood pump (35%), and acute mechanical failure of ECMO system (10%).

EXTRACORPOREAL MEMBRANE OXYGENATION IN SPECIAL PATIENT GROUPS

Children

There are important differences in ECMO applications in pediatric patients compared to adults. These include indications, setup of ECMO circuit, and cannulation sites. According to the last ELSO report; 71% of ECMO cases were children and 47% of the entire cohort were newborns. Because of the lack of robust data, ECMO decision in pediatric patients is challenging. The most common indications for pediatric ECMO include congenital defects (left ventricle outlet obstruction, right ventricle outlet obstruction, and septal defects), cardiomyopathy, myocarditis (viral, bacterial, and aspiration), and ARDS. About 13% of all ECMO cases were performed in patients with cardiac arrest with the highest rate being in neonates by 36%. VA-ECMO is typically applied in the femoral vessels in adults, while this is not the case in children. Neck cannulation enables uninterrupted chest compression during pediatric ECMO support.

Long-term neurological outcomes after ECMO in pediatric patients are still a research topic. In a review of pediatric patients with respiratory failure treated with ECMO support between 2002 and 2012, survival was found as 57% despite comorbidities. However, this rate was 72% in patients without comorbidity. In that study, predictors of poor prognosis were determined as a patient age under 18 years, hepatic or renal failure, immune dysfunction, diagnosis of fungal pneumonia, and pertussis or ARDS secondary to sepsis.

Heparin coating of pumps, oxygenators and artificial surfaces have resulted in a higher biocompatibility and lower complication rates. In addition, improvements in anti-coagulation and bleeding control will make ECMO safer for children.

Elderly

The number of studies on the use of ECMO in elderly is limited. In addition, indications for the use of ECMO in this population are still not clear, and the use of VA-ECMO in elderly patients is controversial. However, the importance of ECMO for cardiopulmonary resuscitation (CPR) is expected to rise as geriatric population increases.

Advanced age has been reported to be a well-known predictive factor of survival for ECMO. Possible reason for this is the increase in comorbidities with ageing. However, some studies have reported that VA-ECMO was effective in elderly patients and yielded survival rates similar to young patients. In a study by Lee et al. investigating the impact of age on survival of the patients with cardiac failure treated with ECMO support, mortality rate was higher in ≥65 years of patients, but after adjusting for comorbidities, age was no longer an independent risk factor of mortality. However, pre-ECMO low serum bicarbonate and high serum creatinine serum levels were reported to be independent predictors of VA-ECMO mortality related to age. In addition, Narotsky et al., reported that advanced age was not an independent factor of short-term and long-term survival among patients receiving VA-ECMO support.

Pregnant Women

Intensive care unit admissions vary between 0.7 and 13.5 per 100 deliveries in peripartum patients, and mortality rate is 3.3% in high-income countries and 14% in low-moderate income countries. Mortality has been reported as about 40% in pregnant or postpartum women with ARDS or cardiac arrest who were admitted to ICUs.

The use of ECMO during pregnancy or postpartum period has been rarely reported since it is thought to increase the risk of developing maternal or fetal hemorrhage. The literature about ECMO support during pregnancy is limited with case reports, case series, and systematic reviews. According to these reports, peripartum patients receive ECMO support for respiratory and cardiovascular indications, the main etiology is ARDS among the respiratory indications, while the most common cardiovascular indications are reported as pulmonary embolisms and peripartum cardiomyopathy. Again according to the same studies, mortality rate is lower in peripartum patients requiring VV-ECMO compared to those receiving VA-ECMO support.

Moore et al., conducted a comprehensive literature review about the use of ECMO support during pregnancy and reported overall maternal survival as 78% and fetal survival as 65%. In contrast, in a literature screening by Ong et al., case reports on ECMO support during pregnancy period were reviewed and maternal survival was found as 91% and fetal survival as 79%.

Obese

In general, a circuit flow indexed to weight or body surface area is needed to sustain rest and recovery of the lungs in patients with severe hypoxia. In addition to the difficulties in the cannulation, obesity poses an important challenge in obtaining an adequately indexed flow. In addition, increased risk of comorbidities such as diabetes mellitus, hypertension, and coronary artery disease causes an additional difficulty for ECMO support. Therefore, there are drawbacks in many centers about the use of ECMO support in obese patients. However, outcomes have not been reported sufficiently in this patient group. Furthermore, accumulating evidence indicates that obesity has a protective effect against critical diseases. This may explain why obesity is not associated with worse results in patients with ARDS who are managed conventionally.

In the literature, there is data supporting the use of ECMO support in patients with critical weight. In a multivariate analysis by screening ELSO registry between 2002 and 2006, Brogan et al. reported that body weight was significantly higher in the survivor patients. Al-Soufi et al., investigated the relationship between body weight and results in all patients supported with VV-ECMO between 2005 and 2011 and concluded that body weight was not correlated with increased mortality. However, since body weight was used as a parameter in both studies rather than body mass index, no sufficient conclusion could be drawn about the use of ECMO support in obese patients.

Extracorporeal Membrane Oxygenation in COVID-19

During the 2009 influenza A (H1N1) pandemic, ECMO treatment was found to be beneficial, and the mortality rate was

21% in patients with H1N1-related ARDS who received ECMO support, which has been increased the use of ECMO support. Again in a cohort study conducted about the same pandemic, the mortality rate was 23.7% in patients with H1N1-related ARDS who received ECMO support, while this rate was 52.5% in patients who were not treated with ECMO. In a retrospective study conducted on Middle East respiratory syndrome-related coronavirus (MERS), it was highlighted that ECMO should be used as a rescue treatment, and the mortality rate was found to be lower in ECMO group compared to the conventional group (65% vs. 100%).

According to a new report published in JAMA, 26.1% of 138 COVID-19 patients were admitted to the ICU, and 61.1% had ARDS. According to this report, the rate of mortality from COVID-19 was found as 4.3%. So far there is no COVID-19 specific treatment. According to an interim guidelines formulated by the World Health Organization (WHO), ECMO should be considered as rescue treatment for COVID-19 with refractory hypoxemia despite lung preserving ventilation. However, experience with the use of ECMO support in COVID-19 patients is highly limited. In a study by yang et al., 31 of 52 critically ill adult patients diagnosed with COVID-19 and treated in the ICU died on the 28th day. Six patients received ECMO support and five of these patients died. In another study by Guqin et al. 10 of 48 ARDS patients with laboratory confirmed COVID-19 received ECMO support. Two of them were discharged with clinical improvement, three died and the remaining five patients were still on ECMO support at the time of the study.

According to ELSO, as of June 1, 2020, ECMO support was used in 1,371 patients with confirmed diagnosis of COVID-19 pneumonia, and among these patients 390 (55%) of 706 patients who survived were discharged. There are many factors that may influence outcomes of ECMO treatment in COVID-19 pneumonia. These factors may include the duration of mechanical ventilation, severity of the underlying disease, experience of the trained medical personnel, and ECMO equipment. However, it should be remembered that medical staff who performed ECMO support can be easily infected by the virus.

FUTURE PROJECTIONS

It is obvious that as ECMO technology develops and the experience of the implementing teams increases, and this application will be used more widespread. With the development of technology in the future, more compact ECMO circuits will prevent femoral cannulation, and invasive mechanical ventilation will be minimized, thus, rehabilitation of patients and ambulation will be more feasible. With the smaller circuit components and more efficient gas exchange membranes, portable extracorporeal gas exchange devices will be developed, which will enable a potential paradigm shift in the field of artificial lung.

Despite the increased popularity of ECMO in cardiopulmonary diseases, there are numerous questions on the patient groups in which this support should be provided. Large-scale randomized controlled studies are needed about the use of this technology and for comparison ECMO with the other treatment options in cardiovascular failure. In these studies, cost-benefit analysis should be made in order to better understand the economical impacts of ECMO, which is a resource intensive intervention. In the lack of quality data, ECMO cannot be adequately included in basic cardiac and pulmonary practice guidelines.

SUMMARY

Extracorporeal membrane oxygenation is a method that can be indicated for the management of patients with cardiac and/or respiratory failure and is applied by multidisciplinary experienced teams. Advances in ECMO technology have led to increasing use of this technique in respiratory and cardiac failure. Although there are various arguments recommending the use of ECMO from a physiopathological point of view, further studies are needed to determine the patient eligible for this method and the optimal starting time of ECMO support. More data and stronger evidence to be obtained on this subject will provide a better understanding and extension of ECMO indications.

52 CHAPTER

Procedural Sedation and Analgesia

Devendra Richhariya, Bhawana Sharma

INTRODUCTION

There is an ever-increasing patient population including children and elderly, requiring sedation and analgesia when being treated in the emergency department. Emergency department is the place where sedation and analgesia are provided for unscheduled procedures. In procedural sedation and analgesia processes (PSA), various anxiolytics, sedatives, hypnotics, and/or dissociative medication are being used. These agents provide amnesia, decreased awareness, increase patient comfort and safety during diagnostic and therapeutic procedures in emergency department. Also, during the PSA, various methods of airway protection such as airway adjuncts or endotracheal intubation are not required. "Procedural sedation is a technique of administering sedatives or dissociative agents with or without analgesics to induce a state that allows the patient to tolerate unpleasant procedures." Before further discussion, one should know the various levels of sedation and analgesia. On the basis of effect on various body function, sedation levels are divided into minimal, moderate, deep sedation, and general anesthesia (**Table 1**).

- *Mild sedation*—also termed as "anxiolysis" where patient response is normal but slow airway, breathing, and circulation remain normal and need no support.
- *Moderate sedation*—patient response is purposeful to verbal/physical stimuli, airway breathing and circulation parameter are maintained and usually need no support.
- *Dissociative sedation*—patient response is variable and trance-like state airway, breathing and circulation parameters are maintained and usually need no support. Dissociative sedation is a type of moderate sedation. Dissociation is a state in which the cortical centers are prevented from receiving sensory stimuli, but cardio-pulmonary activity and responses are preserved.
- *Deep sedation*—patient responds only after repeated stimuli, airway and breathing may be suppressed but circulation is generally maintained.
- *General anesthesia*—patient not arousable even by painful stimulus, airway support required because of breathing impairment, circulation may impair.

TABLE 1: Different levels of sedation, recommendation for monitoring and their effects on bodily functions.

Level of sedation	*Responsiveness*	*Airway*	*Spontaneous ventilation*	*Cardiovascular function*	***Monitoring*** (conscious level, heart rate, blood pressure, oxygen level)
Minimal sedation/ anxiolysis	Normal response to verbal stimulation	Unaffected	Unaffected	Unaffected	Record HR, RR, BP every 15 min, and continuous oxygen saturation
Moderate sedation/analgesia (conscious sedation)	Purposeful response to verbal or tactile stimulation	No intervention required	Adequate	Usually maintained	Continuous monitoring of every parameters
Deep sedation/ analgesia	Purposeful* response following repeated or painful stimulation	Intervention may be required	May be inadequate	Usually maintained	Continuous monitoring of every parameter
General anesthesia	Unarousable even with painful stimulus	Intervention often required	Frequently inadequate	May be impaired	Continuous monitoring of every parameter

(BP: blood pressure; HR: heart rate; RR: respiratory rate)

SEDATION POLICY AND GUIDELINES

Institution- and evidence-based policy should be in place in a hospital, which allows the emergency physician to create appropriate sedation plan for each patient. Emergency physician who is trained in providing the sedation, performing the procedure and the nurse who is trained in monitoring the patient is appropriate for practice in emergency department. Both physician and nurse are able to do the immediate resuscitation. Leadership of the emergency department, both physician and nurses should develop the policies where scope of nursing practice is determined where the nurse can also safely administer sedation in resource-limited setting.

INDICATIONS IN EMERGENCY DEPARTMENT

In emergency department, various types of sedation may be indicated for different procedures depending upon the urgency, invasiveness, and painful procedure. The need for sedation is sometimes more urgent than a full preprocedural evaluation (**Table 2**).

PRESEDATION PATIENT EVALUATION

Despite careful planning and performance, the depth of sedation needed or achieved cannot always be predicted. It is therefore important to prepare for managing deeper levels of sedation than anticipated. Most of the agents used can produce variable levels of sedation, so pay particular attention to dosing and to the patient's responses to the medications.

Risk Assessment

Complications are primarily determined by the interaction of the depth of sedation and the patient's current medical condition. One of the most common tools to assess patient's underlying clinical condition is the American Society of Anesthesiologists' *physical status classification system*. Class I—patient is healthy and no associated comorbidities; Class II—patient having mild or controlled disease such as mild asthma, obesity-controlled diabetes, and pregnancy; Class III—severe systemic disease moderate to severe asthma, pneumonia, and end-stage renal disease (ESRD); Class IV—life-threatening illness such as sepsis, severe cardiac dysfunction, and DIC; and Class V—polytrauma multiorgan dysfunction.

TABLE 2: Indications for sedation in an emergency department.

Type of sedation	*Indications*
Emergent	Cardioversion for life-threatening arrhythmias, neuroimaging for head trauma, reduction of fractures or dislocations with soft tissue or vascular compromise, care of contaminated wounds, or intractable pain
Urgent	Stable fractures, abscess incision and drainage, care of clean wounds, foreign body removal, and laceration repair
Nonemergent	Removal of a soft tissue foreign body, placing splints on fractures that require minimal manipulation, or changing splints on fractures that have already been reduced

Patient Assessment

Focused history is important to establish fasting state, prior experiences with sedation or anesthesia, current medications, and allergies. Focused physical examination reveals any potential difficult airway or cardiopulmonary compromise. A potentially difficult airway should be anticipated when the following findings or conditions are present—short neck, micrognathia, large tongue, trismus, morbid obesity, a history of difficult intubation, or anatomic anomalies of the airway and neck. At a minimum, difficult airway equipment should be present and available.

Airway Assessment Procedures for Sedation and Analgesia

If respiratory compromise develops during sedation/analgesia, positive pressure ventilation, with or without tracheal intubation, may be necessary. This may be more difficult in patients with atypical airway anatomy. Also, some airway abnormalities may increase the likelihood of airway obstruction during spontaneous ventilation. Some factors that may be associated with difficulty in airway management are listed here.

- *History*:
  - Previous problems with anesthesia or sedation
  - Stridor, snoring or sleep apnea
  - Advanced rheumatoid arthritis
  - Chromosomal abnormality (e.g., trisomy 21)
- *Physical examination*:
  - *Habitus*: Significant obesity (especially involving the neck and facial structures)
  - *Head and neck*: Short neck, limited neck extension, decreased hyoid-mental distance (<3 cm in an adult), neck mass, cervical spine disease or trauma, tracheal deviation, and dysmorphic facial features (e.g., Pierre–Robin syndrome)
  - *Mouth*: Small opening (<3 cm in an adult), edentulous, protruding incisors, loose or capped teeth, dental appliances, high and arched palate, macroglossia, tonsillar hypertrophy, and nonvisible uvula
  - *Jaw*: Micrognathia, retrognathia, trismus, and significant malocclusion

Cardiorespiratory conditions increase the complication rate. Most agents can cause vasodilation and hypotension, particularly in patients with pre-existing hypovolemia. Drugs or alcohol intoxication or reduced level of consciousness increases the risk of hypoxemia and hypoventilation. If possible, delay procedural sedation in intoxicated patients until mental status improves.

PREPARATION

Current Practice Guidelines

- *Preprocedure fasting*: In urgent or emergent situations where complete gastric emptying is not possible, do not delay moderate procedural sedation based on fasting time alone.

- *Routine capnography*: Capnography may be used as an adjunct to pulse oximetry and clinical assessment to detect hypoventilation and apnea earlier than pulse oximetry and/or clinical assessment alone in patients undergoing PSA in the emergency department. Capnography includes all forms of quantitative exhaled carbon dioxide analysis.
- *Number of personnel required*: For minimal and moderate levels of sedation, one emergency physician simultaneously administering sedation and performing the procedure with a nurse monitoring the patient appears to be an appropriate practice. However, for deep sedation, two physicians, one to perform sedation and monitor the patient and the other to perform the procedure.

Equipment

Sedation area must have all size-appropriate equipment for airway management and resuscitation. An ideal list is provided in **Table 3**.

Monitoring

There are two types of monitoring: (1) Interactive and (2) Electronic. *Interactive monitoring* is the direct observation of the patient to assess the depth of sedation and observe for hypoventilation or apnea, upper airway obstruction, laryngospasm, vomiting, or aspiration. Thus interactive monitoring requires an unobstructed view of the patient's face, mouth, and chest wall. *Electronic monitoring* uses equipment to assess arterial oxygenation, ventilation, blood pressure, and cardiac rate and rhythm. Moderate and deep sedation require constant observation and continuous monitoring.

Pulse oximetry is not a substitute for monitoring ventilation. Quantitative capnography may be used as an adjunct to pulse oximetry and clinical assessment to detect hypoventilation and apnea earlier than pulse oximetry and/or clinical assessment alone in patients undergoing PSA in the ED. Capnography during procedural sedation allows the early recognition of adverse events.

Monitoring of vitals including heart rate, blood pressure, and pulse oximetry must be taken and recorded legibly before beginning sedation and after each dose of medication, upon completion of procedure, beginning of recovery period, and upon discharge. For mild sedation, intermittent measurements are sufficient. For moderate and deep sedation, it is recommended that blood pressure should be assessed every 5 minutes and heart rate and pulse oximetry should be continuously monitored. Patients are at the highest risk of hypoxia and hypoventilation during the period immediately after IV medication administration (until the peak effect of the medication has been reached) and during the immediate postprocedure period (when external stimuli are discontinued and the stimulating pain of the procedure has subsided).

TECHNIQUE FOR PROCEDURAL SEDATION AND ANALGESIA

Preprocedure Analgesia and Selection of Sedative Agents

Preprocedure administration of analgesics such as opioids makes the patient more comfortable during painful procedures. Fentanyl 1–2 μg/kg often required to control the pain. Sedatives should be administered after time of peak action of analgesics in nonurgent to semiurgent procedures as it decreases postprocedure analgesic requirement and oversedation may result, if analgesic medications are given after sedation. Shorter-acting agents are preferred to drugs with a longer duration of action to minimize postprocedure respiratory depression. Various factors should be considered while choosing the appropriate agents and doses are patient age, comorbidities, and sedation target level (**Table 4**).

Oxygen Supplementation

The use of supplemental oxygen throughout procedural sedation is a common emergency department practice. The

TABLE 3: Emergency equipment for sedation and analgesia.

Basic airway management equipment (age- and size-appropriate)	*Advanced airway management equipment*	*Emergency medications*	*Pharmacologic antagonists*
• Sources of compressed O_2 (tank with regulator or pipeline supply with flowmeter) • Source of suction • Suction catheters • Yankauer-type suction • Face masks • Self-inflating breathing bag-valve set • Oral and nasal airways • Lubricant	• Supraglottic airway devices • Laryngoscope handles (tested) • Laryngoscope blades • Endotracheal tubes • Stylet • Gum-elastic bougie	• Epinephrine • Ephedrine • Vasopressin • Atropine • Nitroglycerine • Lidocaine • Glucose (IV or oral) • Diphenhydramine • Hydrocortisone, methylprednisolone, or dexamethasone • Benzodiazepines • B-blocker • Adenosine	• Naloxone • Flumazenil • Amiodarone

Other equipment *(age- and size-appropriate)*: *Gloves, tourniquets, alcohol wipes, sterile gauze pads, intravenous catheters, intravenous tubing, intravenous fluid, assorted needles for drug aspiration, intramuscular injection, appropriately sized syringes, tape*

TABLE 4: Drugs for procedural sedation.

Drugs	*Dose*	*Onset of action*	*Effectiveness*	*Comments*
Propofol	• 0.5–1 mg/kg • Repeat dose 0.25–0.5 mg/kg • In elderly 0.25–0.5 mg/kg	<1 min	<10 min	• Good for orthopedic reduction as rapid onset and short duration of action • Respiratory depression may occur • Do not provide analgesia
Ketamine	1.0–1.5 mg/kg over 1 min and repeat dose 0.5–1 mg/kg and for only analgesia 0.1–0.3 mg/g	<1 min	10 min	• Act as both sedative an analgesia, safer in comorbid conditions, provides cardiorespiratory stability • Avoid in psychiatric illness
Etomidate	• 0.1–0.2 mg/kg repeat dose 0.05 mg /kg	<1 min	<5 min	Useful for short procedure and cardioversion, minimum cardiac, and respiratory depression
Ketamine +Propofol (ketofol-single syringe)	0.5 + 0.5 mg	<1 min	<10 min	• Ketamine adds analgesic properties. Blunt propofol induces hypotension, good for prolonged procedure • Longer time for recovery if ratio increased
Midazolam	• 1–2.5 mg repeat dose 0.5–2.5 mg, repeat dose in every 3 min • For elderly dose—0.05 mg/kg	<5 min	30–60 min	• Useful for longer procedures • Not provides analgesia, so combined with analgesic • Cardiovascular and respiratory depression
Fentanyl	0.5–1.5 µg/kg repeat dose is the same every 2–3 min. In elderly dose is 0.25 µg/kg	<2 min	30–60 min	• Monotherapy used for minimal sedation • Respiratory depression may occur
Alfentanil	• 10 µg/kg • Repeat dose also same • Reduced doses are used in elderly	<1 min	<10 min	• Fast onset and short duration of action • Increased risk of apnea
Remifentanil	• 0.16 µg/kg/min infusion or 1 µg/kg bolus • Less doses in elderly	Immediate	10 min	• Fast onset and short duration of action • Increased risk of apnea

benefit is that enhanced oxygen reserves permit a longer period of normal oxygenation in the event of apnea or respiratory depression. The disadvantage is that supplemental oxygen therefore negates oximetry as an early warning device. Two studies of emergency department propofol sedation without supplemental oxygen have reported desaturation rates of 11.6% and 31%. These rates are higher than the 5–7% similarly observed in studies with supplemental oxygen. A randomized controlled trial showed no apparent benefit to supplemental oxygen during emergency department moderate sedation; however, this question has not been similarly studied for deep sedation. In the case of apnea, a preoxygenated patient will tolerate a longer period of apnea without requiring assisted ventilation, with the associated risk of gastric insufflation. Thus, although unproven, the administration of supplemental oxygen with propofol seems prudent, particularly when the patient's respiratory status can be monitored with capnography, in addition to pulse oximetry.

Sedation Management

Observe and monitor the patient until the peak effect of the initial sedative dose has been reached. If necessary, titrate with additional medications to the desired sedation level. Once the patient has achieved the target sedation level, the actual procedure may begin. If the patient begins to regain alertness before completion of the procedure, additional sedative doses may be required. However, additional sedative doses given to extend procedural sedation are associated with an increased risk of respiratory depression. As larger cumulative doses of the drug are given, the half-life of each bolus will increase. After the patient recovers from sedation, analgesics are administered as needed, for patient comfort.

Complications

Reported rates of complication during procedural sedation in emergency department vary from 0.1 to 4%. Factors associated with an increased rate of complications include age >65 years, level of sedation, premedication with fentanyl, use of short-acting agents and procedural sedation, and analgesia performed at night, when PSA could be administered by physicians with varying levels of training and experience and when consultant-level supervision is not always physically present.

Serious adverse events include the need for assisted ventilation, endotracheal intubation, or treatment of hypotension or cardiac dysrhythmias. Minor adverse events resolve spontaneously and include sedation to a deeper level than intended, transient hypoxia, or emesis. Complications can occur unexpectedly, so careful preparation, appropriate procedural monitoring, and careful selection of the target

TABLE 5: Aldrete score—assessment of the patient recovery and safety for discharge.

Activity	*Respiration*	*Circulation*	*Consciousness*	*Oxygen saturation*
Score 2: Moves all extremities voluntarily/on command	*Score 2*: Breathes deeply and coughs freely	*Score 2*: BP + 20 mm Hg of preanesthetic level	*Score 2*: Fully awake	*Score 2*: SpO_2 > 92% on room air
Score 1: Moves 2 extremities	*Score 1*: Dyspneic, shallow or limited breathing	*Score 1*: BP + 20–50 mm Hg of preanesthetic levels	*Score 1* : Arousable on calling	*Score 1*: Supplemental O_2 required to maintain SpO_2 > 92%

Aldrete score: A score of ≥9 is appropriate for safe discharge.				

sedation level will minimize the rate of occurrence and severity of adverse events.

Follow-up and Patient Instructions

At the completion of sedation and the procedure, patients should be monitored until they return to baseline mental status and cardiopulmonary function. A structured assessment, such as the *Aldrete score* (**Table 5**), can be used to assess the patient's recovery and safety for discharge. The duration of observation before discharge is variable. It depends on the quantity of sedatives given, the patient's response, the duration of the procedure, and the occurrence of any adverse events. Most adverse events occur during procedural sedation itself, typically within a few minutes of sedative administration. The occurrence of adverse events > 5 minutes after completion of the procedure is rare (<1%). Patients should be instructed to return if they develop respiratory complaints or nausea or vomiting. The follow-up interval required for patients who undergo emergency department procedural sedation is usually related to the procedure rather than the sedation itself.

SUMMARY

Noninvasive and minimally invasive procedures are performed not only in operating room but also in emergency department; for various procedures sedation, analgesia, or both may be required for interventional or diagnostic procedures. Systematic assessment and care are required for PSA. The requirement of patient may be an antianxiety drug, pain medicine, immobilization, simple reassurance, or a combination of these interventions. The procedures performed in emergency department may be painful or painless so, sedation management can range from minimal sedation, to the extent of deep sedation. Procedural sedation in emergency department usually requires single agents or combinations of multiple agents to reach desired effects of analgesia plus anxiolysis. For successful imaging, patient immobility is the key. Immobility can be achieved by moderate to deep sedation or minimal anesthesia. On the other hand, moderate sedation, deep sedation, and minimal anesthesia can be all utilized for emergency department procedures.

53 CHAPTER

Pain Management in Emergency Department

Radhika Rani Chandra, Devendra Richhariya

INTRODUCTION

Pain is an unpleasant and emotional experience, originating in normal or potential damaged tissues. Pain is the most common presenting complaints (75–85% as primary complaints) in emergency department and most undertreated condition also. In our experience, in most of the cases, treatment of pain improves the patient satisfaction. *Pain management is urgently indicated in* acute subarachnoid headache, acute myocardial infarction, acute aortic dissection, acute pancreatitis, acute appendicitis, acute renal and ureteric colic due to calculus, ectopic pregnancy, anal fissure, trauma with head injuries, trunk and limb fractures, joint dislocations, electrical and thermal burns, acute rheumatoid arthritis in joints, analgesia during chest tube insertion, and reducing fractures and dislocations. Pain should be assessed by various available scales and which is also helpful in documenting the drug response. *It is important to note the potential causes for pain control failure in emergency department,* e.g., failure to assess pain, failure to document pain, failure to implement pain guidelines, and failure to meet patient expectation. Emergency physician should have good knowledge of the analgesics and anesthetics, their contraindications, side effects, administration methods, and monitoring requirements. Uncontrolled pain is a medical emergency and considered as quality parameter also.

Various terminologies are used related to pain:

- *Allodynia*—pain from stimulus that normally not give rise pain.
- *Amnestic*—drugs that inhibit formation of memories.
- *Local anesthesia*—drugs that make area insensitive to pain by injecting agent locally.
- *Analgesia*—agents that cause pain relief.
- *Hypnotic*—agents that induce onset of sleep.
- *Nociceptor*—pain sensitive receptor which is also responsible for pain transmission.
- *Noxious stimulus*—potentially damaging stimulus
- *Procedural sedation*—agents that used during painful procedure that causes sedation and amnesia.
- *Somatic pain*—localized in the body tissues such as nociceptive pain and neuropathic pain
- *Psychotic pain* is pain with no known physical cause.
- *Acute pain* is protective mechanism that alerts the individuals to harmful objects, sudden in onset, and relief after removal of its mediators that stimulate receptors, acute pain stimulates, autonomic nervous system causes increased heart rate and respiratory rate, elevated blood pressure, pallor or flushing, dilated pupils, diaphoresis, increase in blood sugar, and gastric acid secretion decrease in gastric motility. Acute pain also causes fear, anxiety, and general sense of unease.
- *Chronic pain* develops gradually, persistent or intermittent chronic pain can produce depression and sleeping disorders.

PATHOPHYSIOLOGY

Pain is spontaneous physiologic response to noxious stimuli which is expressed (pain) by various behavioral, cognitive, and sociocultural parameters. Pain experience by any individual is variable and depends on various factors such as present and past medical history, cognitive state, emotional maturity, and patient surrounding environment. So assessment of pain by another person is generally inaccurate and for quantification of pain, self-reporting is considered gold standard. Nociceptors, C fibers, and A-delta fibers of peripheral nervous system respond to noxious stimuli and initiate sensation of somatic pain, by sending neuronal discharge to dorsal horn of the spinal cord (**Fig. 1**). All the inputs from the various peripheral nerves and sensory stimuli are integrated, modulated, and transmitted to brain (hypothalamus, thalamic nuclei, limbic system, and reticular activating system from the spinal cord) from the spinal cord. In the brain, again processing and integration are done and then perception of pain is generated. Visceral pain pathway is more complex than somatic pain (easily localized) and that's why poorly localized. There are four types of opioid receptors are present in spinal cord and brain (delta, kappa, mu, and nociception) and opioid analgesic work by binding to these receptors. Stimulation of μ1 receptor causes supraspinal analgesia. Stimulation of μ2 receptors causes euphoria miosis respiratory depression, and decreases GI motility also. Delta receptor stimulation produces analgesia. Kappa receptors stimulation produces dysphoria dissociation, delirium, and diuresis. None of the opioid receptor is associated with addiction.

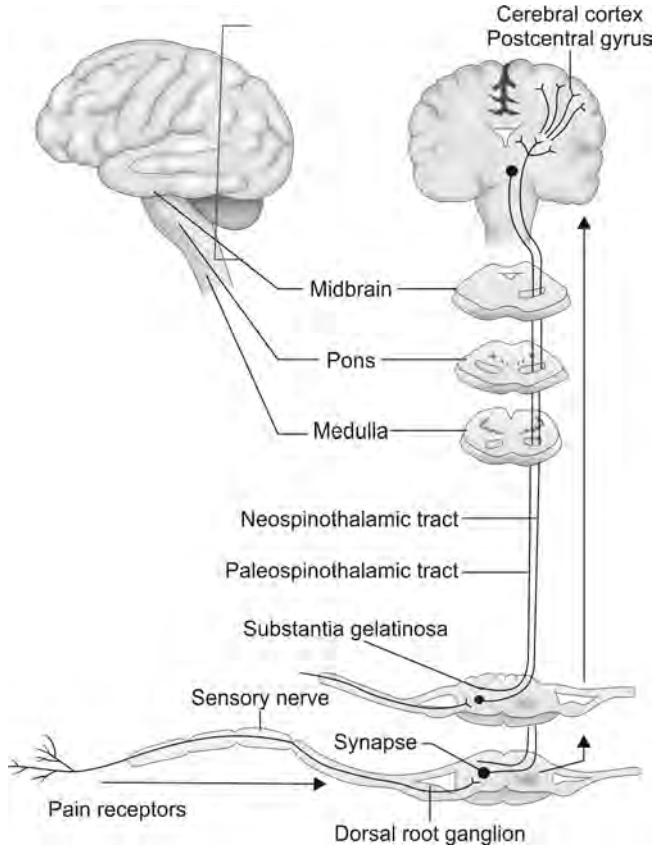

FIG. 1: Pathophysiology of pain.

ASSESSMENT OF PAIN IN EMERGENCY DEPARTMENT

A simple and straightforward method should be adopted when dealing with assessment of acute pain and as a symptom of trauma or disease. Intensity of pain and location of the pain are the main two components in the assessment of pain in clinical practice. However, other important aspects of acute pain, in addition to pain intensity at rest, need to be defined and measured when acute pain treatment is planned. Assessment and treatment of chronic pain or long-lasting pain is more challenging. Multiple tools have been developed for different types and subtypes of acute as well as chronic pain in order to assess qualitative aspects of pain and its impact on function. Multiple studies indicate that pain assessment still a challenge because pain is a subjective, personal, and private experience. Assessment of pain is more challenging for emergency physician if they find difficulty, in communicating with the patient those suffering with cognitive impairment and dementia.

The main objectives of assessment of pain are:
- Recognition of pain and measurement of its intensity
- Treatment adapted to the intensity, the patient and the pathology
- Systematic and regular reassessment permitting an appreciation of the efficiency of the treatment

Assessment and documenting pain required in order to improve management of pain. The points to be considered while assessing pain are:
- Cognitive ability
- Environment (hospital)
- Anxiety
- Cause of pain (e.g., postoperative)

A pain assessment should be performed during admission of a patient. Points to consider:
- Pain history
- Location of pain
- Intensity of pain
- Cognitive development and understanding of pain

When to assess pain?
- Pain scores should be documented for all patients at least once per shift in flow sheet.
- Patient with pain should have pain scores documented more frequently.
- Patient who is receiving oral analgesia should have pain scores documented at least 4 hourly during waking hours.
- Patient noncomplex analgesia such as intravenous opioid and/or ketamine, epidurals, or regional analgesia should have hourly pain and sedation scores documented.
- Document assessment of pain before and after analgesia, and also document effect of analgesia

Assessment of Chronic Pain

Assessment and management of chronic pain are more demanding and rewarding because chronic pain has a major impact on physical, emotional, and cognitive function, on social and family life. A comprehensive assessment of chronic pain requires documentation of (1) history of pain, (2) physical examination, and (3) appropriate diagnostic tests. The pain specific history must be taken about location, intensity, pain modifiers, and possible pathophysiological and etiological issues.

(1) Site of the pain, (2) intensity is the pain, (3) description of the pain (e.g., burning, aching, stabbing, shooting, and throbbing). (4) How did the pain start? (5) What is the time course of the pain? (6) Relieving and aggravating factors of the pain? (7) How does your pain affect your sleep? Your physical functions? Your ability to work? Your family life? Your social life? (8) What treatments have you received? Effects of treatments? Any adverse effects? (9) Are you depressed? (10) Are you worried about the outcome of your pain condition and your health? Physical examination—general physical examination, pain specific evaluation; neurological examination; musculoskeletal system examination; psychological assessment. Several reliable and valid assessment tools are developed for *chronic pain assessment* are:
- The brief pain inventory
- The McGill pain questionnaire and the short-form McGill pain questionnaire
- The Massachusetts general hospital pain center's pain assessment form
- Neuropathic pain screening tools

ASSESSMENT TOOLS FOR PAIN

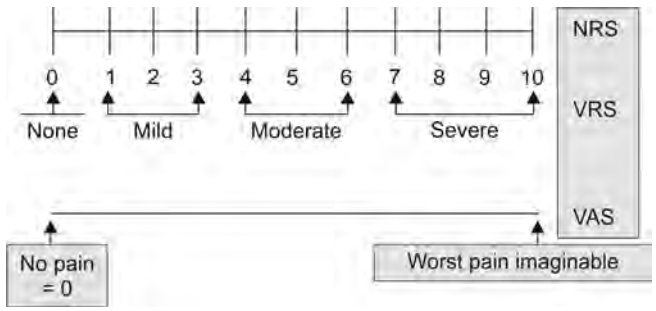
Assessment of Intensity of the Pain

The well-known *Visual Analog Scale (VAS) and Numeric Rating Scale (NRS)* for assessment of pain intensity, well known and are sensitive in assessing acute pain. VAS and NRS are both superior to a four-point *Verbal Categorical Rating Scale (VRS).* They function best and display patient's subjective feeling of

present pain intensity. These scales may be used to record average pain over the last 24 hours, or during the last week. These tools can be used to assess functional impact of pain and also used to assess "unpleasantness" of pain. A study using a large number of patients and simultaneous recordings of pain intensity on VAS, NRS, and VRS scales demonstrated the superiority of the VAS and NRS over VRS (**Fig. 2**). For children, *FLACC (Face, Legs, Activity, Cry, and Consolable) scale* (0–7 years) (**Table 1**) and children >7 years, *Wong–Baker Faces Pain Scale* pain scales (**Fig. 3**) with happy and unhappy faces are well validated. Behavioral pain scale (**Table 2**) is used for assessment of pain in mechanically ventilated, unconscious, or comatose patient. Various pain scales are summarized in **Table 3**.

PHARMACOLOGIC THERAPY FOR PAIN

Drug therapy is the mainstay of pain management in emergency department. Knowledge of appropriate pharmacologic agents for managing the intensity of pain is the key. Ideal pharmacologic agent should be easy to administer with appropriate quality and safety measures. Pain is also associated with anxiety, "suffering" components and loss of control over functions. Adjunctive drug therapy such as anxiolytics should also be also supported by reassurance, and providing information about the problem to the patient. Stepwise approach can be adopted in which pain management is started with low potency drug even if pain is acute and intensity is more. Assess the pain after specific period and escalate the therapy. The stepwise approach makes the patient suffering for prolong period of time. So, another approach is select the appropriate drug therapy initially on the basis of mild, moderate, and severe intensity pain. Mild-to-moderate intensity pain is treated with nonsteroidal anti-inflammatory drugs (NSAIDs) (nonopioids). Severe nociceptive pain should be treated with systemic opioids. Parenteral NSAIDs may control the pain of biliary and renal colic but combination of NSAIDs with opioids analgesics gives better results. Some adjuvants drug therapy is also required along with opioids which reduces the side effects and also reduces the dose requirement of opioids (**Table 4**). Antidepressants and anticonvulsants are also used to treat the pain especially neuropathic pain of postherpetic trigeminal neuralgias (**Table 5**). Topical administration of medication especially at the injury site or inflammation provides pain relief with minimum systemic drug absorption and lower incidence of adverse drug reaction (**Table 6**). In short, the implementation of analgesia is based on two steps—Step 1: Pain relief as quickly as possible, it continues until the goal is not reached; and Step 2: Maintaining the pain relief with appropriate prescriptions.

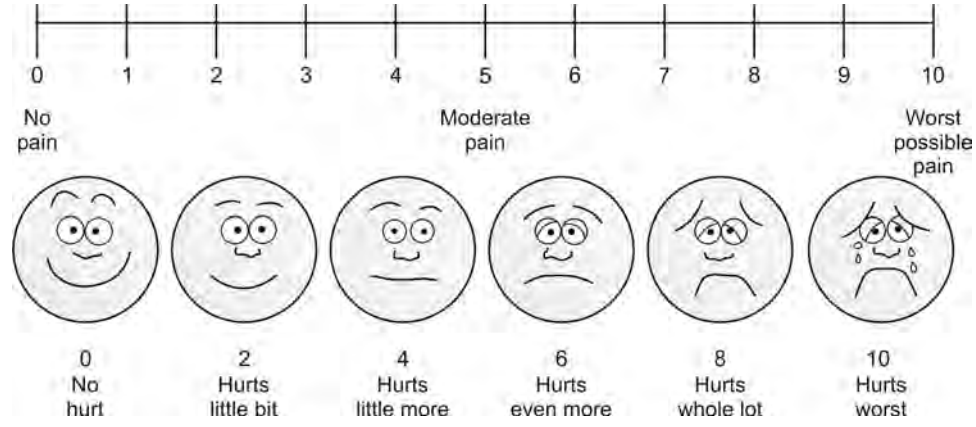


(NRS: numeric rating scale; VAS: visual analog scale)

FIG. 2: Commonly used one-dimensional pain intensity scales: The 11-point NRS, the VAS from no pain (¼0) to worst pain imaginable [¼10 (or 100)] and the four-point categorical verbal rating scale (VRS).

TABLE 1: FLACC—Pediatric Pain Scale for age 0–7 years.

Parameters	*0*	*1*	*3*
Face	No expression	Occasionally grimace	Frequent to constant quivering chin
Legs	Normal position/ relaxed	Uneasy restless tense	kicking/leg drawing
Activities	Lying quiet	Squirming shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry	Moans whimpers	Crying steadily
Consolable	Content relaxed	Reassurance hugging	Difficult to console
Interpretation: 0 = no pain, 1–3 = mild pain, 4–7 = moderate pain, 8–10 = severe pain			
FLACC—F: face, L: leg, A: activities, C: cry, C: consolable			



0 1 2 3 4 5 6 7 8 9 10
No pain
Moderate pain
Worst possible pain
0 No hurt
2 Hurts little bit
4 Hurts little more
6 Hurts even more
8 Hurts whole lot
10 Hurts worst

FIG. 3: Wong–Baker Faces Pain Scale (Age > 7 years).

TABLE 2: Behavioral pain score for unconscious/comatose mechanically ventilated patient.

Facial expression	Relaxed	1
	Partially tighten (brow lowering)	2
	Fully tighten (eyelid closing)	3
	Grimacing	4
Upper limb	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
	Permanently retracted	4
Compliance with mechanical ventilation	Tolerating movement	1
	Coughing but tolerating ventilation most of time	2
	Fighting with ventilator	3
	Unable to control ventilation	4

Precautions

Overdoses and adverse effects can be avoided by choosing appropriate initial dose and titrating it till desired effects then maintenance therapy can continue. Respiratory depression and decreased level of consciousness can occur excessive dose without titration. Short duration of hypotension may occur with first dose of medication due to histamine release. Initial dose should be decreased in with comorbidities such as altered mental status hemodynamic instability, respiratory problems, and polytrauma.

Pain management in elderly is a challenge because they are more sensitive to analgesic effects of opioids, higher peak and longer duration of effects. Elderly are more at risk of adverse effects due to comorbidities and associated polypharmacy. Elderly are the more prone for sedation respiratory depression and cognitive and neuropsychiatric symptoms, thus initial IV opioids dose can be reduced to half.

TABLE 3: Pain scales.

Pain scale name	***Description***	***Validity***	***Comments***
Alder Hey Triage Pain Score (emergency care triage of pediatric patients)	Observational scale completed by staff, five items each scored 0–2 with total score 0–10 possible	Validated for inter-rater variability1	Easy to administer, takes about 10 min, patients need not be able to communicate
Behavioral Pain Scale (BPS) (critically ill-sedated adult patients)	Observational scale completed by staff, scores from 3 to 12	Validated for inter-rater variability and reliability	Validated for use with patients with a low level of consciousness due to head trauma
Brief Pain Inventory (BPI) (adult cancer patients	Self-report of pain intensity (sensory dimension) and how pain interferes with patient's life (reactive dimension)	Validated and translated into numerous languages	Has been validated for use in patients with chronic and nonmalignant pain and osteoarthritis
Clinical Global Impression (CGI) (psychiatric patients)	Observational assessment of patient's global function before and after study medication; it measures psychopathology	Validated and reliable	Easy to administer
Critical Care Pain Observation Tool (CPOT) (Nonverbal critically ill adults)	Observational scale of behaviors, facial expressions, body movements, and muscle tension	Moderate to high inter-rater reliability and significant correlations between CPOT and self-reported pain scales 7; sensitivity 86%, specificity 78%	For intubated patients, compliance with ventilator is assessed; for nonintubated patients, vocalization is assessed
COMFORT Scale [children unable to report pain (has been evaluated in patients age 12–36 months)]	Observational care completed by staff evaluating alertness, anxiety, respiratory response, crying, movement, muscle tone, and facial tension	High inter-rater reliability	Requires staff training
Visual Analog Scale (VAS) (adult pain patients)	Self-report by patient who selects a point on a 100-mm line that indicates pain level; in some cases, a percentage may be used (0 is "no pain" and 100% is "worst pain imaginable")	Validated, familiar, and among the most frequently used pain scales in the US	Easy to administer, fast, and easy for patients to understand but measures pain intensity only
Verbal Rating Scale (VRS) (adult and pediatric pain patients)	Self-report by patient to verbal questions of healthcare professional, asking them to describe their pain using five categories (no pain, mild pain, moderate pain, severe pain, and unbearable pain)	Correlates highly to VAS	Measures pain intensity only and is subject to variations depending on how each patient understands "mild," "moderate," and "severe" pain

Continued

Continued

Pain scale name	Description	Validity	Comments
FACES (Wong-Baker) [pediatric patients (age 3–7) treated for acute pain in emergency department]	Self-report using 6-item ordinal scale made up of 6 faces showing no pain (smiling face) to worst pain imaginable (grimace)	Validated with good agreement between FACES and visual analog scale	May also be used for adults when there is a language barrier
Numerical Rating Scale (NRS) (adult and pediatric pain patients)	Self-report on scale of 0–10 with 0 meaning "no pain at all" and 10 "the worst pain imaginable"	Reliable and validated	Widely used minimal training required, easy for patients to understand; measures pain intensity only
Dallas Pain Questionnaire (DPQ) (adult patients with chronic spinal pain)	16-item self-report measuring pain intensity, function, anxiety, depression, and social interest	Good external reliability and internal consistency	DPQ is divided into two sections called "factors"; factor 1 represents functional activities, factor 2 emotional capacities
Descriptor Differential Scale (DDS) (ALERT and nonimpaired adults)	Self-report in 12-item questionnaire	Good reliability and is sensitive to even small changes in pain intensity	Easy for patients to use but requires some training for healthcare team to interpret
Lequesne-Algofunctional Index (adult pain patients with circadian types of pain)	Self-report in 10-item questionnaire that puts pain in temporal context (pain at night, upon rising) and situations (pain standing, pain walking, and so on)	Validated	Easy to administer, takes about 10 min, and is well suited for pain that fluctuates over course of day
Mankowski Pain Scale	Self-report on 0–10 scale with descriptions to help better quantify pain	Validated for chronic pain patients	Developed by Andrea Mankowski, a chronic pain patient
McGill Pain Questionnaire (MPQ) (adults with various pain syndromes)	Self-report, 20 items grouped as sensory, affective, evaluative, and miscellaneous; patients score each 0–5. The Pain Rating Index (PRI) is the sum of the rank values	Validated and designed to better capture the subjective experiences of pain	Also rates the Present Pain Index (PPI) as a separate scale (0–5)
Neck Pain and Disability Scale (NPDS) (adults with cervical pain syndromes)	Self-report of 20 items as visual analog scales with descriptors, describing different aspects or behaviors associated with the neck	Reliable, internally consistent, correlates well with other scales	
OSWESTRY Disability Index (adults with low back pain)	Self-report of pain intensity and function (disability)	Validated and correlates highly with the Roland-Morris Disability Index	Fast and easy to administer, easy for patients to understand
Palliative Care Outcomes Scale (PCOS) (adult palliative cancer patients)	Two nearly identical tools: a self-report by the patient and corresponding observational report by staff; documents patient's well-being over past 3 days in physical, psychological, and spiritual domains	Validated with good internal reliability; good agreement between patients and staff on many items	May be useful in better determining prospective care for end-of-life patients
Pediatric Pain Questionnaire (PPQ) (pediatric pain patients ≥6 years)	Self-report on visual analog scale of present pain, worst pain intensity, and disease severity	Good correlation between PPQ and healthcare professionals' observations	Easy to administer
Roland-Morris Back Pain Questionnaire (adults with low back pain)	Self-report, 24-item checklist in which patients are asked which statements apply to them that day; all items have equal weight (1 point) and score is total	Validated and correlates highly with the OSWESTRY Disability Index	Short, simple, easy to use; each item on the scale begins, "because of my back pain…"
Support Team Assessment (STAS) (adults in palliative care)	Self-report and corresponding observational report (to be completed by family members or healthcare professionals)	Measures prospective outcomes	When observational scales were compared to self-reports, observations by healthcare professionals were closer to patient self-reports than observations by family members

Continued

Continued

Pain scale name	*Description*	*Validity*	*Comments*
Checklist of Nonverbal Pain Indicators (CNPI) (cognitively impaired adult patients)	Observational test completed by staff based on specific behaviors, restlessness, vocalization	Inter-rater reliability 93%	Requires staff training
Discomfort in Dementia (DS-DAT) (adults with dementia or Alzheimer's disease)	Observational 9-item tool for completion by staff over 5-min assessment period	Inter-rater variability exists in 3 of the 9 items	Requires staff training to administer accurately
Edmonton Symptom Assessment System (palliative care patients, typically end-of-life cancer patients)	Twice-daily assessment using 8 visual analog scales to be completed by patient alone or by patient with assistance (from nurse or family member)	Validation evidence is not robust	Data from the 8 scales are transferred to a graph; the sum of all scores is the "symptom distress score" has been translated into several languages

TABLE 4: Pharmacologic management of pain.

Opioids analgesic therapy		
Drugs	***Initial dose for adult***	***Comments***
Morphine	• 2–6 mg intravenous • 10 mg IM/SC	Nausea vomiting transient hypotension
Fentanyl	50–100 µg IV	Less CV depression than morphine
Meperidine (pethidine)	• 25–50 mg IV • 50–100 mg IM/SC	With MAO inhibitors may precipitate serotonin syndrome if taken within 14 days
Tramadol	50–100 mg in 100 mL NS IV over 30–45 min as infusion	CNS side effects are common
Opioid agonist-antagonist analgesic		
Butorphanol	1 mg IV or 2 mg IM every 4 h	Sedation dizziness nausea
Pentazocine	30 mg IV/IM/SC every 4–6 h	CNS side effects
Adjunctive medications with opioid		
Ondansetron	4–8 mg IV/PO	Can prolong QT interval
Prochlorperazine	5–10 mg IV/IM/PO	Can cause extrapyramidal reactions
Promethazine	25–50 mg IV/IM	Can cause extrapyramidal reactions
Metoclopramide	5–10 mg IV/IM/PO	Can cause extrapyramidal reactions
Nonopioids analgesics		
Acetaminophen (paracetamol)	• 325–1,000 mg PO every 4–6 h • >50 kg 1 g IV every 6 hourly • <50 kg 15 mg/kg IV every 6 hourly	• Liver dysfunction • Maximum dose not >3 g/day
Aspirin (acetylsalicylic acid)	325–650 mg every 4 hourly	GI irritation, mucosal bleeding, platelet dysfunction tinnitus, CNS toxicity
Ibuprofen (NSAIDs)	400–800 mg PO every 4–6 hourly	GI upset, platelet and renal dysfunction. Bronchospasm
Naproxen (NSAIDs)	250–500 mg PO every 8–12 h	GI upset, platelet and renal dysfunction. Bronchospasm
Indomethacin (NSAIDs)	25–50 mg PO every 8 hourly	GI upset, platelet and renal dysfunction. Bronchospasm

(CNS: central nervous system; CV: cardiovascular; GI: gastrointestinal; MAO: monoamine oxidase inhibitor; NSAID: nonsteroidal anti-inflammatory drug)

Care must be taken while using the opioids and other analgesic in patient with impaired hepatic and renal functions because most of them are metabolized by kidney and liver. Hydromorphone and fentanyl are preferred choice in renal dysfunction patient. Low-dose analgesics in severe hepatic dysfunctions minimize the risk of overdose.

Patient with respiratory dysfunction, e.g., chronic obstructive pulmonary disease (COPD), cystic fibrosis, and various neuromuscular disorders affecting respiratory functions (muscular dystrophies and myasthenia gravis) are monitored carefully as they are at risk of severe respiratory depression after opioids analgesics.

TABLE 5: Drug therapy for neuropathic pain.

Drugs	*Initial dose*	*Maximum dose*	*Uses*
Amitriptyline	25–50 mg PO (evening)	10–50 mg/day, maximum 150 mg/day	For chronic pain
Carbamazepine	100 mg PO twice/day	• 200–400 mg PO twice/day • Maximum 1,200 mg/day	Trigeminal neuralgia
Oxcarbazepine	300 mg PO/day	450–1,200 mg PO twice/day	Trigeminal neuralgia
Gabapentin	• For neuropathic pain 300 mg PO three times/day • For postherpetic neuralgias 300 mg PO on day 1 then • 300 mg PO twice/day on day 2,300 mg PO thrice/day • (1,800–3,600 mg/day) maximum 3,600 mg/day		• Neuropathic pain • Postherpetic neuralgias
Pregabalin	50 mg PO three times/day or 75 mg PO twice daily	• 150 mg PO twice/day or 100 mg PO three time/day • Maximum 600 mg/day	• Neuropathic pain • Postherpetic neuralgias
Duloxetine	30 mg PO once daily	Maximum 60 mg PO/day	Diabetic neuropathy

TABLE 6: Topical agents for pain management.

Agents	*Comments*
Diclofenac	1% gel or 1.3% topical patch, can be apply on knee ankle elbow shoulder joints up to 4 times/day
Ibuprofen	5% gel can be applied 4 times/day on affected area
Ketoprofen	2.5% apply on affected area until absorbed 2–4 times/day
Lidocaine	5% gel and 5% topical patch apply thick layer over affected area. In 30–60 min numbness will develops. Use patch only once for 12–24 h
Capsaicin	• 0.025 and 0.075% cream and 0.1% gel 8% patch • Apply cream and gel on affected area and rub until get absorbed • Patch only for postherpetic neuralgias
Methyl salicylate	10% patch apply only one patch at a time on affected area only for 8–12 h, maximum 2–3 patch/day

ANESTHETIC AGENTS IN PAIN MANAGEMENT

Local Anesthesia

Pain arising from the acute injury and the procedures in the emergency department can adequately be controlled by local anesthetic. Route of administration of local anesthetic may be topical, subdermal, or infiltration around the peripheral nerves (regional anesthesia).

Esters and amides are the two classes of the local anesthetics (**Table 7**), affect the smaller nerve fibers and act by reversible blocking the sodium channels and inhibit the propagation of nerve impulse. Reduction in pain and temperature occurs first followed by loss of touch, deep pressure sensation, and motor functions in the last. Appropriate selection of anesthetic agents is important and depends on their onset of action, duration of anesthesia, and potential systemic toxicity by local anesthetics. Systemic toxicity of local anesthetics is dose related and sodium channel blockade primary affect brain and heart. Toxicity may range from minor neurological symptoms to refractory seizure and cardiovascular collapse. Neurological toxicity seizure should be treated with benzodiazepine. Cardiac depression and or cardiac arrest should be treated with intravenous 20% lipid emulsion specially bupivacaine (high lipid solubility)-induced toxicity (20% lipid emulsion 1.5 mL/kg over 1 min followed by 0.25 mL/kg continued for 10 min after hemodynamic stability occurs). Standard resuscitative measures should be applied for cardiac arrest, and smaller doses of epinephrine are recommended and vasopressin and lidocaine should be avoided. Prilocaine and benzocaine result in cyanosis, if methemoglobin concentration exceeds 1.5 g/dL. Prilocaine and benzocaine can cause oxidation of ferrous iron of normal hemoglobin into ferric form creating the methemoglobin.

Topical Anesthesia

There are three major situations for use of topical anesthesia before any dermal instrumentation (*on intact skin), intact mucosa* and before wound repair *on open skin.* For suturing of any dermal laceration, effect of topical anesthesia is almost equivalent to local anesthesia. Mixture of lidocaine 2.5% + prilocaine 2.5% was the first topical agent used for intact skin. Liposome-encapsulated tetracaine, liposome-encapsulated lidocaine, and tetracaine gel are as effective as lidocaine and prilocaine mixture. For open dermis, mixture of lidocaine, epinephrine, and tetracaine is used (lidocaine 4% + epinephrine and tetracaine 0.5%).

Intradermal and Subdermal Anesthesia

Intradermal injections of local anesthesia are painful, produce visible wheals, and raise the surface and useful for removing the cutaneous lesion. Subdermal injection is less painful, slower onset of action, and most common method used in emergency department for delivering local anesthesia in suture of clean laceration or as a field block in contaminated wound.

TABLE 7: Local anesthetic agents.

	Agents	*Concentration for subdermal use*	*Concentration for regional anesthesia use*	*Onset (min)*	*Comments*
Amides	Bupivacaine	0.50–0.75%	0.25–0.50%	2–10 min	High lipid soluble and high protein binding
	Levobupivacaine	0.25%	0.50%	10–20 min	High lipid soluble and high protein binding
	Lidocaine	0.5–1.0%	1–2%	<1 min	Medium lipid soluble and medium protein binding
	Mepivacaine	0.5–1.0%	1–2%	3–20 min	Low lipid soluble and medium protein binding
	Prilocaine	4%	NA	5–6 min	Medium lipid soluble and medium protein binding
Esters	Procaine	0.25–0.50%	0.5–2.0%	5 min	Low lipid soluble and low protein binding
	Chloroprocaine	1–2%	1–2%	5–6 min	Low lipid soluble and low protein binding
	Tetracaine	NA	0.2–0.3%	6–7 min	High lipid soluble and high protein binding

REGIONAL ANESTHESIA (PERIPHERAL NERVE BLOCK)

Regional anesthesia is a technique in which local anesthesia is infiltrated adjacent to peripheral nerve (also known as nerve block). Regional anesthesia or nerve block is used for complicated fracture and dislocation, laceration, debridement, and abscesses. Serious complication by regional anesthesia is reduced with adopting careful technique. Adequate anesthesia reduces patient anxiety, and provides greater patient satisfaction. Regional anesthesia on extremities and for laceration repair provides better pain control than subdermal infiltration of anesthetic. Regional anesthetic also eliminates wounds distortion caused by large volume subdermal injection. Pain associated with peripheral nerve block can be reduced by applying topical anesthetics before the procedure.

Local anesthetic for peripheral nerve block should be selected on the basis of onset of clinical effect, duration of analgesia, and toxicity risk. Lidocaine is most popular agents while bupivacaine, levobupivacaine provides longer duration of action. Peripheral nerve block requires (lidocaine—10–20 min and bupivacaine 15–30 min) time to achieve optimal analgesia. Pain and temperature are affected first followed by deep pressure and motor function in the last.

In emergency department, regional nerve block is performed by landmark technique but anatomic variation is the major disadvantage in this technique. Thus two other techniques, peripheral nerve stimulator (using electrically insulated needles) and ultrasound guidance are used to locate the peripheral nerve. Ultrasound-guided procedure shortens the procedure time, reduces the risk of vascular injury, and enables the blocks with using lower anesthetic dose. Using the high-frequency linear array transducer nerve appear as white honeycomb structure in short axis and hyperechoic in long axis. Needle can be visualized as hyperechoic bright white structure in short and long axis both helpful in injecting the anesthetic agents around the target nerve.

NONPHARMACOLOGIC INTERVENTION FOR PAIN

Role of nonpharmacologic intervention for pain is limited in emergency department. Application of hot or cold packs, immobilization, and limb elevation of injured limbs are common nonpharmacologic intervention in emergency department. Other technique can be applied after discharge from the emergency department, e.g., cognitive behavioral technique for mild pain and anxiety. In such technique, reassurance, explanation, and relaxation breathing exercises are used. Nonpharmacologic interventions are the important adjunct in managing the moderate to severe pain. Skilled person can teach these techniques to patient. Other less commonly used techniques are transcutaneous electrical nerve stimulation and acupuncture in which no need for IV access and no systemic effects occur.

SUMMARY

Pain is the most common presentation in emergency department. Pain management should be priority. Over the last decade, various methods for assessment of pain and management strategies are developed. Adequate pain treatment in emergency improves the quality and patient satisfaction. Every emergency physician should be expert in efficient and effective management of painful condition.

Point-of-care Ultrasound in Resuscitation

54
CHAPTER

Won-Jun Kuk, Mohamed Moheb El Abd, Tiffany Fong

INTRODUCTION

Shock is a life-threatening condition defined by the inadequate oxygenation and perfusion of tissues relative to their metabolic demand. Hypotension is frequently correlated, but its presence is not required to make a diagnosis of shock. A number of conditions may lead to shock, and while they are all associated with high rates of morbidity and mortality, they differ in their management strategies. Because prolonged shock and hypotension have been linked to poorer outcomes, the early identification of shock etiology and initiation of the most appropriate interventions are vital in the care of such patients. Shock has traditionally been categorized into four subtypes:

1. *Hypovolemic shock* is caused by the loss of intravascular volume. This may result from traumatic hemorrhage; nontraumatic hemorrhagic conditions such as gastrointestinal bleeding or ruptured ectopic pregnancy; or volume loss from vomiting, diarrhea, poor oral intake, increased insensible fluid losses, or renal losses (e.g., diabetes insipidus or hyperosmolar hyperglycemic syndrome).
2. *Distributive shock* is a state of relative hypovolemia from the pathologic redistribution of intravascular volume. This is frequently seen in sepsis, due to both vasodilation and increased vascular permeability that decrease effective circulating volume. Anaphylaxis and neurogenic shock are additional examples.
3. *Cardiogenic shock* is caused by a critical reduction in cardiac function and forward flow, leading to end-organ hypoperfusion. Cardiac dysfunction may be related to myocardial disorders (e.g., acute coronary syndrome, cardiomyopathy, and myocarditis), dysrhythmias (both tachycardias and bradycardias), and mechanical causes (e.g., valvular dysfunction, thrombi, and tumors).
4. *Obstructive shock* results from an obstruction of the heart or great vessels. It is the rarest cause of shock, but requires immediate intervention directed at the specific underlying cause. Examples include pericardial tamponade, massive pulmonary embolism, and tension pneumothorax. Though early identification and treatment of the etiology of shock are important to reduce morbidity and mortality, this is often a challenging task. Point-of-care ultrasound (POCU) has emerged as an important tool to support clinical decision making at the bedside. A sonographic physiologic assessment for shock, often described as the *RUSH examination* (rapid ultrasound in shock), has gained popularity. This framework organizes the potential etiologies of shock into three broad, sonographically assessable systems that drive hemodynamics, simplified as:
   i. *The pump*: Cardiac function
   ii. *The tank*: Intravascular volume status
   iii. *The pipes*: Vascular emergencies in the venous and arterial system

Careful evaluation of these components can enable clinicians to quickly identify the underlying etiology of shock in patients with undifferentiated hypotension and subsequently allow early initiation of the most appropriate treatment.

STEP 1: PUMP

The first step in approaching a patient in shock will be determining their cardiac status, otherwise termed "the pump." This evaluation has three key questions which can be rapidly assessed with a focused transthoracic bedside echocardiogram:

- Is there a pericardial effusion compressing the heart, causing mechanical obstruction to forward flow and leading to obstructive shock (i.e., cardiac tamponade)?
- What is the global contractility of the heart? Does the left ventricle have reduced ejection fraction, suggestive of cardiogenic shock, or is the heart hypercontractile, suggesting hypovolemic or distributive shock?
- Is there right heart enlargement that may suggest a massive pulmonary embolism causing an obstructive shock?

The focused echocardiography is performed with the phased array transducer. It comprises four views: (1) Parasternal long-axis, (2) parasternal short-axis, (3) apical four-chamber, and (4) subxiphoid. **Figure 1** demonstrates probe positioning. The parasternal views are obtained with the transducer placed just left of the sternum; the probe marker faces the patient's right shoulder for the long-axis view, then is turned 90° to the left shoulder to obtain the short-axis view. The probe may need to be adjusted across several intercostal spaces to determine the optimal window of visualization. The apical four-chamber

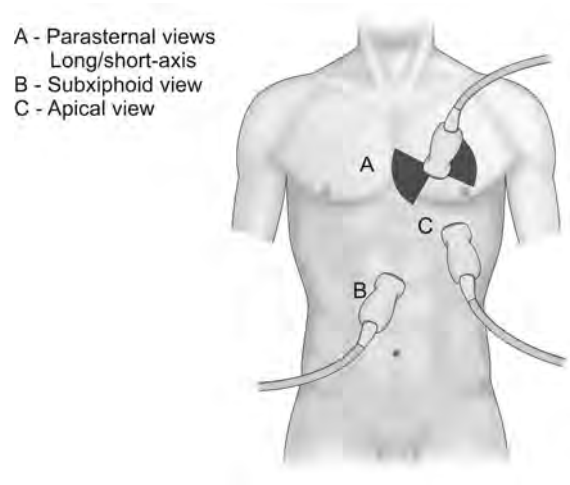

FIG. 1: Sonographic views for "pump" evaluation.

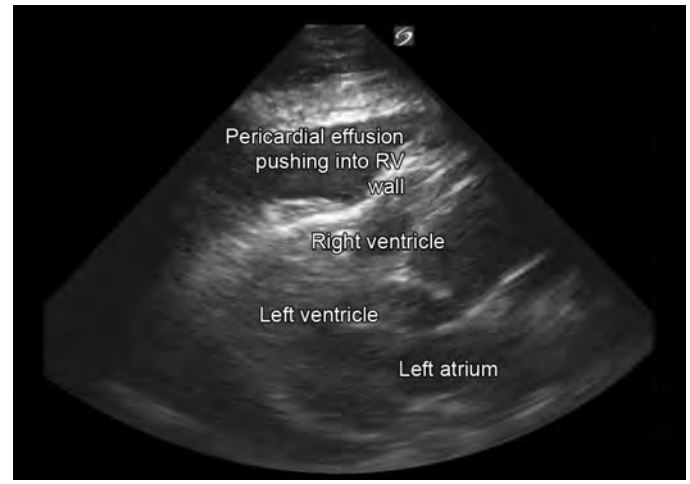

FIG. 2: Parasternal long-axis view of pericardial tamponade with the effusion collapsing the right ventricular wall during diastole.

view is best evaluated by placing the probe below the nipple line at the point of maximal impulse (PMI) with the probe marker facing the patient's left. The subxiphoid view is obtained with the probe flat against the abdomen inferior to the xiphoid tip of the sternum with the marker facing the patient's left. These four views each offer a different perspective of the heart to assist the clinician in answering each of the focused questions above.

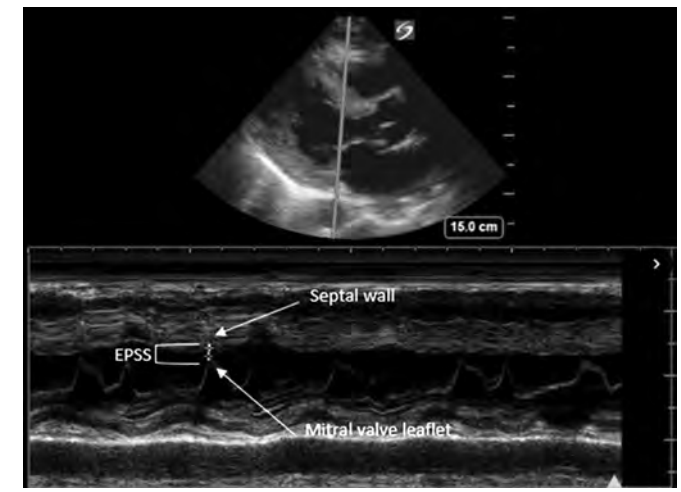
Pericardial Effusion

The first step is to evaluate for a pericardial effusion. Studies have shown that emergency physicians can reliably identify the presence of pericardial effusion even with limited training. Effusions can vary in echogenicity and appear anechoic if they contain blood or simple fluid, or more echogenic if blood is clotted or in complex effusions. Effusion size can also vary from a thin stripe layering posteriorly or inferiorly in dependent portions of the pericardial space to larger effusions that can wrap circumferentially around the heart. The pericardium is a thick, fibrous structure, which can allow even relatively smaller effusions to produce tamponade physiology when accumulation is acute and rapid. On the other hand, chronic pericardial effusions can grow to significant volumes as the pericardium stretches to adjust to the slow increases in volume, and thus avoid hemodynamic collapse.

If a pericardial effusion is identified, the next step will be to assess for tamponade physiology. Cardiac tamponade results when the pericardial effusion exerts sufficient pressure to restrict the heart from fully expanding and filling during diastole. The right side of the heart is a lower pressure system and is therefore more vulnerable to external pressure than the left side of the heart. Therefore, tamponade physiology can be assessed by evaluating for collapse of the right atrium during systole or right ventricle during diastole. This will appear as an inward deflection of the free wall of the right-sided chambers, sometimes described as "a man jumping on a trampoline" (**Fig. 2**). Finally, the inferior vena cava (IVC) should also be evaluated. Because tamponade is an obstructive process that reduces forward flow, the IVC will become plethoric as right heart filling pressures increase.

Global Left Ventricular Contractility

The next step is to assess the global contractility of the heart, or the ejection fraction. This can be achieved by "eyeballing"



(EPSS: E-point septal separation)

FIG. 3: Normal EPSS measurement in parasternal long-axis view.

or visually estimating left ventricular (LV) contractility through observation of the excursion of the endocardium and thickening of the myocardium through systole and diastole. Cardiac contractility can be broadly categorized as normal, reduced, severely reduced, or even hyperdynamic (an above normal ejection fraction where the LV walls may be seen completely contracting into the ventricular cavity). While these determinants may appear subjective, studies have shown that emergency physician estimates of LV contractility correlated well compared to those measured by cardiologists, with a correlation coefficient of 0.86.

In addition, using a parasternal long-axis view, the operator can observe the movement of the anterior leaflet of the mitral valve toward the interventricular septum during diastole, termed the E-point septal separation (EPSS). Good LV contractility is implied by a mitral leaflet that opens vigorously during diastole, and closely approaches (or even touches) the septal wall. This can be visually estimated or objectively measured using M-mode. In the parasternal long-axis view, an M-mode cursor is placed at the tip of the anterior mitral valve leaflet. The M-mode tracing will produce characteristic waves of the leaflet motion, allowing measurement of the distance between the valve during its maximal opening and

the interventricular septum (**Fig. 3**). As cardiac contractility decreases, this distance between the tip of the mitral valve leaflet and septum will increase. The EPSS is normally <7 mm. An EPSS >1 cm correlates with lower ejection fraction.

Knowledge of LV contractility is vital to medical decision-making during resuscitation. A reduced ejection fraction is helpful in diagnosing a cardiac etiology of shock (e.g., acute coronary syndrome and/or cardiogenic shock). A hypercontractile or hyperdynamic heart can be seen in distributive and hypovolemic shock. Furthermore, knowing the squeeze of the pump provides valuable data related to the heart's ability to tolerate additional fluid. Finally, repeated bedside echocardiograms can be used for therapeutic monitoring. Demonstration of improvement or deterioration after intervention may provide guidance for additional treatments.

Right Ventricular (RV) Strain

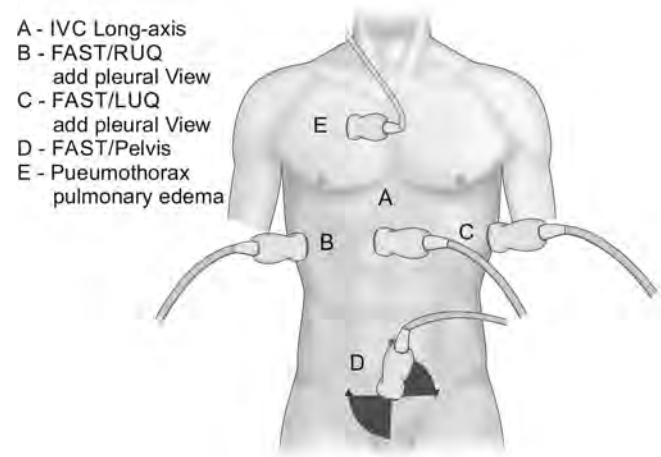
The third goal in evaluation of the pump is to identify evidence of right heart strain. In a normal heart, the LV is larger and more muscular than the right ventricular (RV) due to its role pumping against the higher pressures of the systemic vasculature. On echocardiogram, a normal ratio of LV to RV size is 1:0.6. Any condition that increases the pressure within the pulmonary vascular circuit can cause dilation of the right heart, causing the RV to appear equal to or even larger in size than the LV. Further evidence of right heart strain is visualization of the interventricular septum pushing from the RV into the LV cavity. This can be visualized on a parasternal short-axis view and is called the "D-sign," as flattening of the interventricular septum causes the LV to take on the appearance of the capital letter "D" (**Figs. 4A** and **B**).

The classic cause of acute right heart strain is a large pulmonary embolism. A thrombus causes obstruction in the pulmonary vascular circuit, acutely raising pulmonary pressures. Of note, chronic lung illness such as pulmonary hypertension, chronic obstructive pulmonary disease (COPD), and chronic effects of recurrent smaller pulmonary emboli can also cause right heart strain. While acute, chronic, and acute-on-chronic right heart strain may be difficult to distinguish, a dilated RV that is also hypertrophied suggests the influence of a chronic process. In acute right heart strain, the ventricle does not have time to compensate, and thus ventricular hypertrophy should not be seen.

STEP 2: TANK

The second step in the evaluation of shock is determining the intravascular volume status, or "the tank." This step is further broken down into three components (**Fig. 5**):

- *Fullness of the tank*: The IVC is evaluated to estimate volume status. The internal jugular vein (IJV) has also been described as a surrogate for jugular venous pressure and volume status.
- *Leakiness of the tank*: Focused assessment with sonography for trauma (FAST) assesses for any intra-abdominal or intrathoracic bleeding or fluid loss that decreases effective intravascular volume. Lung ultrasound evaluates for pulmonary edema.



(FAST: focused assessment with sonography for trauma; IVC: inferior vena cava; LUQ: left upper quadrant; RUQ: right upper quadrant)

FIG. 5: Sonographic views for "Tank" evaluation.

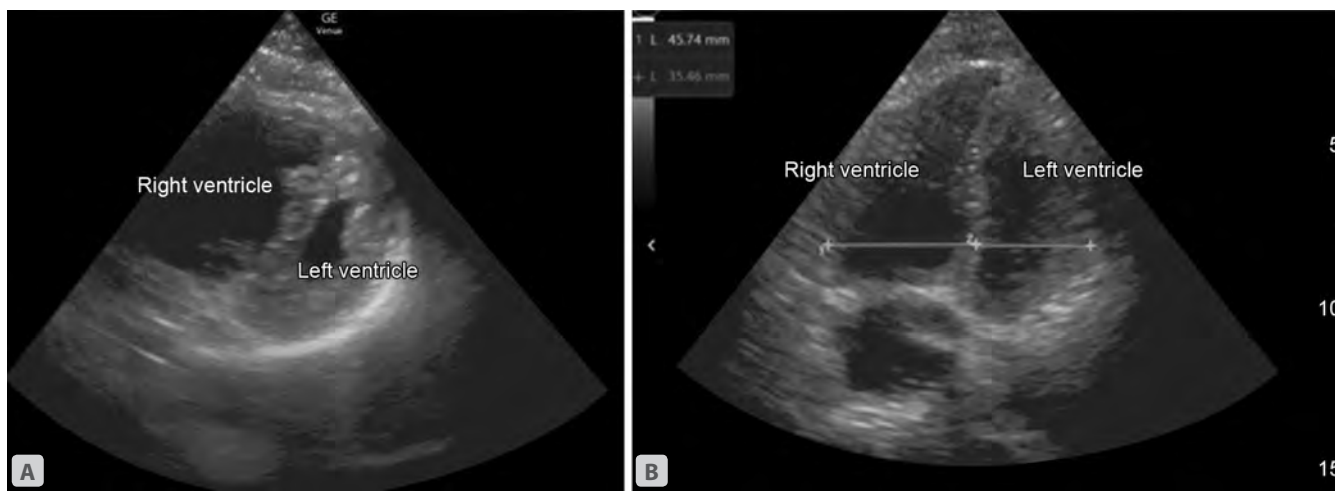


FIGS. 4A AND B: Right heart strain (A) "D-sign" in the parasternal short-axis caused by high RV pressures flattening the interventricular septum. (B) Apical four-chamber view showing a dilated RV that is larger in size than the LV.

- *Tank compromise*: Lung ultrasound is performed to evaluate for a pneumothorax, which can increase intrathoracic pressures and cause decreased venous return to the heart.

Fullness of the Tank

The first step in evaluating the patient's intravascular volume status is to assess the IVC. Historically, central venous pressures (CVP) have been used as a surrogate for a patient's volume status, but have not been shown to predict volume responsiveness. Sonographic measurements of the IVC, including vessel size and collapsibility, have been shown to accurately and noninvasively estimate volume status while also correlating well to CVP. More recent literature suggests more nuance in interpretation of IVC ultrasound and some limitations of this as a tool for volume assessment. However, IVC may be most reliable at the extremes of size (flat vs. plethoric).

The IVC can be visualized by a low frequency transducer in a longitudinal orientation in the epigastrium, just right of midline. The IVC runs parallel to the aorta and can be distinguished by its thinner walls and respiratory variation. Furthermore, visualization of the IVC can be confirmed by anatomic landmarks, including its convergence with the right atrium and the hepatic veins. Two features of the IVC will be assessed—size and respirophasic variation.

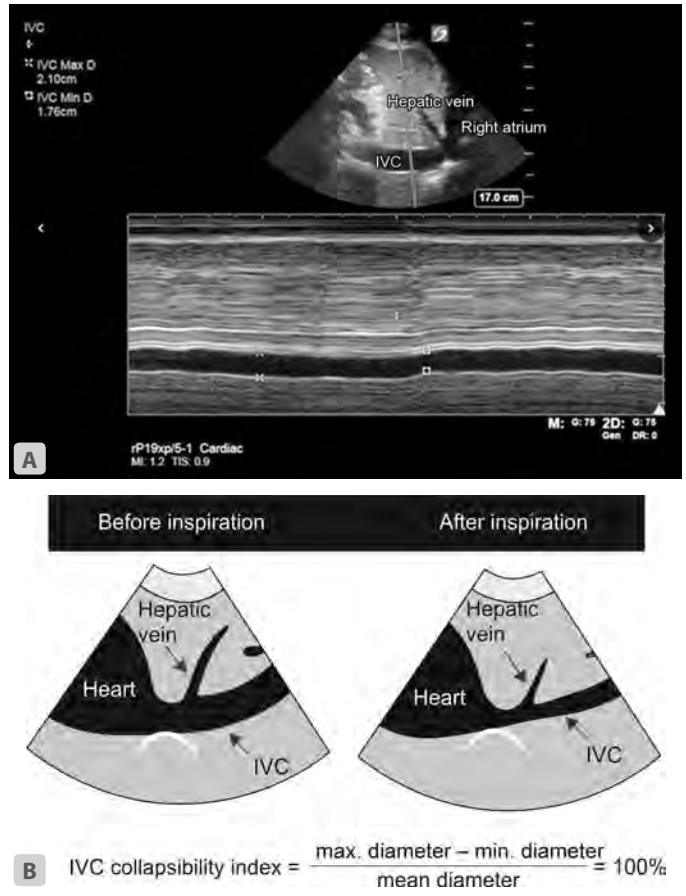
In spontaneously breathing patients, inspiration will cause IVC collapse due to negative pressure generated in the chest. This can be objectively measured in M-mode by placing the cursor approximately 2 cm distal to the junction of the right atrium and IVC, and graphically documenting the changes in vessel caliber through the respiratory cycle (**Figs. 6A** and **B**). The IVC diameter can be determined by measuring the wall-to-wall distance at the same location.

A patient with a small caliber IVC (<2 cm in diameter) and an inspiratory collapse >50% is associated with a decreased CVP, and suggests an underlying hypovolemic or distributive shock. Conversely, a patient with a larger caliber IVC (>2 cm in diameter) and an inspiratory collapse <50% is roughly associated with an increased CVP, suggesting an underlying cardiogenic or obstructive shock.

Unfortunately, it may be difficult to evaluate the IVC in some patients due to body habitus or bowel gas. In these patients, a transhepatic coronal view (with transducer placed at the right mid-axillary line) may be obtained, using the liver as an acoustic window. In addition, sonographic evaluation of jugular venous distention can be performed. The IJV is identified using a high-frequency linear array transducer with the patient's head elevated to 30° (**Fig. 7**). The IJV is evaluated in the short-axis to determine its diameter, and then in the long-axis to determine its respiratory collapsibility as well as the point on the neck where the walls of the vessel meet. Distended IJV diameter, minimal respiratory variation, and closing levels more superiorly toward the angle of the jaw suggest an elevated CVP. The opposite findings would suggest a decreased CVP.

Leakiness of the Tank

After assessing the patient's intravascular status, the next step is to evaluate for any abnormal "leakiness of the tank." This refers to either internal blood loss (e.g., trauma with hemoperitoneum or hemothorax) or fluid extravasation from increased hydrostatic pressures, (e.g., cardiac, renal, or hepatic failure resulting in pulmonary edema, pleural effusions, or ascites).



FIGS. 6A AND B: (A) Inferior vena cava (IVC) assessment using M-mode, (B) Calculation of IVC collapsibility index as a measure of respiratory variation of IVC diameter in spontaneously breathing patients.

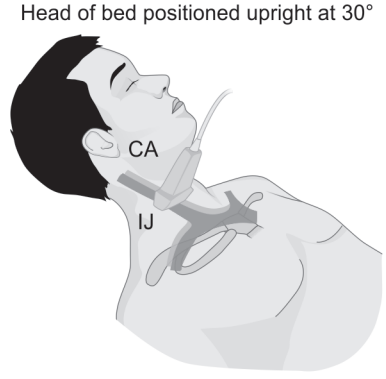

FIG. 7: Internal jugular vein sonographic assessment.

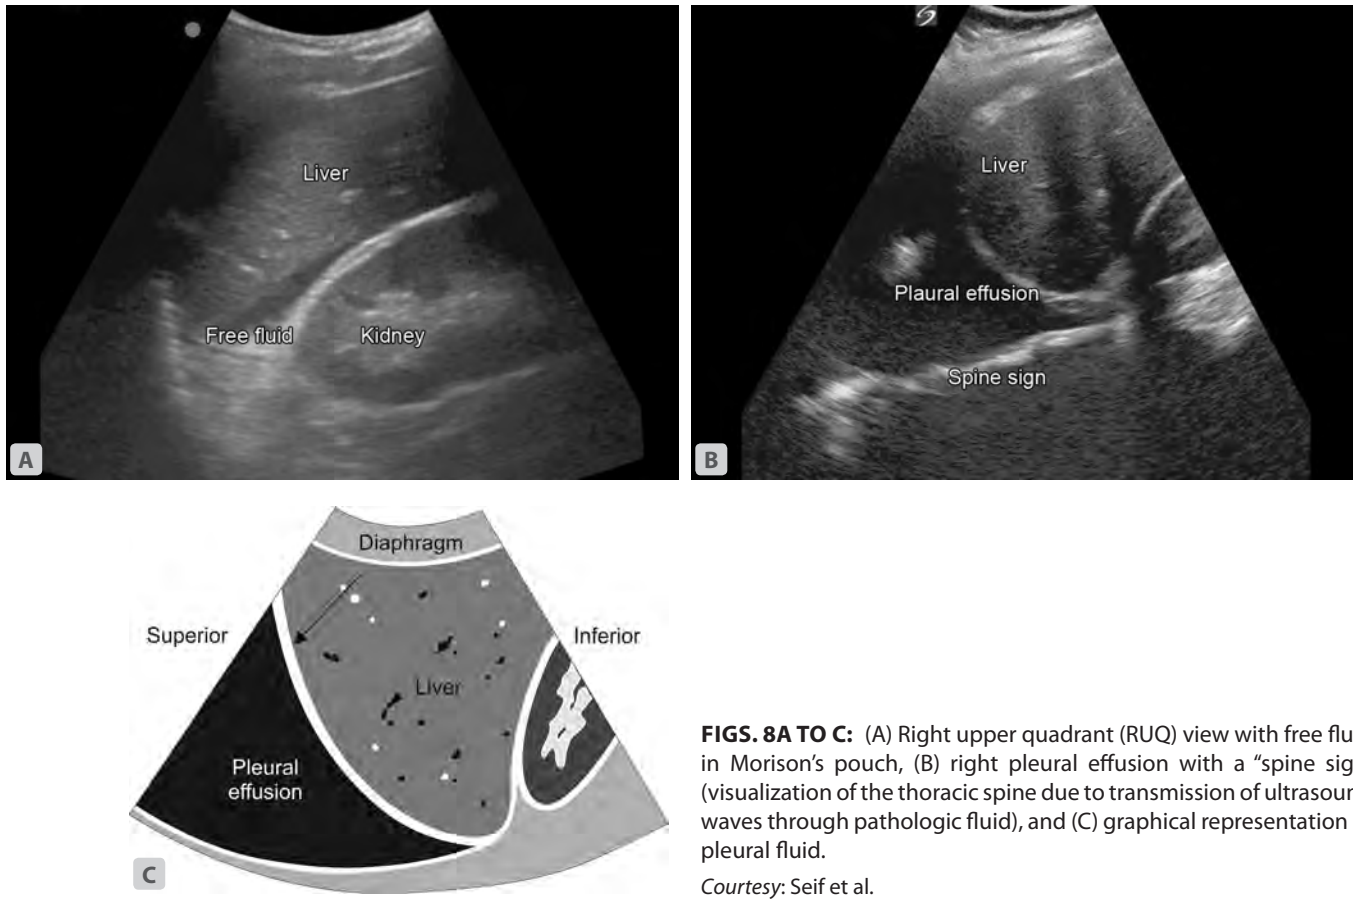
A FAST examination is performed to evaluate for fluid in the peritoneal and thoracic cavities (**Figs. 8A** to **C**). The exam assesses potential spaces in three discrete locations: (1) The right upper quadrant (RUQ), (2) left upper quadrant (LUQ), and (3) pelvis. Specifically, the RUQ view evaluates for free fluid in the space between the liver and kidney (Morison's pouch), the right paracolic gutter (near the inferior tip of the



FIGS. 8A TO C: (A) Right upper quadrant (RUQ) view with free fluid in Morison's pouch, (B) right pleural effusion with a "spine sign" (visualization of the thoracic spine due to transmission of ultrasound waves through pathologic fluid), and (C) graphical representation of pleural fluid.

liver), the subdiaphragmatic space, and in the thorax above the right hemidiaphragm. The LUQ view evaluates the space between the spleen and kidney (splenorenal recess), the left paracolic gutter, the subdiaphragmatic space, and the left thorax above the left hemidiaphragm. The pelvis view evaluates the peritoneal recesses between the bladder and rectum in male patients, and between the uterus and rectum (pouch of Douglas) in female patients. Anechoic collections in any of these potential spaces represent free intraperitoneal fluid.

For female patients presenting with undifferentiated shock, it is important to also consider the possibility of a ruptured ectopic pregnancy. Direct visualization of an ectopic pregnancy with a transabdominal ultrasound is challenging. However, a ruptured ectopic can present with the sonographic findings of an empty uterus combined with a positive FAST. Visualization of an intrauterine pregnancy in the pelvic view significantly lowers the concern for ectopic pregnancy.

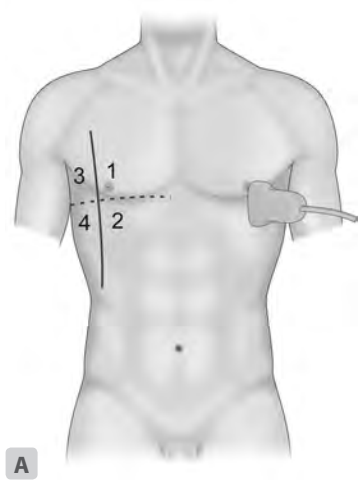
The second examination to assess for leakiness of the tank is a lung ultrasound. This focuses on identification of pulmonary edema. Using a phased array or curvilinear transducer, the thin, echogenic pleural line between two ribs is visualized. Bilateral anterior and lateral views may be obtained (**Fig. 9A** to **C**).

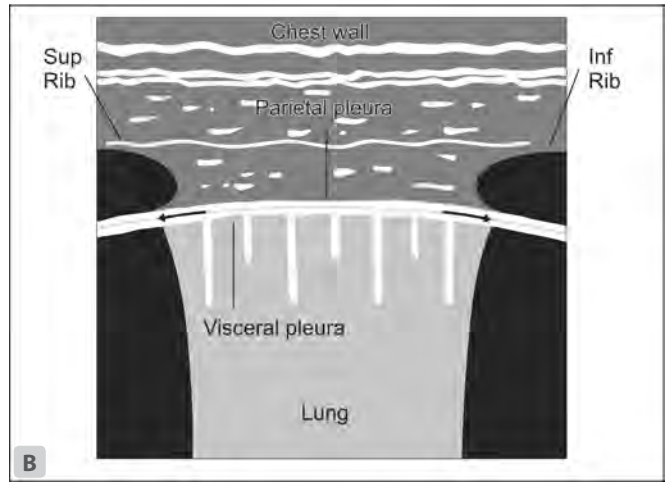
Conditions that elevate hydrostatic pressures can cause fluid accumulation in the interstitium of the lung. Extravascular lung water is detected on ultrasound by identifying B-lines or "lung rockets." B-lines are artifacts that originate from the pleural line and are caused by reverberating ultrasound energy from a focus of fluid surrounded by air. On ultrasound, they appear as thin, vertically-oriented, brightly echogenic lines that originate from the pleural line and extend into the far field of the ultrasound. The visualization of three or more B-lines in any single view is considered pathologic (**Fig. 10**). Presence of pathologic B-lines in multiple locations bilaterally is suggestive of pulmonary edema. Studies have shown that sonographic findings of pulmonary edema correlate well with signs of volume overload seen on chest radiography, and in many cases is more sensitive than X-ray.

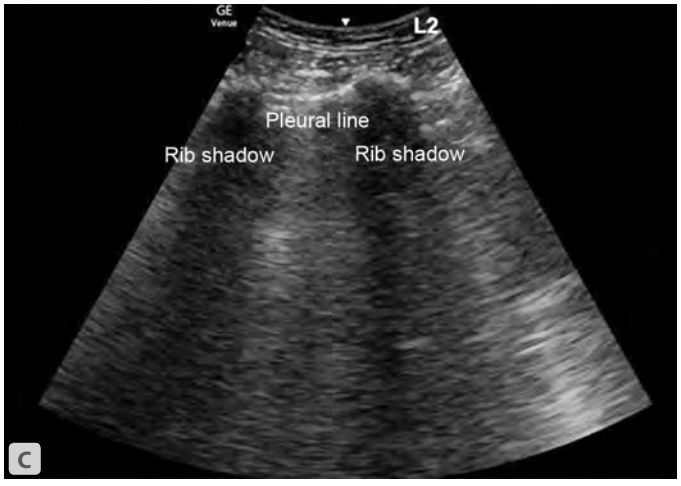
Compromise of the Tank

The final component in evaluation of the tank is to assess for a tension pneumothorax. While a high-frequency linear transducer provides the greatest detail of the pleural line, a phased array or curvilinear transducer may also be used. In the supine patient, the transducer is placed at the most anterior aspect of the thorax in the midclavicular line. In a normal lung, the visceral and parietal pleura slide against each other during respiration. This movement is described as a shimmering or "ants marching." In contrast, in patients with pneumothorax, air between the two pleural layers allows only the parietal layer to be visualized as a single stationary line.

The presence of lung sliding can also be represented graphically using M-mode. A patient without pneumothorax will have pleural sliding that displays on M-mode as "waves on a beach." The lack of motion within the chest wall produces the linear horizontal "waves" and motion of the pleura and lungs below produces the irregular, granular pattern of the "sand." In the presence of a pneumothorax, only repeating horizontal lines will be seen, signaling the lack of lung motion. This is called the "barcode" or "stratosphere" sign (**Figs. 11A** and **B**).







FIGS. 9A TO C: (A) Lung zones assessed during RUSH examination; (B) graphical representation of anatomic structures seen on lung ultrasound; and (C) normal lung ultrasound.

FIG. 10: B-lines on lung ultrasound. Three or more B-lines are considered pathologic.

STEP 3: PIPES

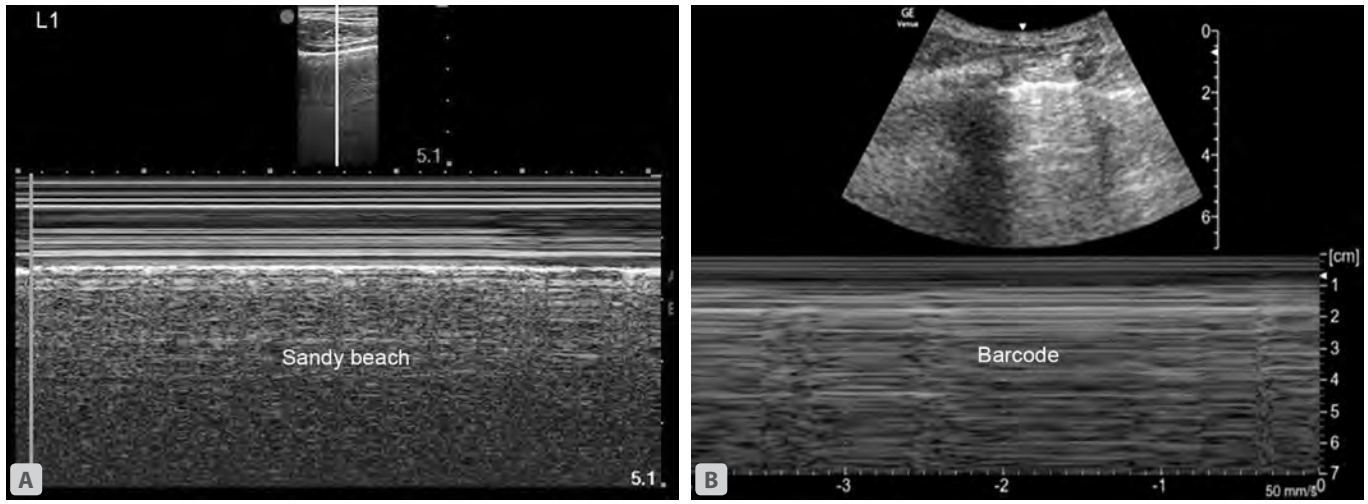
The third major system to evaluate in patients with shock is the "pipes," or the major arteries and veins of the body (**Fig. 12**). The key clinical question to answer is if these pipes are ruptured or obstructed.

Rupture of the Pipes: Aortic Aneurysms and Dissection

Sonographic evaluation begins with an arterial assessment, targeting vascular catastrophes such as abdominal aortic aneurysm (AAA) and aortic dissection as a cause of shock (**Figs. 13A** to **C**). Both can have devastating consequences and require early diagnosis and surgical management to improve outcomes.

Emergency physicians can diagnose AAA using bedside ultrasound with high sensitivity and specificity. With the patient in a supine position, a curvilinear or phased array transducer is placed in the epigastrium in a transverse orientation with the marker oriented toward the patient's right. Firm, steady pressure may be required to displace bowel gas. The aorta sits anterior to the semicircular vertebral body and appears as a round, thick-walled, pulsatile, and noncollapsible structure adjacent to the IVC. The abdominal aorta is visualized at the epigastrium to view its proximal portion, with the celiac artery or superior mesenteric artery serving as an anatomic landmark. It is followed distally until it bifurcates into the two common iliac arteries, occurring near the level of the umbilicus. Finally, the aorta can be visualized in its longitudinal axis by rotating the probe 90°.

The maximal diameter of the aorta is measured from outer wall to outer wall in the short axis. A AAA is diagnosed when



FIGS. 11A AND B: Evaluation for pneumothorax using M-mode: (A) Normal lung with "waves on a beach" and (B) pneumothorax with "barcode" sign.

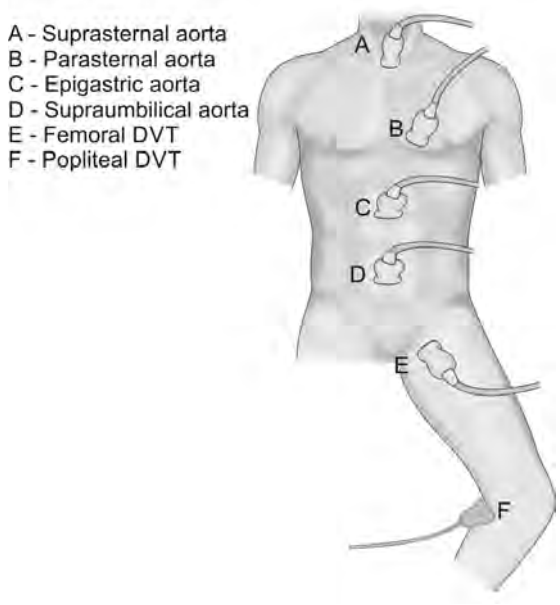


FIG. 12: Sonographic views for "pipe" evaluation.

Source: Perera P, Mailhot T, Riley D, Mandavia D. The RUSH Exam: Rapid ultrasound in shock in the evaluation of the critically Ill. Emerg Med Clin North Am. 2010;28(1):29-56.

the vessel diameter exceeds 3 cm, though rupture is more commonly seen in aneurysms measuring >5 cm. For the iliac arteries, measurements >1.5 cm are considered aneurysmal. Mural thrombus can also be observed within the lumen of the aorta. During measurement, care should be made to include the entire aorta with thrombus; if the lumen alone is measured, AAA may be missed.

An abdominal aortic dissection may be seen as an intimal hyperechoic flap inside the vessel. Though ultrasound is less sensitive than computed tomography (CT) to identify dissection, it may help to more quickly rule-in this pathology.

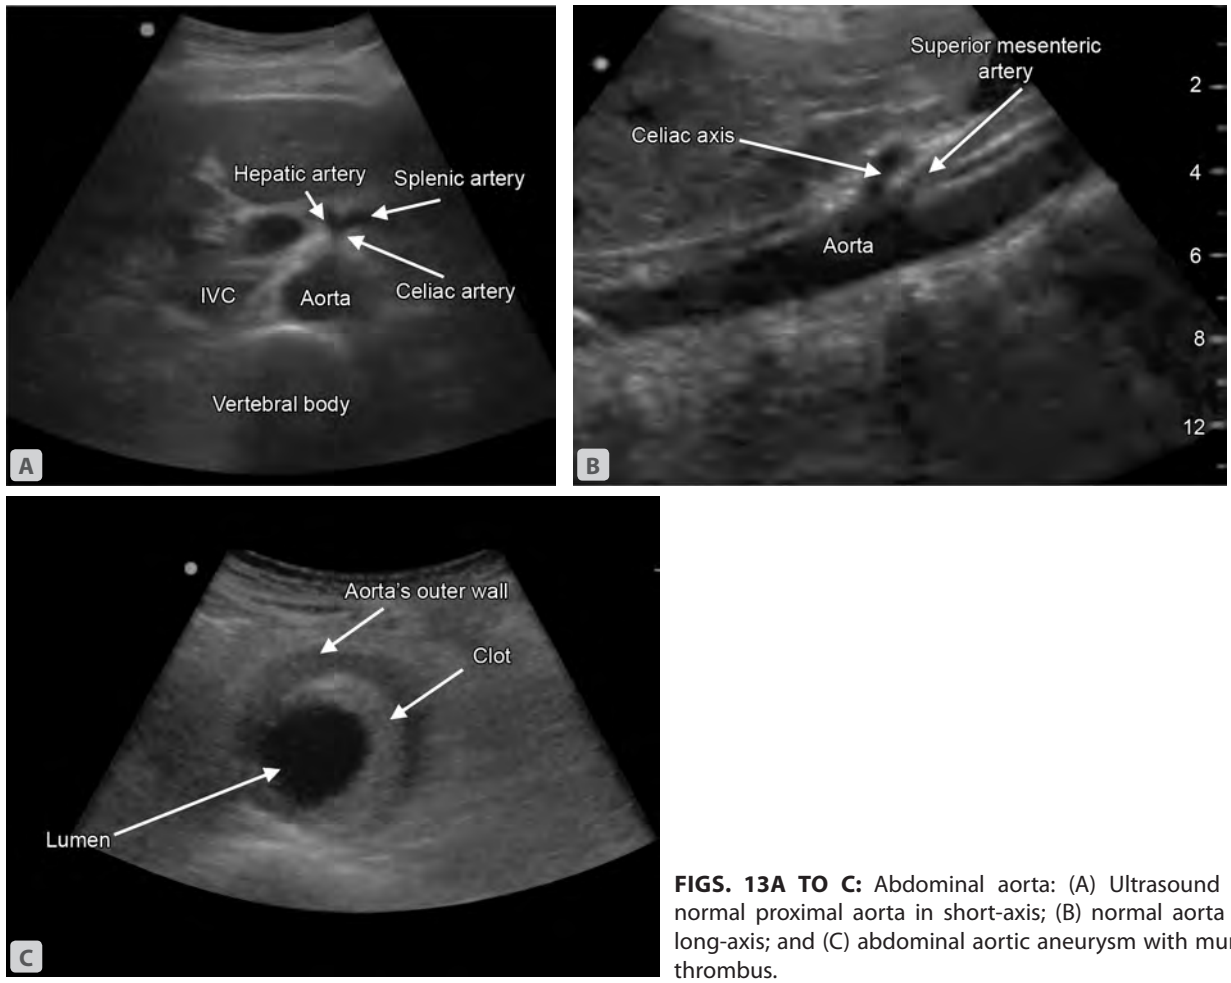
Next, the thoracic aortic is assessed. The sensitivity of transthoracic echocardiography to detect aortic dissection is poor and if clinical suspicion exists, further evaluation with more sensitive imaging modalities such as CT, magnetic resonance imaging (MRI), or transesophageal echocardiography should take place. However, bedside ultrasound may detect thoracic aortic dissections, and in those cases, lead the patient to a more expedient diagnosis of this time-sensitive condition.

Two ultrasound views may assist in this diagnosis. The parasternal long-axis view of the heart allows visualization of the aortic root. Aortic root dilation >3.8 cm is considered abnormal. The suprasternal view allows visualization of the aortic arch. This view is obtained by placing the phased array probe within the suprasternal notch and aiming the probe caudally and anteriorly (**Figs. 14A** and **B**). The presence of an intimal flap in either of these views diagnoses an aortic dissection. Pericardial effusion and evidence of aortic regurgitation may also be visible.

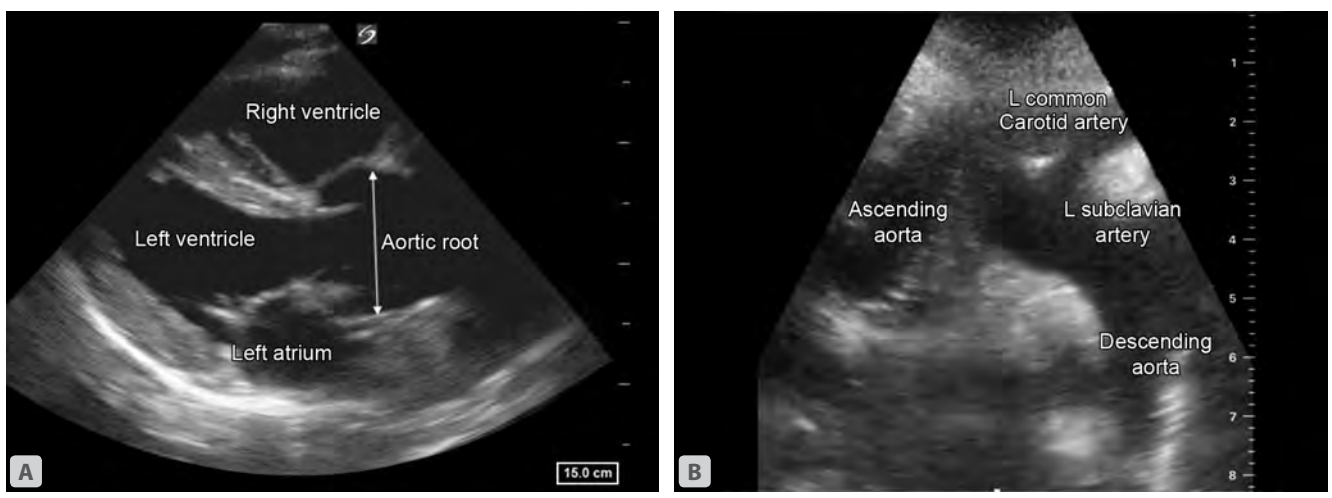
Clogging of the Pipes: Venous Thromboembolism

If a pulmonary embolism is suspected as an etiology of shock, then a lower extremity deep vein thrombosis (DVT) study should be done. The majority of pulmonary emboli originate from lower extremity DVTs (**Fig. 15**). At times, thrombus may be directly visualized on ultrasound. A well-formed blood clot may appear hyperechoic, while a fresh blood clot will appear hypoechoic. However, compression sonography is required for evaluation of DVT. A normal vein will completely collapse with compression, while a vein containing thrombus will show no compression or incomplete compression (**Fig. 16**).

A focused examination for DVT uses a high-frequency linear transducer to assess compressibility of the (1) common femoral vein, (2) proximal femoral vein, and (3) popliteal vein. This focused protocol has been shown to have high sensitivity to detect DVT.



FIGS. 13A TO C: Abdominal aorta: (A) Ultrasound of normal proximal aorta in short-axis; (B) normal aorta in long-axis; and (C) abdominal aortic aneurysm with mural thrombus.



FIGS. 14A AND B: (A) Measurement of aortic root in parasternal long-axis view; (B) suprasternal view of the aortic arch.

SUMMARY

A simplified three step assessment by point of care ultrasound during resuscitation helpful in identifying an underlying etiology of shock and appropriate intervention can be implemented (**Table 1**).

As adoption of ultrasound-based resuscitation protocols (**Fig. 17**) has become more widespread, many studies have emerged to evaluate the utility of these protocols in managing undifferentiated patients with shock or hypotension. Some studies have shown that in the hands of a highly skilled sonographer, a multiorgan POCUS evaluation can effectively

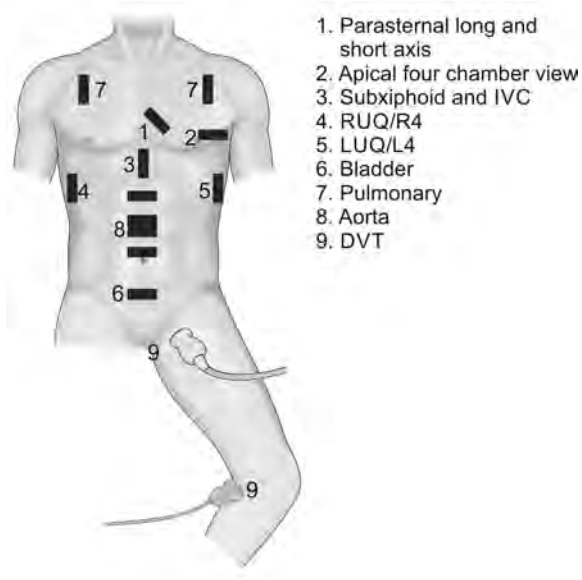
TABLE 1: Sonographic findings, and categories of shock and initial management.

RUSH evaluation	*Hypovolemic shock*	*Cardiogenic shock*	*Obstructive shock*	*Distributive shock*
Pump	• Hyperkinetic heart • Small chamber size	• Hypocontractile heart • Dilated cardiac chambers	• Hypercontractile heart • Pericardial effusion • Cardiac tamponade • Right heart strain • Cardiac thrombus	• Hyperkinetic heart (early sepsis) • Hypocontractile heart (late sepsis)
Tank	• Flat IVC • Flat jugular veins • Free fluid in thorax or abdomen	• Distended IVC • Distended jugular veins • Pulmonary edema (diffuse B-lines) • Pleural fluid • Peritoneal fluid (ascites)	• Distended IVC • Distended jugular veins • Absent lung sliding (pneumothorax)	• Normal or flat IVC (early sepsis) • Focal B-lines or other sonographic findings of pneumonia
Pipes	• Abdominal aneurysm • Abdominal dissection	Normal	DVT	Normal
Initial interventions	• Fluid bolus • Hemorrhage control • Transfusion • Surgery consult	• Inotrope • Pressor • Diuresis	• Pericardiocentesis • Tube thoracostomy • Thrombolysis/ anticoagulation	• Fluid bolus • Antibiotics

diagnose shock etiology and allow initiation of the correct therapeutic intervention. However, a recent randomized control trial did not demonstrate benefits in patient-centered outcomes including survival, hospital length of stay, rates of CT scanning, inotrope use, or fluid administration. A meta-analysis reported that ultrasound was well suited to rule-in causes of shock, but was poor at ruling-out causes of shock.

These results may seem to argue against the use of POCUS during emergency department resuscitations; however, they more so reinforce the idea that POCUS should not be



(DVT: deep vein thrombosis**;** LUQ: left upper quadrant; RUQ: right upper quadrant)

FIG. 17: Recommended sequence for point-of-care ultrasound resuscitation protocol.

performed indiscriminately for patients in shock, but rather should be targeted to the clinical context of the patient. The RUSH protocol is broad, incorporating multiple ultrasound examination elements that can be time-consuming to perform. Numerous other ultrasound-based diagnostic protocols have also been described to evaluate the critically ill patient. While the underlying components comprising, these protocols are often identical, these protocols differ in their sequence of evaluation and number of elements included. The RUSH protocol should be considered a general framework for systematic evaluation of hypotension, and the sequences included should be tailored to the presentation of each patient. Furthermore, these studies neglect a significant benefit of POCUS in the management of the critically ill patient—serial ultrasound assessment to guide ongoing therapy.

Future work will require further standardization of ultrasound in resuscitation for patients with varying presentations. When used in isolation, multiorgan-based ultrasound protocols are imperfect, but as one component of a complete evaluation of a hypotensive patient, and used in conjunction with other clinical data points, ultrasound can reduce diagnostic uncertainty and provide needed guidance early in clinical decision making.

CHAPTER

Ultrasound-guided Procedures

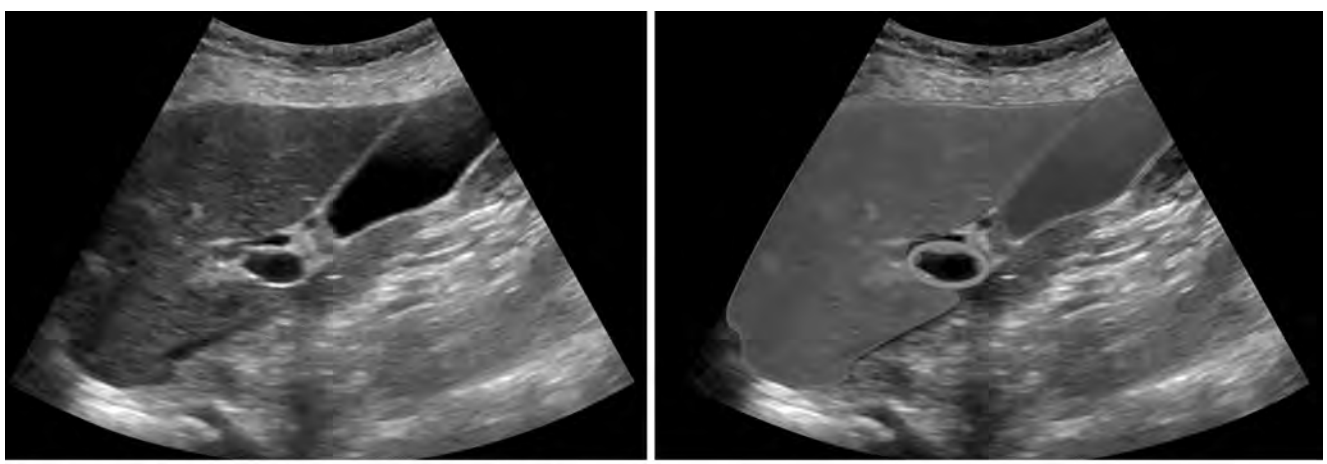
Richa Manglorkar, Mohaned Moheb El Abd, Tiffany Fong

INTRODUCTION

Vascular access is an essential and frequently lifesaving procedure in emergency and trauma care. Ultrasound (US) guidance for vascular access permits direct real-time visualization of the needle and surrounds structures and improves the quality and safety of needle guided procedures, including improved procedural success, reduced number of attempts, and fewer complications. The challenges of inherently poor anatomic landmarks, presence of aberrant anatomy, and weak or absent pulses in hypotensive or cardiac arrest patients can be mitigated by the use of ultrasound. Use of ultrasound guidance, particularly in central venous catheterization has become a standard of care and recommended by numerous professional societies as well as the Agency for Healthcare Research and Quality and National Institute of Health and Care Excellence as a top safety practice. As ultrasound guidance of vascular access procedures has become more widespread and clinician proficiency has increased, so has the spectrum of procedures performed under ultrasound guidance, to include peripheral veins and arterial puncture. Studies show that even with limited ultrasound training, physicians, nurses, and other healthcare personnel have been successful in learning and adopting these techniques.

PHYSICS OF ULTRASOUND

Ultrasound transducers contain piezoelectric elements that convert electrical energy into mechanical energy. This mechanical energy causes compression and rarefaction of particles, generating a sound wave. After the sound waves pass through a medium and are reflected back by an object, they are then converted back into electrical energy that is processed by a computer into the gray-scale images seen on the ultrasound display. The brightness displayed on the ultrasound system is dependent upon the strength of the reflected echoes (**Fig. 1**). Fluid-filled structures transmit most sound waves producing an anechoic or dark appearance on ultrasound.



Blue: The gallbladder in longitudinal view is an anechoic structure.
Green: The walls of the portal vein represent a hyperechoic structure.
Orange: The liver parenchyma represents a hypoechoic structure.

FIG. 1: Varying echogenicity of structures seen on ultrasound. ***(For color version, see plate 3)***

Various types of fluid, including blood, bile, or urine have this appearance. Dense structures that reflect most sound waves are hyperechoic and appear as bright on ultrasound. Examples include bone, calcified structures such as gallstones, and the diaphragm and pericardium. On a spectrum between anechoic and hyperechoic materials are hypoechoic objects, displayed as shades of gray. Hypoechogenicity may be seen in solid organs such as the kidneys. Isoechoic describes structures that produce echoes that are similar to surrounding materials.

TRANSDUCERS

Three major transducers are commonly used in point-of-care ultrasound: (1) Curvilinear, (2) phased-array, and (3) linear. Each transducer has a different sound wave frequency, shape, crystal array, and application. The curvilinear probe utilizes frequencies of 2–5 MHz and allows visualization of deep solid organs such as the liver, kidney, gallbladder, and aorta. The phased-array probe utilizes frequencies of 1–5 MHz and its compact shape allows visualization of deep dynamic organs such as the heart and lungs between the ribs. The linear probe utilizes frequencies of 5–15 MHz and allows high resolution imaging of superficial structures such as veins, arteries, and nerves. This transducer is most often used for procedure guidance (**Fig. 2**).

KNOBOLOGY

Knobology refers to the functionality and manipulation of various controls on the ultrasound system. This section will review basic ultrasound controls essential to optimizing views for ultrasound-guided procedures.

Depth

Depth should be adjusted so that the structure of interest remains in the center of the screen, thus maximizing image resolution. Occasionally, it may be important to include other structures in view for landmarks or avoidance. An example is maintaining adequate depth to visualize the pleura when performing subclavian central venous catheterization to avoid pneumothorax.

Gain

Gain adjusts the level of amplification of echoes after the returning signal is received by the transducer. Increasing gain brightens images, decreasing gain darkens images. Gain should be adjusted until known anechoic (black) structures appear as dark as possible.

Color Doppler

Color Doppler assesses the presence and directionality of flow and is most commonly used for vascular structures (**Figs. 3A** to **C**). By convention, blue represents flow away from the probe and red represents flow toward the probe. This directionality may be useful in determining the difference between arteries and veins.

TECHNIQUE OVERVIEW

The technique most commonly used in ultrasound-guided vascular access procedures is direct or real-time visualization. From the time, the needle enters the skin until it reaches the target structure; its position and trajectory are visually tracked with ultrasound. This technique provides many advantages such as ensuring proper positioning of the needle tip and avoiding puncture nearby structures including arteries and nerve bundles.

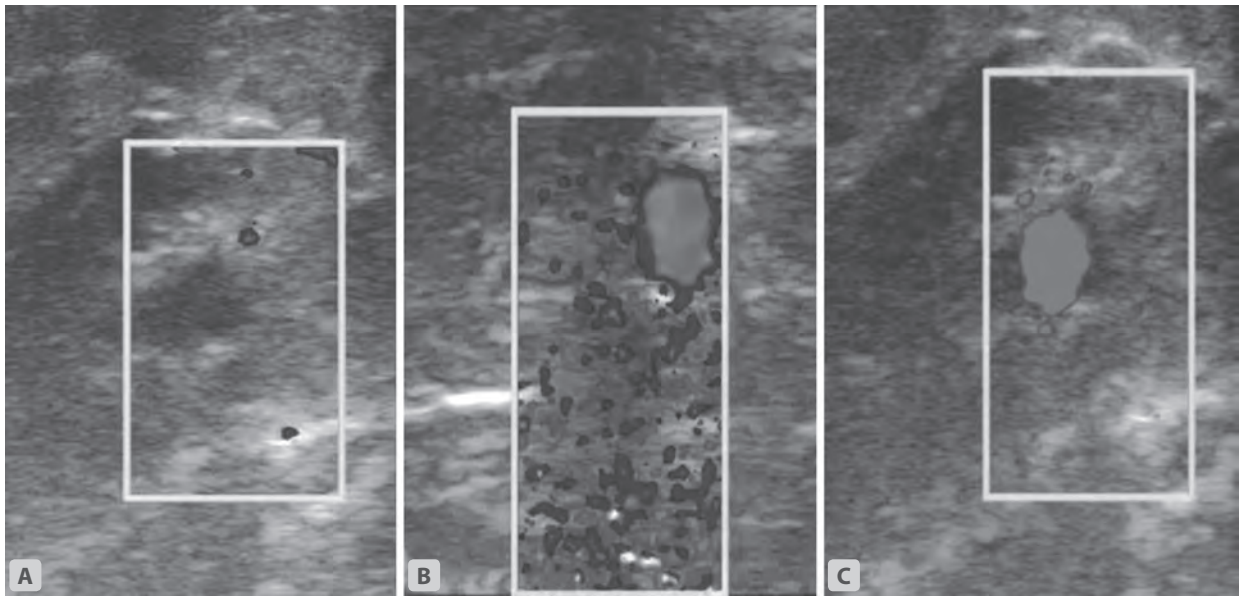
Procedural guidance may be performed using an out-of-plane technique (also known as short-axis, transverse, or cross-sectional relative to the structure of interest) or an in-plane technique (also referred to as long-axis) (**Table 1**). Each technique has its own advantages and disadvantages.

PERIPHERAL VENOUS CATHETER PLACEMENT WITH ULTRASOUND GUIDANCE

Placement of peripheral intravenous (IV) lines is an essential skill that is used in multiple settings varying from outpatient clinics to intensive care units. The ability to obtain peripheral access is an integral part of patient care. Patient factors can

From left to right:
Curvilinear probe: Low frequency, used for deep abdominal structures (i.e., liver, kidney)
Phased-array probe: Low frequency, used for deep dynamic structures (i.e., heart, lungs)
Linear probe: High frequency, used for superficial vascular structures (i.e., veins, arteries)

FIG. 2: Ultrasound transducers.



FIGS. 3A TO C: Use of color Doppler to identify vascular flow; (A) A nonvascular structure with no flow seen on Doppler; (B) A vascular structure with flow away from the probe consistent with a vein; (C) A vascular structure with pulsatile flow toward the probe consistent with an artery. ***(For color version, see plate 4)***

TABLE 1: Techniques for ultrasound-guided procedures.

	Short axis/out-of-plane technique	***Long axis/in-plane technique***
Advantages	• Arteries and veins can be simultaneously visualized • Minimal probe adjustment • Technically easier to perform	• Tip and entire length of the needle are visualized • Less likely to go through the back wall of the vessel
Disadvantages	Probe position requires adjustment for the needle tip to be visualized while advancing the needle	• More challenging to obtain long-axis view • Lose visualization of surrounding structures

make IV insertion difficult, including but not limited to body habitus, IV drug use, end-stage renal disease, and hypovolemia. Greater success successfully may be seen in such patients with the use of ultrasound guidance. Indications contraindications and requirements of supplies are given in **Table 2**.

Anatomy

- *Upper extremities*: The most commonly accessed veins for ultrasound-guided peripheral IVs are in the upper extremities. Traditional IVs placed by palpation methods are frequently performed in the dorsum of the hand, forearm, or antecubital fossa. In contrast, ultrasound-guided IVs frequently target the larger but often deeper cephalic, basilic, and brachial veins. The cephalic vein is ideal as it is a large, superficial vein located at the lateral aspect of the arm. The brachial and basilic veins run more medial along in the inner arm, making procedural positioning more difficult. Furthermore, the brachial vein runs in a neurovascular bundle that dives deep to the muscle, making avoidance of arteries and nerves more challenging.
- *Lower extremities*: The lower extremity veins may be used if vascular access in the upper extremity veins is unsuccessful. Potential targets include the greater saphenous and lesser saphenous veins.

Technique

Ultrasound-guided peripheral IV access may be performed using an out-of-plane technique using a transverse view of the vessel, or using an in-plane technique while visualizing the longitudinal course of the vessel (**Table 3**). Steps are described in **Table 4**.

Complications

Pain, arterial puncture or cannulation, hematoma, nerve injury, phlebitis, cellulitis, and extravasation.

CENTRAL VENOUS CATHETER PLACEMENT WITH ULTRASOUND GUIDANCE

Obtaining central venous access is essential in critically ill patients and can be considered in three locations: (1) the internal jugular (IJ), (2) subclavian, and (3) femoral veins. The next section will review the general approach to central venous access. Indications for central venous catheter placement are given in **Table 5**.

TABLE 2: Indication contraindications supplies requirements for catheter placement.	
Indications	• IV medications • IV fluids • Laboratory testing • Blood transfusion • Contrast administration for imaging • Difficult IV access or failure of landmark techniques
Contraindications to IV access at a particular site	• Dialysis fistula • Mastectomy or lymph node dissections • Known or visualized deep vein thrombosis • Cellulitis • Trauma or other pathology to extremities requiring surgical management
Supplies (**Fig. 4**)	• Chlorhexidine or another topical antiseptic • Gauze • J-loop extension tubing or Luer-lock/IV adapter clave • Tourniquet • Gloves (non-sterile acceptable) • Peripheral IV needle with catheter • Clear barrier adhesive dressing (one to secure the intravenous line and a second to use as an ultrasound probe cover as needed) • Sterile ultrasound gel • Saline flush • Ultrasound with high frequency linear transducer • Local anesthetic may be considered (avoid "with epinephrine" as this may constrict target vessels)

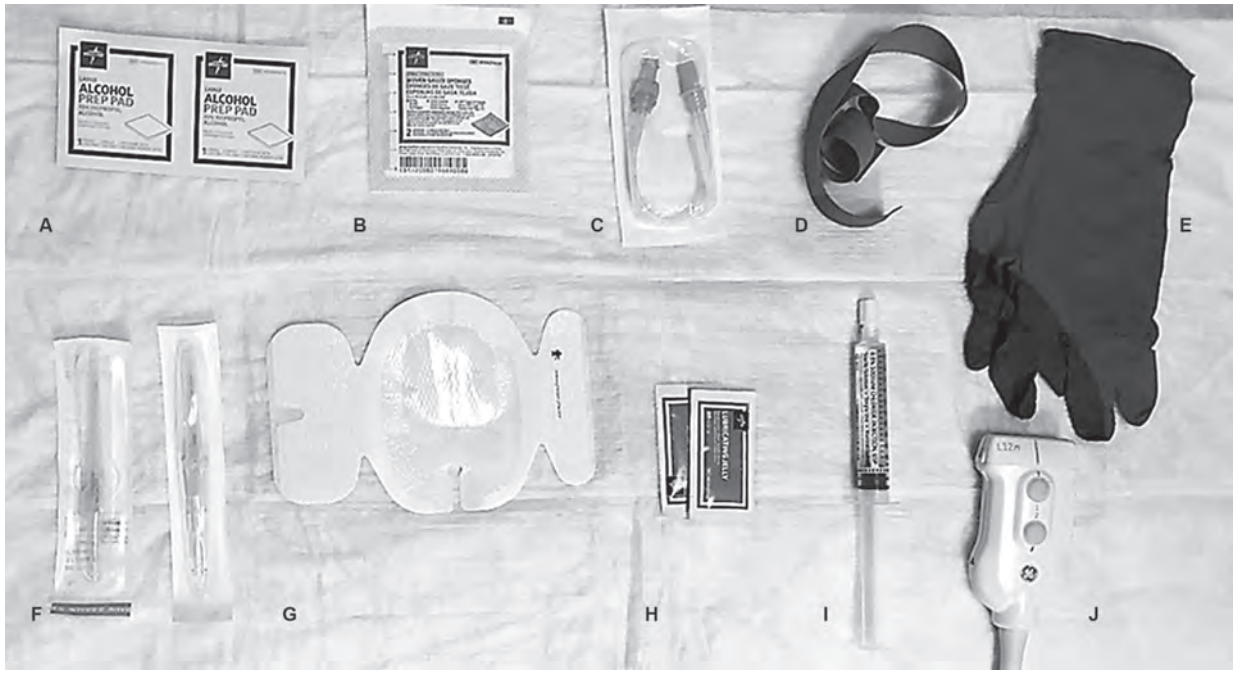


FIG. 4: Supplies required for ultrasound-guided peripheral venous access.

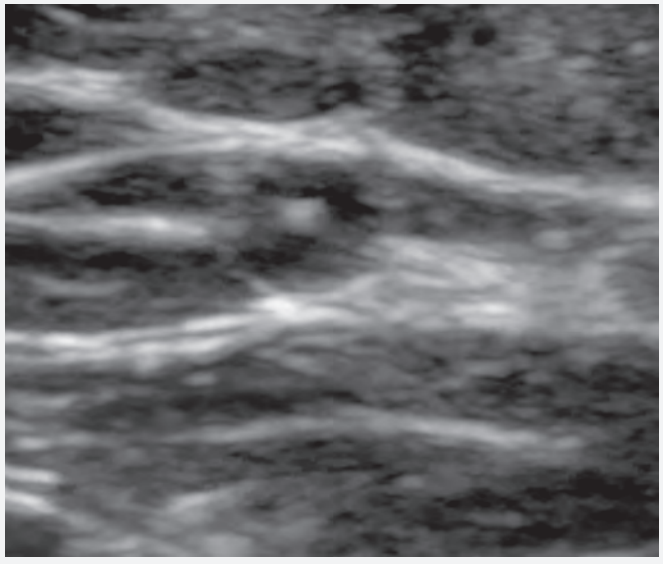
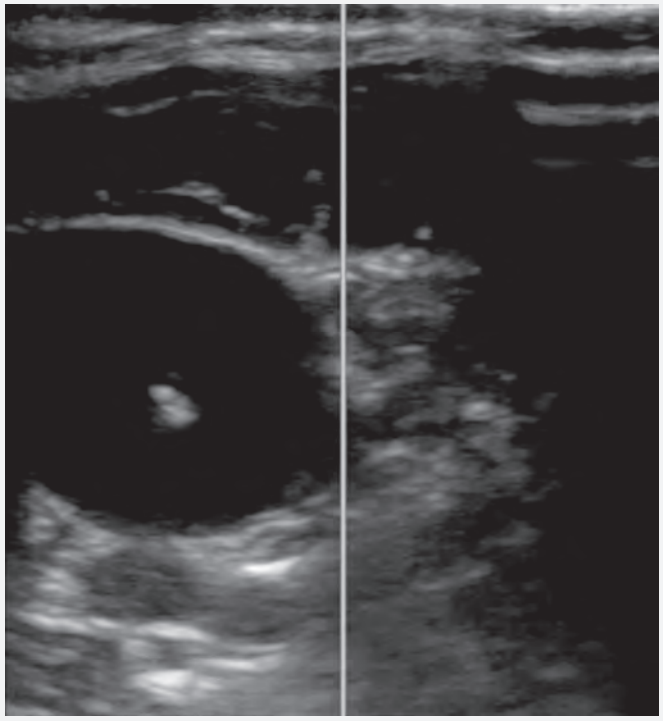
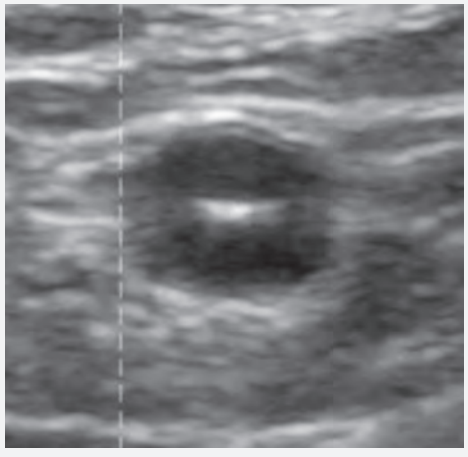
Procedure

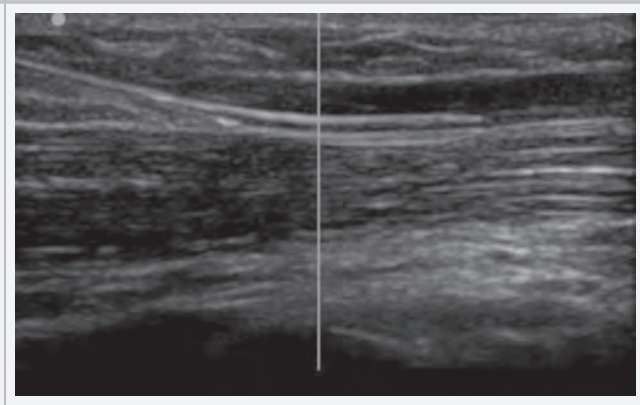
Identify the vein and any nearby arteries and nerves with ultrasound. It is best to survey the anatomy prior to sterilizing the skin and sterile draping. The target vein should be compressed to assess patency. If the vein is nonpatent or noncompressible, this may indicate presence of a venous thrombosis and the site should be avoided. Spectral Doppler can be employed to assess arterial versus venous waveforms. Don proper sterile personal protective equipment and widely sterilize and drape the appropriate site. The site to be punctured is anesthetized with lidocaine. Before injection, it is important to aspirate to ensure the needle tip is not positioned in a vessel (**Figs. 5A** to **C**).

TABLE 3: Technique for ultrasound-guided peripheral IV access.

Out-of-plane (transverse) technique	*In-plane (longitudinal) technique*
  	 








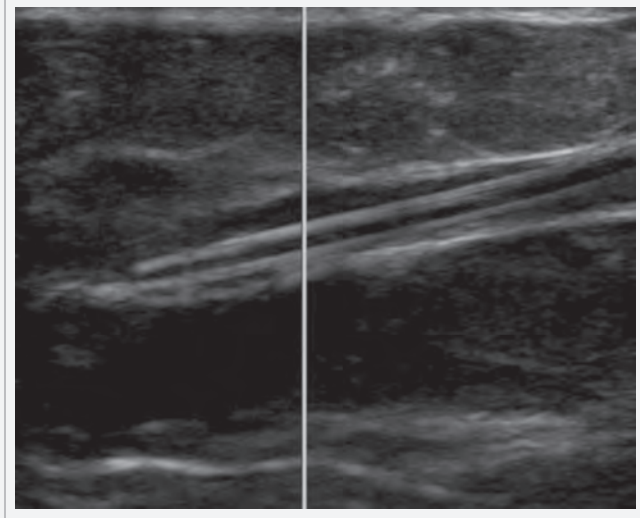


TABLE 4: Transverse approach to peripheral IVs.

Step	*Comments*	*Imaging*
1. *Patient and equipment positioning*	• Place the patient in a comfortable position • Keep the patient's arm abducted to maximize space to perform the procedure • Position the ultrasound machine so that area to be punctured lies in the same visual axis as the ultrasound monitor. At times this will be on the opposite side of the patient • Adjust the height and tilt of the ultrasound display	
2. *Identify a target vein with ultrasound*	• An ideal vein is larger, more superficial, and has a linear course without branch points • Compression is performed to confirm the venous structure and to assess for patency • Note depth of vein and ensure adequate catheter length. A standard 3.18 cm (1.25 inch) IV catheter is appropriate for vein depths <1 cm. A long length IV (4.88 cm, 1.88 inches) is appropriate for vein depth >2 cm	3. *Probe and skin preparation*	• Place a probe cover or clear adhesive barrier on the transducer and apply sterile gel • Clean procedure site with antiseptic (e.g., alcohol wipe or chlorhexidine) and place tourniquet	
4. *Probe manipulation*	• Hold the probe with the nondominant hand and needle with dominant hand • The probe marker should face the operator's left side to allow for movement of probe and movement on screen to correspond • Identify the target vessel and center it on screen	

Continued

Continued

Step	Comments	Imaging
5. *Advance the needle*	• Puncture skin at the center of the probe. The point of entry of the needle relative to the probe corresponds directly to the depth of the vessel (e.g., for a vessel that is 1 cm deep, the needle should enter the skin 1 cm form the probe) • Advance at a 45° angle, keeping the tip of the needle in view at all times. This can be achieved by advancing the probe until the needle tip disappears, and then advancing the needle until the tip is seen again • If the needle tip is not visualized, pause needle advancement, and fan the probe to identify the needle tip	
6. *Enter the vessel with the needle*	• Once the needle "tents" the top of the vessel, slowly advance until the needle tip is seen in the center of the vessel • Look for a flash of blood in the catheter • Do not puncture through the posterior (deep) wall of the vessel	7. *Cannulate the vessel*	• Keep the needle tip steady in the center of the vessel to ensure smooth advancement of the catheter and not the needle • Gently set down the probe • Thread the catheter with the dominant hand	
8. *Remove needle, keeping the catheter in place*	Blood flow may be seen	

Continued

Continued

Step	Comments	Imaging
9. *Secure and confirm IV line*	• Attach J-loop/Luer lock and aspirate with saline flush to confirm blood return • Remove tourniquet. Flush with sterile saline to prevent clot • Secure IV with Tegaderm or other clear adhesive barrier	
10. *Confirm catheter placement with ultrasound*	• If no blood is seen with aspiration, re-evaluate catheter position with ultrasound • When the catheter is appropriately positioned, it will be seen in the longitudinal axis as an echogenic structure within the lumen of the vein	
TABLE 5: Indications of central venous catheter placement.

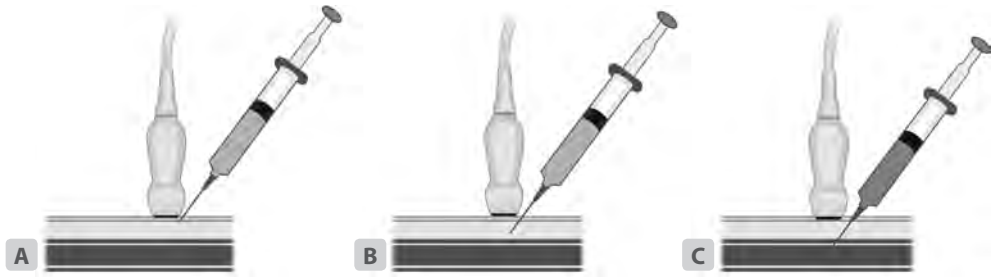
Indications	• Inability to obtain peripheral IV access • Dosing of medications that cause venous sclerosis if used peripherally (e.g., vasopressors, hypertonic saline, and high-concentration potassium) • Need for central venous procedures (e.g., transvenous pacing and Swan–Ganz catheter)
Supplies	• Ultrasound machine with high-frequency linear probe • Sterile transducer cover • Sterile ultrasound gel • Sterile gloves • Central venous catheter kit, containing necessary supplies including sterile personal protective equipment, drapes, local anesthetic solution, syringes and needles, guidewire, scalpel, dilator, catheter, suture, gauze, and clear adhesive dressing
Technique	The high-frequency linear array transducer should be used for this procedure because it allows high resolution imaging of superficial vascular structures. Similar to peripheral IV, central venous access may be performed using a transverse or longitudinal approach

Hold the ultrasound probe in the nondominant hand to obtain either a transverse or longitudinal view. With the dominant hand, pierce the skin and advance the needle, always keeping the needle tip in view on the ultrasound monitor. As with peripheral IVs, begin at a 45° angle. The depth of the vessel will inform the distance from the probe at which needle will enter the skin. For example, if the vein is 2 cm deep, the needle should enter the skin 2 cm away from the probe.

As the needle is advanced and the vessel is entered, the needle tip will be seen within the vessel lumen, as well as a flash of blood and loss of resistance of the syringe. Gently set down the transducer and stabilize the needle with the nondominant hand. Using the dominant hand, remove the syringe from the needle and immediately occlude the top using the finger of your nondominant hand to prevent an air embolism. Pick up then thread the guidewire through the needle using the dominant hand. Once the wire is properly positioned within the vessel, remove the needle over the wire while maintaining the wire's position in the vessel. Ultrasound may be used to confirm that the wire is within the vessel using both transverse and longitudinal views. After anatomic confirmation of wire placement, the catheter may be threaded over the wire, the wire removed, and the catheter secured with suture.

Complications

Similar to peripheral IVs, complications include pain, arterial puncture or cannulation, hematoma, nerve injury, phlebitis,



FIGS. 5A TO C: Ultrasound-guidance of needle advancement; (A) Needle tip starting at the skin distal to the vessel under ultrasound guidance; (B) Advancing the needle through soft tissue through toward the vein while advancing the ultrasound probe to keep the needle tip visible; and (C) Entering the vein with a flash of blood while aspirating and keeping the needle tip in the center of the vessel.

cellulitis, and extravasation. However, central lines also carry additional risk of pneumothorax, hemothorax, or thoracic duct injury (IJ or subclavian), bladder injury (femoral), noncompressible hematoma (subclavian), brachial plexus injury (subclavian), retroperitoneal hematoma (femoral), or central-line associated bloodstream infections.

Specific Sites for Central Venous Access

This subsection will review three separate sites of central venous access in more detail including (1) the IJ vein, (2) femoral vein, and (3) subclavian vein. Each site of access has special considerations regarding anatomy and procedural approach. Despite the following special considerations, all three sites follow the basic steps of cannulation that were previously outlined.

Internal Jugular Vein

- *Background*: Traditionally, IJ catheterization had been performed using anatomic landmarks, leading to failed attempts and procedural complications. The earliest description of ultrasound assistance for IJ access was published in 1984. The IJ often preferred for central venous access due to its superficial position and easy accessibility. A 2015 systematic review compared the use of ultrasound guidance to landmark techniques for IJ cannulation. This revealed a decrease in overall number of attempts, a 57% increase in first attempt success, decreased time to cannulation, and a 71% decrease in rate of complications.
- *Anatomy*: The IJ vein is vertically oriented along the lateral aspect of the neck and is contained within the carotid sheath lateral to the carotid artery and together with the vagus nerve. The IJ lies deep to the platysma, digastric, omohyoid, and sternocleidomastoid muscles. Once the IJ reaches the first rib/thorax it joins the subclavian vein to form the innominate vein, draining to the superior vena cava and ending in the right atrium (**Fig. 6**).
- *Special considerations*: To optimize the patient's position, turn the head toward the contralateral shoulder to open the anatomic space and create a more linear course of the IJ. Furthermore, the patient should be placed in Trendelenburg position (head lower than feet) position to increase venous dilation and to minimize the risk of air embolism. The IJ should be visualized in a more lateral position relative to the carotid artery (**Fig. 7**).

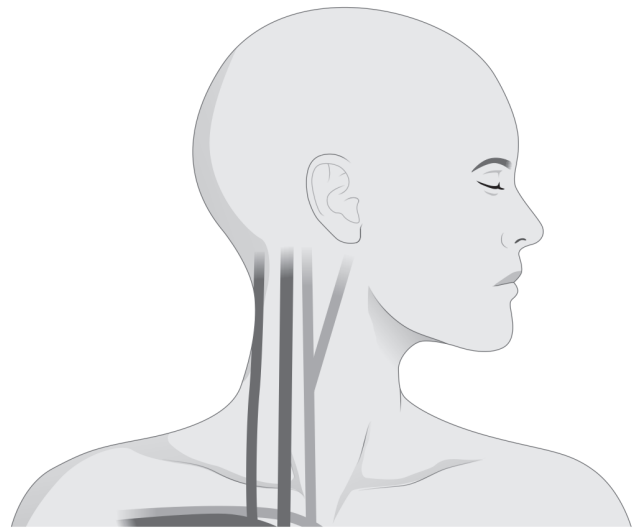


FIG. 6: Anatomy of the internal jugular and subclavian veins relative to the carotid and subclavian arteries.

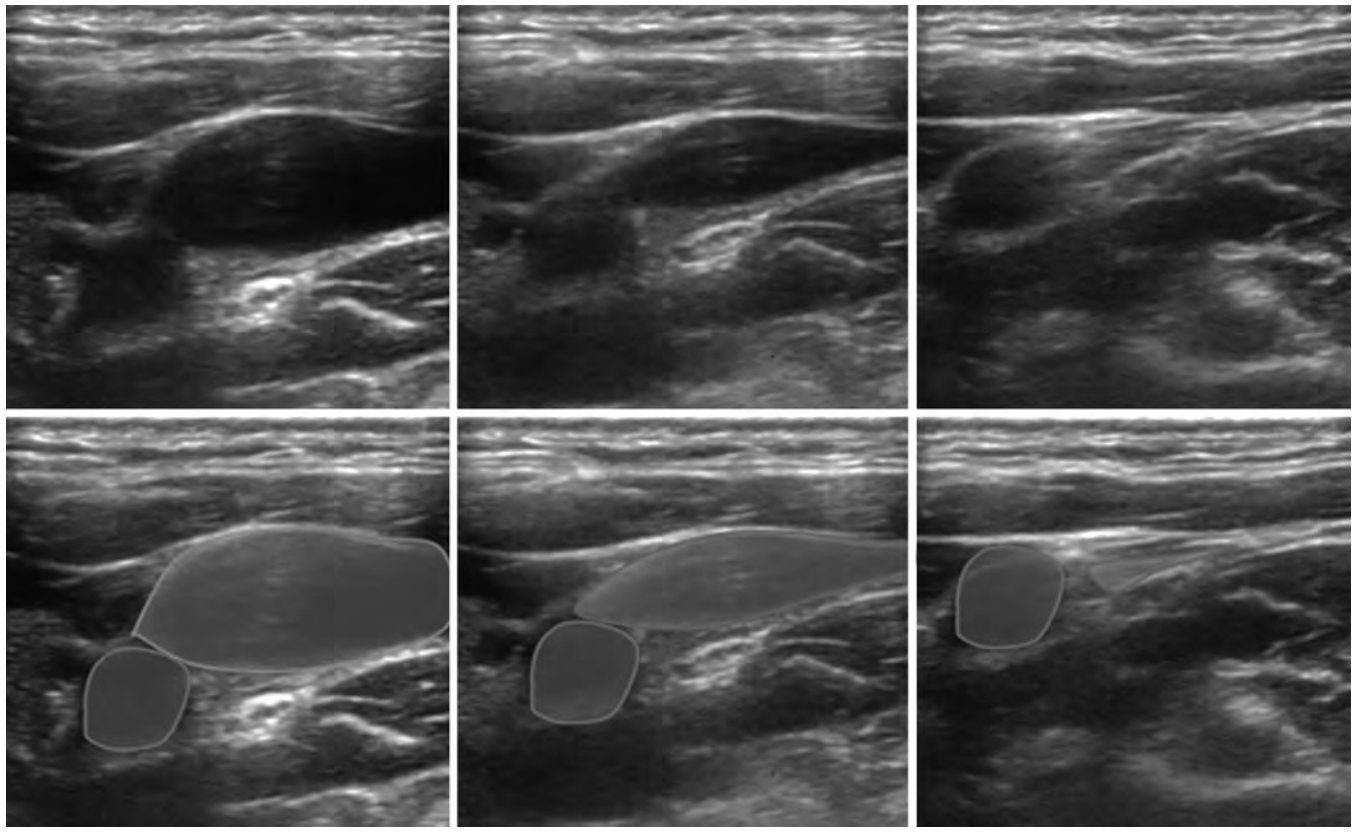
Subclavian Vein

- *Background*: Subclavian central venous access offers several advantages over the IJ site, including increased patient comfort and fewer infectious complications, most notably central-line associated bloodstream infection. Because of its fixed position under the clavicle, it has less size variation than the IJ and may be easier to access in patients with hypovolemia or sepsis. However, its location under the clavicle may also create more technical challenges to accessing it, and more difficult compressibility in the event of inadvertent arterial puncture.
- *Anatomy*: The subclavian vein is formed by the confluence of the cephalic and axillary veins of the upper extremity and runs anterior to the subclavian artery. After the subclavian vein joins the IJ vein to form the innominate vein, it drains into the superior vena cava leading to the right atrium. The right subclavian vein is preferred for cannulation due to its straighter angle with the IJ and relative ease of passage into the superior vena cava (**Fig. 8**).
- *Special considerations*: The use of ultrasound guidance allows two approaches to subclavian vein catheterization.
  (i) *Infraclavicular approach*: This approach is more commonly taught and used to access the subclavian



(Blue: internal jugular vein; Red: carotid artery. Internal jugular and carotid artery shown from left to right with progressive compressibility of the internal jugular vein)

FIG. 7: Sonographic anatomy of internal jugular vein and carotid artery. ***(For color version, see plate 4)***

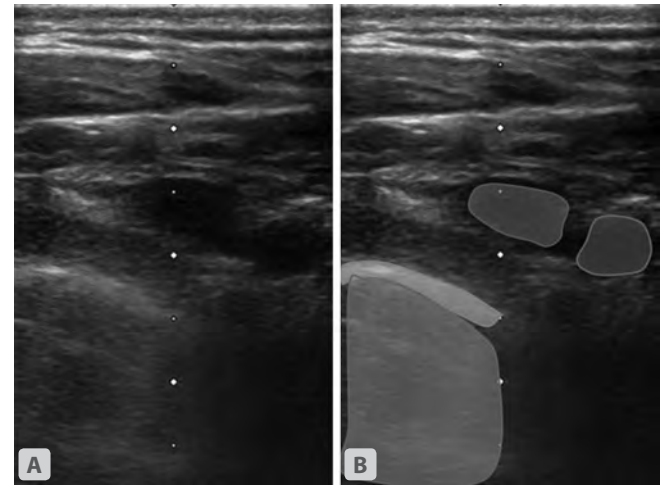

FIGS. 9A AND B: Transverse infraclavicular ultrasound view of the subclavian vessels and lung. ***(For color version, see plate 5)***

vein (**Figs. 9A** and **B**). The linear probe is placed below the clavicle in the infraclavicular fossa to obtain a longitudinal view of the subclavian vein. The subclavian vein should be cannulated at its junction with the axillary vein, in a more lateral position than with a landmark-based approach. Slide the probe along the margin of the inferior clavicle to identify the accessible portion of the vein prior to its dive deep to the clavicle. Fan the probe to identify both the subclavian vein in its long axis, and the subclavian artery posterior to it. Compress to assure vein patency and to confirm arterial and venous structures. Because of the position of the clavicle, compression may be limited and alternatives include use of color or spectral Doppler. The hyperechoic mobile pleural line will be

seen immediately below the subclavian vein. The pleural line should always be kept in view to ensure the needle tip does not puncture the pleura and cause a pneumothorax. Utilizing an in-plane approach, the needle is inserted at the lateral edge of the transducer and advanced slowly toward the subclavian vein.

(ii) *Supraclavicular approach*: The subclavian vein has a short supraclavicular course prior to merging with the IJ to become the innominate vein. This area of confluence offers a shallow and relatively larger area of vein that may be easy to access. However, this technique is more challenging and recommended for operators who have greater experience with in-plane procedures.

The supraclavicular fossa itself has space limitations, and the use of a small footprint high-frequency transducer (or endocavitary transducer) is advised. The transducer is placed on the lateral neck in a transverse plane just superior to the clavicle to identify the IJ. The IJ is traced inferiorly then angled anteriorly to visualize its confluence with the subclavian vein—this is the target site for cannulation. Fan the probe to identify both the subclavian vein in its long axis, and the subclavian artery posterior to it. Again use compression and Doppler techniques to assure vein patency and to confirm arterial and venous structures. Continuously visualize the pleura throughout the procedure to avoid lung puncture and pneumothorax. After local anesthesia, the needle punctures the skin just lateral to the probe using an in-plane approach. It is slowly advanced toward the subclavian IJ junction, just lateral to the clavicular head of the sternocleidomastoid muscle.

Femoral Vein

- *Anatomy*: The femoral vein is located within the femoral sheath medial to the femoral nerve and femoral artery. It lies inferior to the inguinal ligament, lateral to the adductor muscles, and medial to the sartorius muscle (**Fig. 10**). Moving proximally, the femoral vein becomes the external iliac vein, draining into the common iliac vein, and ultimately joining the inferior vena cava. The femoral vein generally has fewer surrounding high-risk structures.
- *Special considerations*: The patient may be placed in reverse Trendelenburg position (feet toward the ground) to increase venous dilation. Additionally, abduction and external rotation of the leg may open up the space of the femoral triangle to allow greater ease of access. On ultrasound, the femoral vein should lie medial to the femoral artery (**Fig. 11**). Select a portion of the common femoral vein below the inguinal ligament for cannulation. Attempts above the inguinal ligament can lead to intraperitoneal complications or retroperitoneal bleeding.

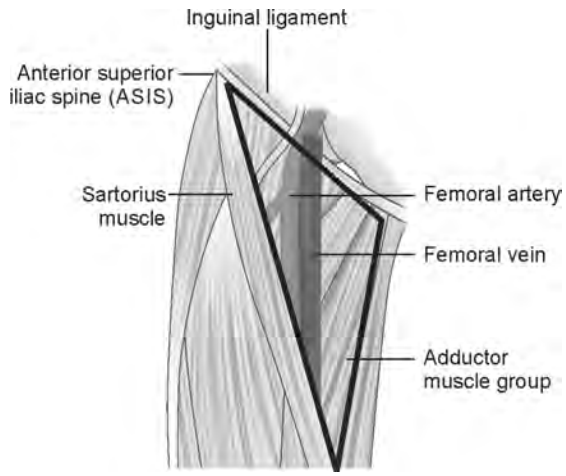

FIG. 10: Anatomy and catheter placement within femoral vein.

ULTRASOUND-GUIDED PERICARDIOCENTESIS

Background

Pericardial tamponade is a life-threatening condition characterized by accumulation of fluid in the pericardial sac resulting in high intrapericardial pressures that impair cardiac filling. Tamponade is a clinical diagnosis that should be suspected in a hemodynamically unstable patient with moderate or large pericardial effusion. Beck's triad describes the classic physical findings of hypotension, muffled heart sounds, and distension of the neck veins. However, these findings are limited to identify tamponade, with 50% of patients demonstrating just one element of the triad and as low as 0% of patients demonstrating all three elements.

Point-of-care ultrasound is a necessary tool to diagnose pericardial effusion and tamponade and to guide the life-saving procedure of pericardiocentesis. Ultrasound facilitates direct visualization of the needle approaching the pericardium and aspirating the effusion and is recommended to increase procedural success, improve survival, and minimize the potential complications.

The hemodynamic effect of pericardial effusion is dictated by both the volume and the rate of fluid accumulation. More chronic, slowly growing effusions allow larger volumes to

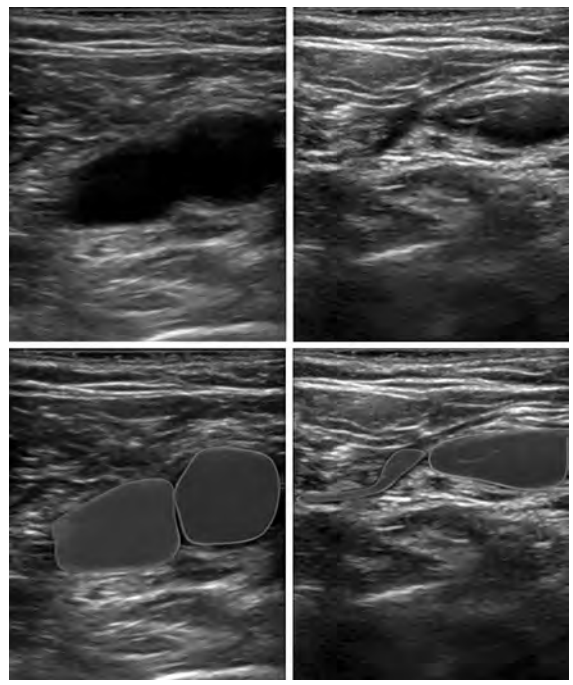

FIG. 11: Ultrasound view of a femoral vasculature with a patent femoral vein. ***(For color version, see plate 5)***

accumulate due to pericardial stretch. In contrast, rapidly expanding effusions can lead to critical increases in pericardial pressure at smaller volumes. Thus, with acute effusions, removal of relatively small amounts of fluid can have a significant hemodynamic effect.

Indications and Contraindications

Pericardiocentesis is immediately indicated when pericardial tamponade is suspected, including cardiac arrest with pericardial effusion and in hemodynamically unstable patients with moderate or large pericardial effusions. There are no absolute contraindications to pericardiocentesis when pericardial tamponade is present. Relative contraindications to emergency pericardiocentesis include coagulopathy, anticoagulant therapy, thrombocytopenia (platelet count < 50,000/mm^3), and presence of small, posterior, or loculated effusions.

Supplies

- Ultrasound system with phased array transducer
- Probe cover or clear barrier adhesive dressing
- Sterile ultrasound gel
- Chlorhexidine or other topical antiseptic
- Small syringe (10 cc) and needle (20–25 gauge) for local anesthetic
- Large syringe (20–60 cc) for pericardiocentesis
- Long 16–18 gauge needle (e.g., from central line kit) or spinal needle
- Local anesthetic (e.g., 1% lidocaine)
- *Optional*: If an indwelling pericardial drain will be placed, a kit containing a 6–8 French pigtail catheter, guidewire, dilator, introducer sheath, three-way stopcock, needles, and syringes may be used.

Anatomy and Pathophysiology

The pericardium is a dense, fibrous sac composed of visceral and parietal layers and is visualized on ultrasound as a strongly echogenic (white) border surrounding the relatively hypoechoic myocardium. The pericardial space normally contains a trace amount of serous fluid that is not prominently seen. When fluid accumulates, an anechoic (black) stripe is seen between pericardium and myocardium, first in dependent areas then circumferentially around the heart as volume of fluid increases. The epicardial fat pad may be mistaken as pericardial effusion, but may be differentiated from effusion by the presence of internal echoes (making it more hypoechoic than anechoic), and its anterior position adjacent to the right ventricle rather than dependent. In addition, left pleural effusions may mimic pericardial effusion; however, pleural effusion can be confirmed through visualization of the effusion posterior to the descending thoracic aorta in the parasternal long axis view (**Fig. 12**). Pericardial tamponade occurs when high intrapericardial pressures that exceed intracardiac pressures, and the lower pressure system of the right heart is more vulnerable. Ultrasound findings of tamponade are collapse of the right ventricle during diastole and right atrium during systole. Poor right heart filling leads to dilation and decreased respiratory variation of the inferior vena cava.

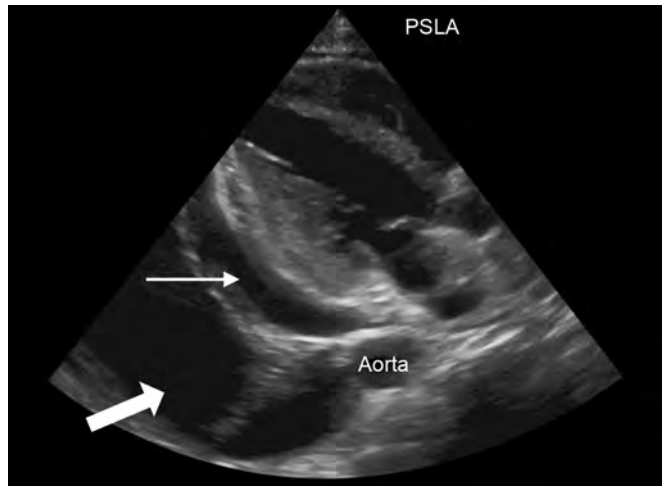

FIG. 12: Distinguishing pericardial and pleural effusion in the parasternal long-axis view. Pericardial effusion (thin arrow) tapers anterior to the descending thoracic aorta while pleural effusion (thick arrow) lies posterior to the descending thoracic aorta.

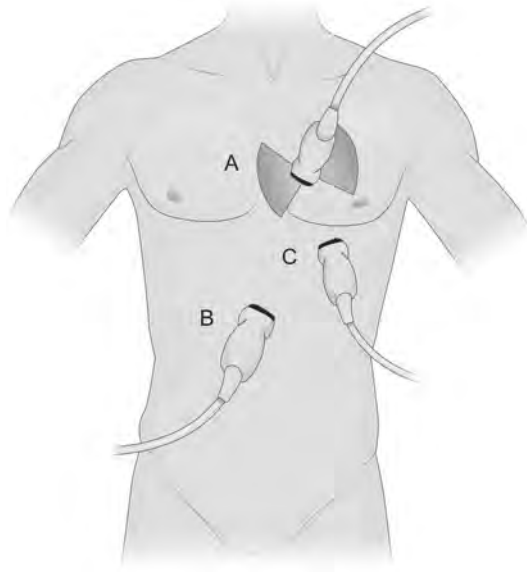

FIG. 13: Three approaches to ultrasound-guided pericardiocentesis approaches: (A) Parasternal; (B) Subxiphoid; and (C) Apical.

Preparation and Technique

Three main approaches can be used for pericardiocentesis: (1) subxiphoid, (2) parasternal, and (3) apical (**Fig. 13**). Ultrasound-guided pericardiocentesis has greater success and safety when the site of approach is selected through ultrasound visualization of the largest collection rather than a routine blind subxiphoid approach. Of note, in cardiac arrest situations, a subxiphoid approach may be preferred to allow for uninterrupted chest compressions.

The patient should have large bore IV access, supplemental oxygen provided, and remain on a cardiac monitor. Pericardial effusion and tamponade are first confirmed by ultrasound. An optimal approach is selected through identification of the largest and most accessible fluid pocket and avoidance of vital

structures. The subcostal approach is easiest in the majority of patients, while an apical approach is closest to the skin.

If time permits, a sterile cover may be placed over the transducer, the area is sterilized with chlorhexidine and covered with a sterile drape. Local anesthesia may be administered if the patient is conscious. If the patient is not in cardiopulmonary arrest, consider raising the head of bed to 30° to better localize the effusion.

Subxiphoid Approach

A subxiphoid cardiac view is obtained with the transducer flat against the abdominal wall inferior to the xiphoid process. A long 16- or 18-gauge needle is inserted between the xiphoid process and left costal margin at a shallow angle (<30°), aiming toward the tip of the left scapula. The subxiphoid approach is thought to be the easiest in the majority of patients.

Apical Approach

A view at the apex of the heart is obtained, just inferior to the left nipple in men and beneath the inferolateral left breast in women. A 16- or 18-gauge needle is inserted just adjacent to the ultrasound transducer and advanced toward the right shoulder to the cardiac apex.

Parasternal Approach

A parasternal long-axis view is obtained with the transducer placed left of the sternal border between the second and fifth intercostal spaces. The needle is inserted in-plane with the transducer at a 45° angle, directed toward the effusion. This approach offers a shorter distance from skin to effusion, and more easily avoids puncture of the liver and lung. However, there is risk of puncture of the internal thoracic artery.

In all approaches, the needle is continuously aspirated while it is advanced. Visualization of the echogenic needle will guide a trajectory toward the largest fluid pocket within pericardium. Once the pericardium is entered, fluid should be withdrawn (**Figs. 14A** to **C**). Fluid can be repeatedly removed until vital signs normalize or until no further fluid can be removed. The heart can then be visualized with ultrasound again to confirm decrease in pericardial fluid and improvement in cardiac filling and function. Resuscitation should continue to take place concurrent to the procedure. A chest radiograph should be obtained postprocedure to exclude the presence of pneumothorax.

If more prolonged drainage is necessary, a pigtail catheter may be left in the pericardial space. After pericardial fluid is aspirated using a sheathed needle, the needle is advanced additional 2 mm, the needle sheath advanced over the needle, and needle removed. Using a Seldinger technique, a guidewire is inserted through the sheath, a small skin incision is made, and the tract is dilated. Lastly, the pigtail catheter is inserted over the wire. It is very important to confirm the location of the guidewire within the pericardial space prior to dilation. If needed, further confirmation of position can be provided by injection of agitated saline or fluid with visualization of bubbling or turbulent flow in the pericardial space. If bubbling or flow is seen within the left ventricle, the needle should be withdrawn and surgery consulted.

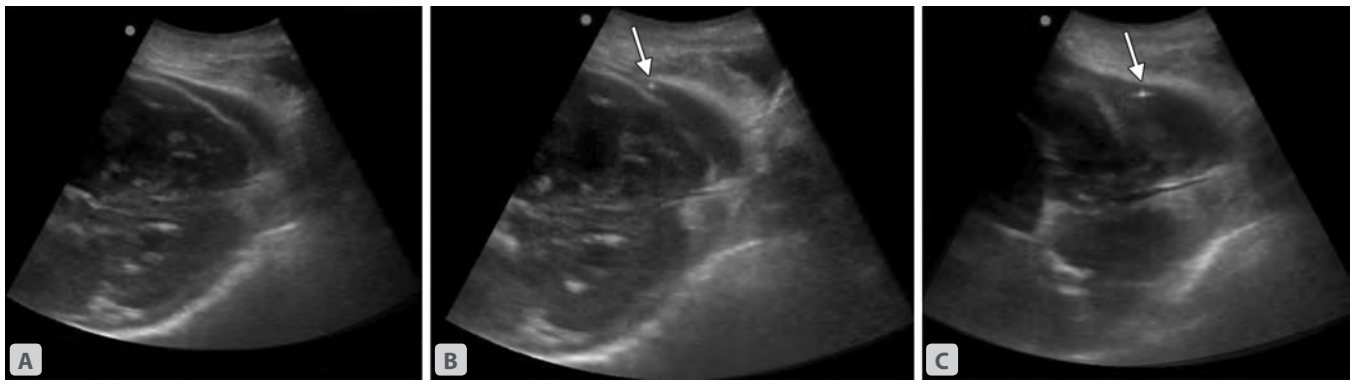
Complications

Pericardiocentesis is necessary as a lifesaving procedure, but may itself have major complications. These include worsening tamponade with cardiac arrest (if a ventricular wall or coronary artery is punctured), laceration of the coronary artery or intercostal vessels, cardiac dysrhythmias, myocardial injury, pneumopericardium, pneumothorax, puncture of the liver or abdominal viscera in peritoneal cavity, diaphragmatic injury (particularly with the subxiphoid approach), and pericardial decompression syndrome. A dry tap is another procedural risk.

ULTRASOUND-GUIDED PERIPHERAL NERVE BLOCKS

Background

Pain is the most common presentation of patients seeking care in the emergency department (ED). Safe and appropriate pain management is an important component of high quality and compassionate care. Ultrasound-guided nerve blocks have emerged as an important tool available to emergency clinicians as part of a multimodal analgesic strategy. In situations where the dosing of systemic analgesics may be limited or contraindicated, nerve blocks can serve a meaningful role (**Fig. 15**). Regional anesthesia has long been used by anesthesiologists in operative settings to provide sensory blockade for surgical procedures while avoiding the complications and side effects of general anesthesia. These nerve block techniques have similarly benefitted patients in the ED by relieving pain while reducing the need for adjunctive



FIGS. 14A TO C: Ultrasound-guided pericardiocentesis with needle tip (white arrow) seen entering the pericardial space.

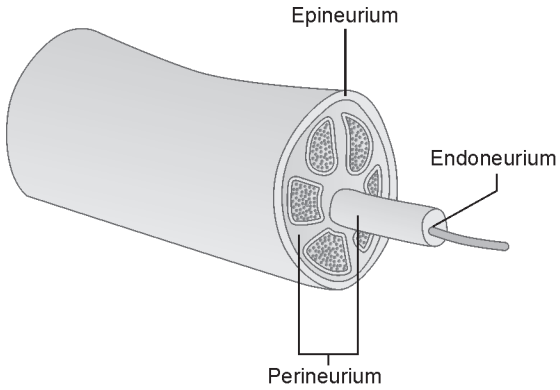


FIG. 15: Schematic representaion of peripheral nerve.

analgesics. In particular IV opioids, while commonly used, can lead to undesired and at times serious dose-related side effects, including respiratory depression, hypotension, and depressed consciousness. Furthermore, in patients with extensive injuries requiring procedural intervention, nerve blocks utilize less local anesthetic when compared to the potentially large volumes required for local infiltration, thus reducing the potential for toxicity. Unlike in the operating room, the goal of ED nerve blocks is not to provide full sensory and motor blockade, but rather to provide significant pain relief in conjunction with standard systemic analgesics, and reduce opioid-related adverse effects.

The addition of ultrasound guidance for nerve blocks permits localization of nerves, blood vessels, and key surrounding structures. It allows real-time confirmation of needle position, enabling local anesthetic to be more safely and precisely delivered to the appropriate location around the nerve. A Cochrane review reported that use of ultrasound guidance is superior to landmark and nerve stimulation methods, producing superior sensory blockade, reduced need for supplementation, and decreased complications during the performance of peripheral nerve blocks. Numerous studies support the ability of emergency physicians to learn and successfully perform ultrasound-guided nerve blocks. While a wide variety of ultrasound-guided nerve blocks have been described in the anesthesia and emergency medicine literature, this chapter will focus on five commonly performed nerve blocks for acute pain management in the ED.

Indications and Contraindications

The indications to perform an ultrasound-guided nerve block are diverse, and will be detailed in the sections describing specific blocks. Nerve blocks have broad utility for acute pain management after injury and for anesthesia during painful procedures, often as an alternative to procedural sedation or to reduce opioid requirement. Patients that may most benefit from nerve blocks include those at risk of respiratory depression (e.g., advanced age, underlying lung disease, obstructive sleep apnea, severe obesity, and polypharmacy), those with altered mental status, those with other indications for judicious opioid use (e.g., chronic opioid use and intolerance to opioid medications), and those with severe pain that is not well managed with systemic analgesics.

Contraindications to nerve blocks include allergy to local anesthetic agents, active soft tissue infection at the site of injection, injuries at risk of compartment syndrome, neurologic deficit in this distribution of the block, and inability to cooperate with the procedure. Coagulopathy or use of anticoagulants, particularly for blocks in noncompressible areas, is a relative contraindication.

Anatomy

Peripheral nerves are more easily identified by ultrasound in their short-axis. Though they may have a variable appearance depending on surrounding tissues, nerves are often echogenic, round or oval in shape, and classically have a "honeycomb" appearance. This is due to their architecture, composed of hypoechoic fascicles surrounded by more echogenic perineural and epineural connective tissue. More proximally (e.g., the brachial plexus), nerves may appear more hypoechoic; distally nerves have fewer myelinated axons and can appear more tendon-like.

It is important to adjust the transducer angle to minimize anisotropy. This is an ultrasound imaging artifact seen in musculoskeletal structures such as tendons and nerves that leads to a darker, less echogenic, and more indistinct appearance when the structure is viewed at a nonperpendicular angle. If a nerve is difficult to visualize, the transducer should be rocked or tilted to change the angle of insonation relative to the nerve thus optimizing its appearance.

Supplies

- Ultrasound system with high frequency linear transducer
- Probe cover or clear barrier adhesive dressing
- Chlorhexidine or other topical antiseptic
- Sterile ultrasound gel
- Small gauge needle (e.g., 25 g) to anesthetize the skin at injection site
- Syringe (10 or 20 cc, dependent on volume of anesthetic required), or control syringe if available
- IV extension tubing
- Blunt tip block needle (commercially available) or 20 g spinal needle
- Local anesthetic
- Gauze
- Creation of preassembled nerve block kits or storage of supplies in one central location will allow the operator to most efficiently gather the necessary materials.

Anesthetic Choice

Considerations when choosing an anesthetic agent include onset, duration, operator comfort, and local availability. Lidocaine and bupivacaine are commonly available in ED settings. For less experienced operators, lidocaine may be preferred over bupivacaine, due to its more favorable safety profile in the event of unintentional injection into vasculature. **Table 6** reviews the recommended dosing, onset, and estimated duration of action of commonly used local anesthetics in the ED (Wallace 2015).

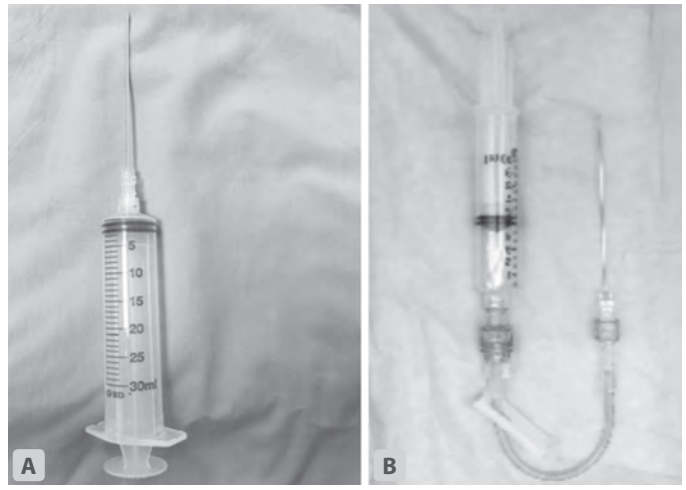
General Technique

Preparation

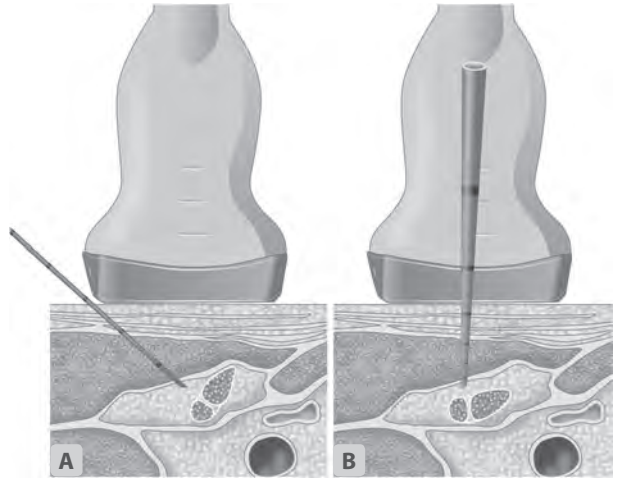
Informed consent should be obtained prior to the procedure. A discussion with relevant consulting services involved in the

TABLE 6: Dosing, onset, and duration of action of commonly used local anesthetics.

Anesthetic	*Maximum dose*	*Onset*	*Duration*
Lidocaine 1% without epinephrine	4.5 mg/kg	Rapid	60–120 min
Lidocaine 1% with epinephrine	7 mg/kg	Rapid	90–180 min
Bupivacaine 0.5% without epinephrine	2.5 mg/kg	Slow	180–360 min
Bupivacaine 0.5% with epinephrine	3 mg/kg	Slow	300–480 min



FIGS. 16A AND B: Needle and syringe setup for nerve block syringe containing anesthetic solution can be (A) connected directly to the block needle for a single-operator technique or (B) to a spinal needle through extension tubing during a two-operator technique.



FIGS. 17A AND B: In-plane and out-of-plane approaches to nerve block.

patient's care (e.g., orthopedics or trauma surgery) should take place prior to the block and consensus reached regarding appropriateness of nerve block for the presenting injury and longitudinal care plan. The presence of existing protocols for nerve blocks developed with relevant stakeholders from each department will facilitate these discussions.

The patient should have IV access and be placed on a cardiac monitor prior to the procedure. Patient positioning will be variable depending on the nerve block performed. However, ideal positioning allows the clinician to see the injection site, ultrasound display, and cardiac monitor in the same line of view. Often this is facilitated by placement of the ultrasound system on the other side of the bed contralateral to the injury.

The high-frequency linear transducer used for the procedure should be cleaned and a probe cover or clear adhesive dressing applied to the footprint of the transducer. The area is prepared with chlorhexidine and sterile ultrasound gel should be used. Once the target nerve is identified, a small gauge needle can be used to anesthetize the skin at the injection site.

The nerve block procedure may be performed with one or two operators. A single operator administering the injection on their own will use a syringe directly attached to the needle. During a two-operator technique, IV extension tubing is attached between the needle and the syringe; this allows the primary operator to have better manual control of the needle while the assistant performs the aspiration and injection once the needle tip is appropriately positioned (**Figs. 16A** and **B**). Higher volume blocks (>10 mL) may be more easily performed with two operators. Prior to starting the procedure, ensure that the block needle and tubing are primed with the anesthetic solution, as injection of air may interfere with ultrasound image quality or lead to complications.

In-plane versus Out-of-plane Approach

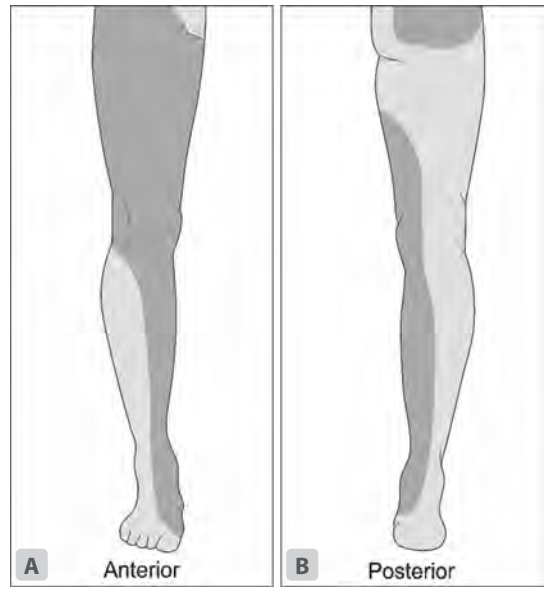
The nerve is visualized in its transverse axis and the nerve block procedure may be performed using either an in-plane (longitudinal) or out-of-plane (transverse) technique (**Figs. 17A** and **B**). An in-plane approach is generally preferred. Here, the needle is introduced under the lateral edge of the transducer, and the entire length of the needle is visualized as it approaches the target nerve. This makes the needle easier to track, and decreases the risk of injury to important soft tissue structures or puncture of the nerve itself. Use of a shallow angle may facilitate visualization of the needle. In an out-of-plane approach, the needle enters skin perpendicular to the long-axis of the transducer, and only a cross section of the needle (ideally the tip) is visualized. The out-of-plane approach is often more technically challenging. With either approach, to maximize block success and minimize complications, the operator should be aware of the position of the needle tip at all times. The needle should never be advanced if the position of the tip is uncertain. To localize the needle tip, the transducer can be tilted to scan through to the tip of the needle or rotated to better align with the trajectory of the needle. Alternatively, the needle can be withdrawn slightly to visualize tissue movement to confirm its position. Lastly, a small amount of anesthetic solution can be injected allowing identification of the needle tip at the collection of anechoic fluid. Techniques for specific blocks will be described subsequently in this chapter.

Postblock Care

The patient should remain on cardiorespiratory monitoring for at least 30 minutes following nerve block. Members of the healthcare team should be informed about the block, and

the extremity marked. Due to numbness and weakness of the blocked extremity, the patient must be cautioned to exercise care to avoid falls or injury to the extremity during the duration of nerve blockade.

Complications: Compartment syndrome, particularly after fractures, burns, or crush injury, is a feared but uncommon complication. There has been no evidence to date to suggest that nerve blocks have led to delayed diagnosis of a compartment syndrome. However, with high-risk injuries, discussion with the appropriate consulting services should take place prior to performing a nerve block. Nerve damage after a nerve block is also uncommon, and if it occurs, is usually transient or mild. The risk of nerve injury is higher if injection takes place within the epineural sheath, thus the operator should stop the injection if the resistance to injection of anesthetic solution is encountered, or if the patient reports painful paresthesia. These may suggest intraneural needle placement. A complete preblock sensory and motor examination should be performed and documented in the medical record. Local anesthetic systemic toxicity (LAST) is a rare but life-threatening complication caused by the sodium channel blockade of local anesthetic agents. The symptoms of LAST occur over a dose-dependent clinical spectrum, beginning with perioral numbness, lightheadedness, tinnitus, and audiovisual disturbances. This may progress to seizures, altered mental status, and coma, followed by dysrhythmias and cardiovascular collapse. The onset of LAST can take place within minutes if inadvertent intravascular injection occurs, or may be delayed up to 30 minutes as subcutaneous absorption takes place. For this reason, patients should be closely monitored for at least 30 minutes after the nerve block procedure. The treatment of LAST begins with supportive airway management, advanced cardiac life support (ACLS), and seizure suppression with benzodiazepines. For lidocaine toxicity, supportive management alone may be sufficient, given the shorter half-life of this drug. Lipid emulsion therapy may be required for bupivacaine or other agents with a relatively long half-life. Dosing of 20% lipid emulsion is a 1.5 mg/kg bolus followed by a 0.25 mL/kg/min infusion, continued until the patient is hemodynamically stable for 10 minutes. Prior to performing a nerve block, the operator must be aware of the availability and location of the lipid emulsion, and local protocols for administration. LAST is a devastating but avoidable compilation of nerve blocks. The operator must take care to calculate the maximum dose of anesthetic in advance of the procedure, use the lowest effective dose, and ensure aspiration before infiltration to avoid intravascular dosing.



FIGS. 18A AND B: Distribution of femoral block.

(FN: femoral nerve; FA: femoral artery; Dotted line: fascia iliaca)

FIG. 19: Ultrasound of femoral nerve.

Specific Blocks

Femoral Block Indications

The femoral block aims to anesthetize the femoral nerve (and may also block the obturator and lateral femoral cutaneous nerves) through anesthetic spread beneath the fascia iliac (**Figs. 18A** and **B**). It provides analgesia for hip fractures or dislocations, femoral shaft fractures, patellar fracture or dislocation, and anesthesia for anterior thigh or patellar laceration repairs or abscess drainage.

Anatomy and scan technique: The femoral nerve is a major branch of the lumbar plexus traveling with the femoral vessels under the inguinal ligament into the femoral triangle. To image the nerve, the patient should be in a supine position, with the hip externally rotated and abducted if possible. The transducer is placed parallel to the inguinal crease and the femoral artery and vein first identified. Slide laterally until the hypoechoic, triangular femoral nerve is visualized, deep to the fascia iliaca and immediately lateral to the femoral artery (**Fig. 19**).

The area is disinfected with chlorhexidine and the injection site should be anesthetized locally. The needle will enter the skin approximately 1-cm lateral to the ultrasound transducer, advancing medially toward the femoral nerve while maintaining visualization of the needle tip. Once the needle is below the fascia iliaca and approximately 1 cm from the nerve, aspirate to ensure the needle is not intravascularly positioned, then slowly inject 1–2 mL of local anesthetic to confirm appropriate needle placement. This will reduce the risk of intravascular injection and puncture of the nerve.

When the needle is correctly positioned, injection will result in displacement of the femoral nerve and fascia iliaca. If not, the needle should be repositioned. A total of 10–20 mL of anesthetic solution is adequate for femoral nerve blockade, though the operator should maintain awareness of the maximum weight-based dose for the patient.

Popliteal Sciatic Block Indications

The sciatic block is easily performed near the popliteal fossa and anesthetizes the lower leg distal to the knee, providing analgesia for tibia and fibular fractures, ankle fractures and dislocations, Achilles tendon ruptures, or foot injuries (**Figs. 20A** and **B**). If there is concern for compartment syndrome, this block should take place in consultation with the service that will have longitudinal care of the patient.

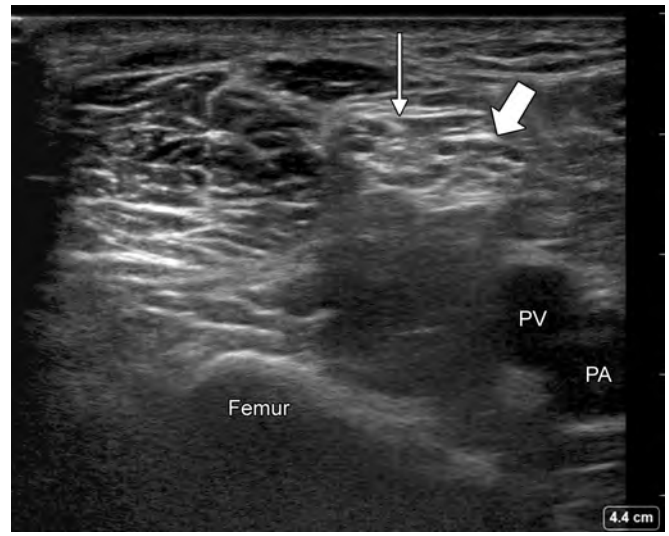
Anatomy and scan technique: The sciatic nerve is formed by the lumbosacral plexus, traverses the posterior thigh. It bifurcates into the common peroneal nerve (medial) and tibial nerve (lateral) just before entering the popliteal fossa. To image the nerve, the patient should be placed in a prone position; if this is not achievable, the patient may remain supine with leg elevated and supported with pillows/blankets to allow access to the popliteal fossa (**Fig. 21**). The knee should be mildly flexed if possible. The high-frequency linear transducer is placed at the popliteal crease, and the popliteal artery and vein are first identified. The hyperechoic and oval-shaped tibial nerve will be seen superficial and lateral to the popliteal vein; the common peroneal nerve will lie superficial and lateral to the tibial nerve. Slide the transducer proximally until the two nerves unite to form the distal sciatic nerve, usually 5–10 cm from the popliteal crease and at a depth of 2–4 cm.

The area is disinfected with chlorhexidine and the injection site should be anesthetized locally. Given the relatively superficial position of the nerve, needle entry should take place several centimeters from the probe in the lateral thigh, allowing for a shallow angle to enable visualization of the needle. The needle tip is slowly positioned just above and adjacent to the sciatic nerve where it begins to bifurcate within the common sciatic nerve sheath. Aspirate to ensure the needle is not intravascularly positioned, then slowly inject 1–2 mL of local anesthetic to confirm appropriate needle placement. Local anesthetic spread should be seen within the sheath around the nerve(s), both proximal and distal to the nerve division. A total of 15–20 mL of anesthetic solution will provide nerve blockade, though the operator should maintain awareness of the maximum weight-based dose for the patient.

Posterior Tibial Block Indications

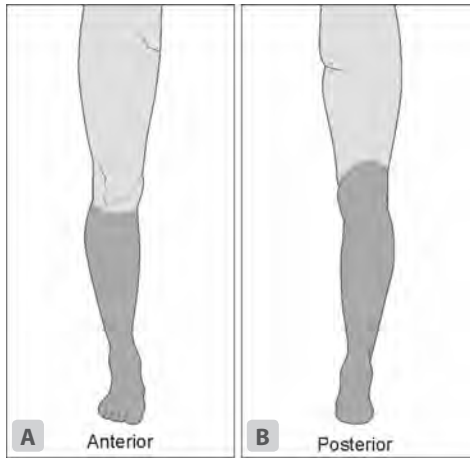
The posterior tibial nerve innervates the heel and sole of foot and provides analgesia for calcaneal fractures and anesthesia for repair of sole of foot lacerations and foreign body removal (**Fig. 22**).

Anatomy and scan technique: The posterior tibial nerve arises from the tibial branch of the sciatic nerve and is most easily visualized at the medial ankle. With the patient in a supine position and lower leg externally rotated, a high-frequency linear transducer is placed in a transverse orientation at the level of the medial malleolus. The nerve has a classic hyperechoic honeycomb appearance and can be identified just posterior to the posterior tibial artery. It may resemble nearby tendons including the tibialis posterior, flexor digitorum longus, and flexor hallucis longus. Of these structures, the posterior tibial



(Thick arrow: tibial nerve; Thin arrow: common peroneal nerve; PA: popliteal artery; PV: popliteal vein)

FIG. 21: Ultrasound of popliteal sciatic nerve.



FIGS. 20A AND B: Distribution of sciatic block.

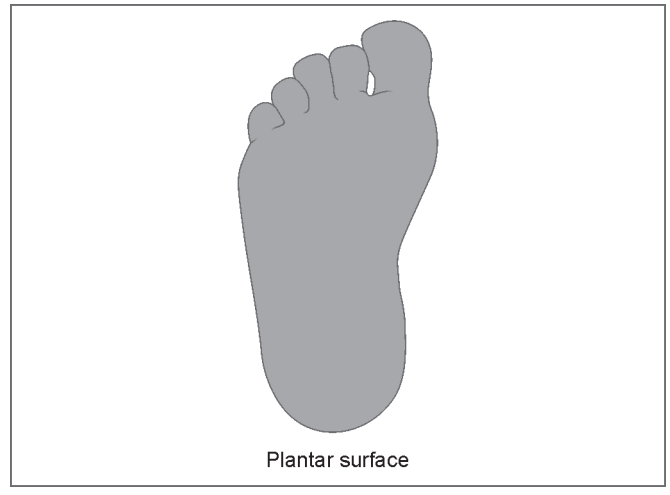


FIG. 22: Distribution of posterior tibial nerve block.

nerve is most intimately related to the artery, which can aid in its identification. To confirm, the transducer may be moved proximally—the nerve will maintain its appearance while tendons will transition into muscle (**Fig. 23**).

Procedure: As the posterior tibial nerve is superficially positioned, only a 1.5 inch 22- or 25-gauge needle is required. The area is disinfected with chlorhexidine and the injection site should be anesthetized locally. The needle is inserted just posterior to the medial malleolus and posterior tibial artery, directed posteriorly. Either an in-plane or out-of-plane technique may be used depending on patient positioning and ergonomics. Aspirate to ensure the needle is not intravascularly positioned. A total of 3–5 mL will be adequate for a successful block.

Interscalene Block of the Brachial Plexus Indications

The interscalene block anesthetizes cords of the brachial plexus to provide upper extremity analgesia and anesthesia for shoulder fractures and dislocations, clavicle fractures, humerus fractures, and elbow fractures and dislocations, forearm fractures, and upper extremity laceration repairs and drainage of large abscesses (**Fig. 24**). This is a more advanced nerve block due to nearby key structures (e.g., carotid artery, subclavian vessels, and pleura). In addition, this block is associated with phrenic nerve blockade leading to hemidiaphragmatic paralysis. Patients with acute or chronic respiratory disease may not be good candidates for this block. Furthermore, high volumes of anesthetic can spread to the sympathetic chain, leading to a transient Horner's syndrome.

Anatomy and scan technique: The brachial plexus originates from the ventral rami of C5-T1 and its cords can be found in the interscalene groove of the neck between the anterior and middle scalene muscles. Position should be optimized prior to the procedure with the patient supine with the head of bed elevated 30°, head turned away from the side being blocked, and a towel roll placed under the ipsilateral scapula (**Fig. 25**). The transducer is placed in a transverse orientation just below the level of the cricoid cartilage, and the carotid artery, IJ vein, and sternocleidomastoid muscle are identified. Slide laterally until the anterior and middle scalene muscles are seen, and the cords of the brachial plexus will be visualized in the groove between these two muscles as three large hypoechoic circles at 1–3 cm depth. They are frequently described as a "traffic light." Alternatively, the supraclavicular brachial plexus can first be identified above the clavicle and tracked superiorly to the interscalene groove. The goal is to place the needle tip in the tissue plane between the anterior and middle scalene muscles. Color Doppler may be used to confirm location of vascular structures.

The area is disinfected with chlorhexidine and the injection site should be anesthetized locally. The needle is inserted at a shallow angle approximately 1 cm from the transducer moving in a lateral to medial direction through the middle scalene muscle, choosing a plane that avoids puncture of the external jugular vein. Maintain visualization of the needle tip at all times. When the interscalene groove is reached, aim the needle tip between two nerve roots (to avoid nerve injury), aspirate to ensure the needle is not intravascularly positioned, then slowly inject 1–2 mL of local anesthetic to confirm appropriate

needle placement through visualization of spread of anechoic anesthetic solution. If no fluid is seen, there should be concern for intravascular injection. Furthermore, significant resistance to injection may suggest an intrafascicular injection. After appropriate needle placement is confirmed, a total of 10–20 mL of anesthetic may be injected and needle repositioning may be needed to facilitate spread around the brachial plexus.

Axillary Block Indications

This block anesthetizes the radial, median, ulnar, and musculocutaneous nerves for analgesia of the upper extremity from the mid-arm distally, and is named for the approach and not blockade of the axillary nerve itself (**Fig. 26**). This block has a lower risk of complications relative to the interscalene block. It may be performed for elbow, forearm, wrist and hand fractures, and dislocations. Although the individual nerves can be identified on ultrasound, this is required as the spread of local anesthetic to nerves around the axillary artery can produce an effective block.

Anatomy and scan technique: Three primary branches of the brachial plexus can be seen surrounding the axillary artery in a superficial location in the proximal arm—the median, ulnar, and radial nerves. The musculocutaneous nerve may also be found in this area in the plane between the coracobrachialis and biceps muscles. The arm is abducted to 90° to allow space for transducer and needle manipulation. The transducer is placed in a transverse orientation on the upper arm just distal to the pectoralis major insertion and overlying both the biceps and triceps muscle. The axillary artery will become apparent (**Fig. 27**). Local anesthetic solution will be infiltrated around the axillary artery and spread to the median, radial, and ulnar nerve, which may not always be well visualized.

The area is disinfected with chlorhexidine and the injection site should be anesthetized locally. Using an in-plane technique, the needle is inserted from anterior directed toward the posterior axillary artery. Anesthetic solution should be first injected posteriorly to the radial nerve. Starting with an anterior injection may displace deeper structures, making them more difficult to access. After the infiltration of approximately 5 mL of anesthetic, the needle is withdrawn and redirected medially and anteriorly to reach the median and ulnar nerves. An additional 5–10 mL of anesthetic will be required here. If the individual nerves are not well seen, a simplified perivascular approach may be used with injection of 5–10 mL of anesthetic solution posterior to the axillary artery. A separate injection is required to block the musculocutaneous nerve—the needle is again withdrawn and directed to this nerve, requiring 5–7 mL of solution. Given the number of needle redirections required for this procedure, frequent aspiration is required to prevent accidental intravascular injection.

SUMMARY

Ultrasound-guided vascular access is a common but essential procedure that may be lifesaving. The use of ultrasound guidance improves procedural success, decreases the number of attempts, and decreases complications—particularly for central venous access. While the procedure may be performed using in-plane and out-of-plane techniques, both require practice and mastery in visualizing the needle tip to assure safety and success.

Pericardiocentesis can be a lifesaving procedure in patients presenting with hemodynamic instability due to pericardial tamponade. Ultrasound allows identification of the largest fluid collection to identify an optimal approach and permits real-time visualization of needle position. The use of point-of-care ultrasound is a gold standard to aid in the diagnosis of tamponade, improve procedural success, and minimize procedural complications.

Ultrasound-guided nerve blocks are an important tool for ED clinicians to provide effective pain management for acute injury or procedural anesthesia that can avoid the complications of systemic opioid administration. Knowledge of sensory distribution key nerves, sonographic anatomy of nerves and surrounding structures, and the dosing and complications of local anesthetic agents will enable the clinician to maximize procedural safety and success.

56
CHAPTER

Cricothyrotomy

Sanjay Shah

INTRODUCTION

Cricothyrotomy also known as cricothyroidotomy is an emergency procedure that is used to secure an airway when routine methods, i.e., endotracheal intubation are failed or ineffective or contraindicated. Cricothyroidotomy is preferred over tracheostomy because it is easy to perform, is associated with less bleeding, and requires less time to perform. Cricothyroidotomy involves insertion of a needle or tube through the cricothyroid membrane into the trachea in an emergency situation to provide oxygen on a short-term basis until a definitive airway can be placed. Cricothyroidotomy can provide supplemental oxygenation temporarily so that one can get time to achieve definitive airway (intubation or tracheostomy) by expert.

APPLIED ANATOMY

Specific knowledge of anatomy of larynx is required for safe and successful performance of cricothyroidotomy. Ignorance of anatomy may lead to failure or complication. Identifying the cricothyroid membrane as shown in **Figure 1** or median cricothyroid ligament (situated between cricoid and thyroid cartilage) and its dissection is the main components of various type of cricothyroidotomy such as needle cricothyroidotomy, percutaneous cricothyroidotomy, or surgical cricothyroidotomy. Emergency physician must be aware about the anatomy related to cricothyroidotomy to avoid dreaded complication such as acute endolaryngeal hemorrhage. Cricothyroidotomy can be a lifesaving procedure in emergency department in case of difficult intubation. Various indications for performing the cricothyroidotomy are described further.

INDICATIONS

Cricothyroidotomy is indicated upon failure to obtain an airway with traditional methods in the following situations—various methods are described for performing the cricothyroidotomy and instruments are arranged according to the method used (**Box 1**).

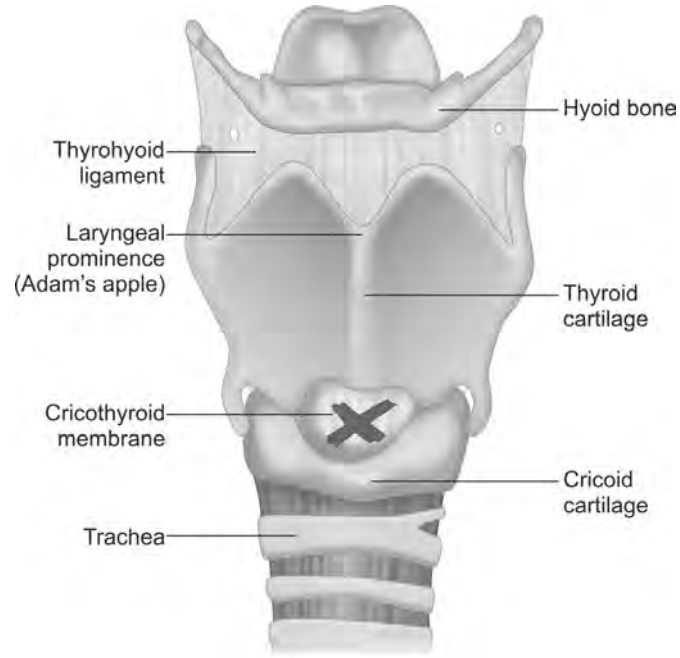

FIG. 1: Applied anatomy of larynx.

BOX 1: Requirements of instruments.

Antiseptic preparation: Antiseptic preparation solution lidocaine sterile drape/gown/gloves syringe (10 mL) bag-valve mask

For surgical cricothyroidotomy: No. 11 scalpel blade, trousseau dilator, tracheal hook, small size (4.5–6) tracheostomy tube, or endotracheal tube

For needle cricothyrotomy: Intravenous (IV) cannula catheter (14 gauge or larger), pediatric endotracheal tube or modified IV extension set for transtracheal jet insufflations (3-mm endotracheal tube adapter with a Y-connector)

For percutaneous cricothyrotomy: "Percutaneous cricothyroidotomy kit" for using the Seldinger technique, includes a finder needle with a dilator and a guidewire

- Trauma causing oral, pharyngeal, or nasal hemorrhage
- Facial muscle spasms or laryngospasm
- Uncontrollable emesis
- Upper airway stenosis or congenital deformities
- Clenched teeth
- Tumors, cancer, or another disease process or trauma causing mass effect

Airway obstruction indications include the following:

- Oropharyngeal edema
- Foreign body obstruction

The following are relative indications for cricothyroidotomy:

- Cervical spine immobilization secondary to injury
- Maxillofacial injuries

Cricothyroidotomy is contraindicated in younger patients with age of the patient <12 years, as the cricothyroid membrane is quite narrow resulting in an increased risk of permanent laryngeal injury. Other contraindications include obstruction distal to cricoid membrane, infection or lesion at site of incision, lack of expertise, history of neck surgery, hematoma, trauma/burns, and obesity which may make localization of landmark difficult.

POSITION OF THE PATIENT

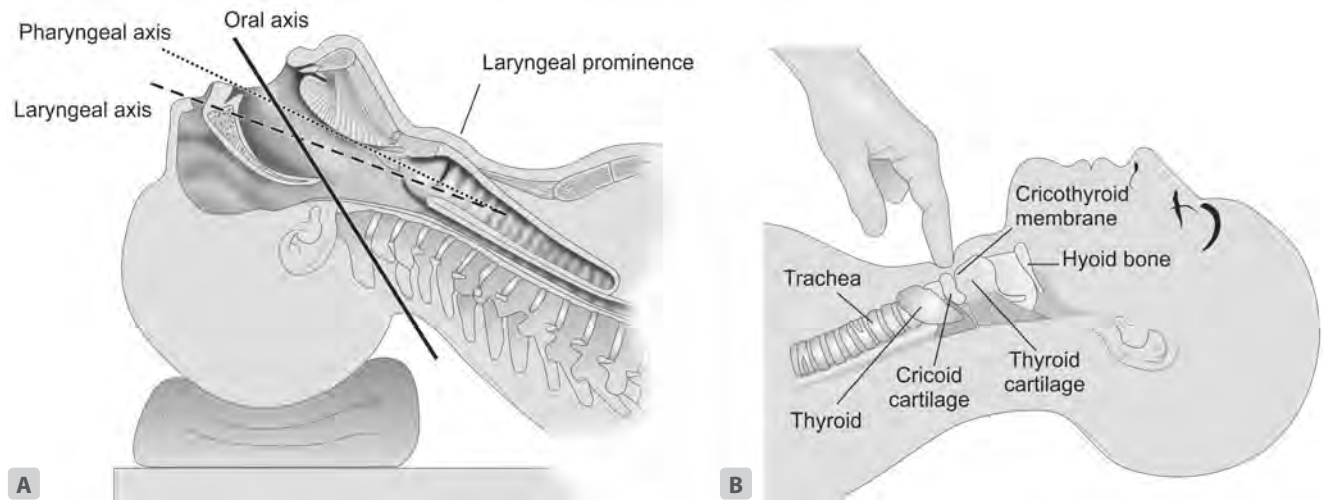
The patient should be placed supine with the neck in the neutral position. Position the patient in such a way that external anatomy or laryngeal prominence is exposed and palpate the cricothyroid membrane (**Figs. 2A** and **B**)

NEEDLE CRICOTHYROTOMY

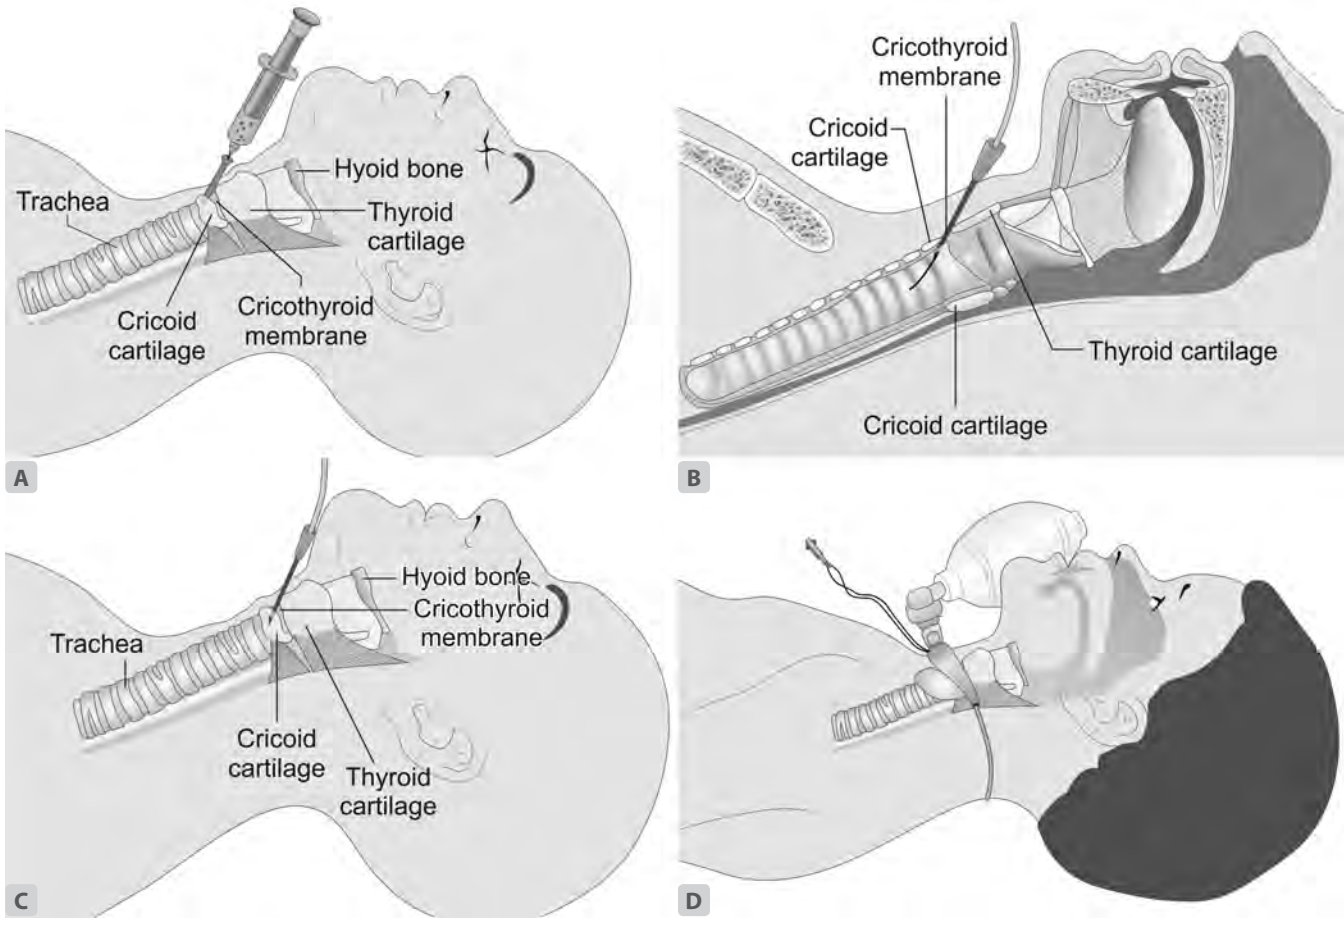
Under all aseptic precautions, proper painting and cleaning with antiseptic solution done over anterior aspect of neck with cervical spine immobilization. Thyroid and cricoid cartilage are palpated and stabilized using thumb and third finger of nondominant hand and cricothyroid membrane palpated with index finger. With the dominant hand, IV cannula catheter attached to the syringe filled with normal saline is inserted at a 45° angle in the caudal direction into the cricothyroid membrane (**Fig. 3A**). With continuous negative pressure applied to the syringe, the needle is advanced. As the needle pierces the cricothyroid membrane and enters the trachea, a distinct pop can be felt. In addition, air bubbles will appear in the syringe with saline (**Fig. 3B**). Catheter is advanced and the needle is pulled out (**Fig. 3C**). Catheter is attached with jet ventilation device, and ventilated at 40–50 lb psi or 15 L/min. If this device is unavailable, attach the barrel of a 3-mL syringe to the catheter, and place an endotracheal tube adapter. An Ambu bag can then be attached to deliver oxygen for ventilation (**Fig. 3D**). Placement is confirmed through observation of chest rise, auscultation, and assessment of end-tidal CO_2.

PERCUTANEOUS CRICOTHYROIDOTOMY (SELDINGER TECHNIQUE)

This is performed by using "cricothyroidotomy kit" (**Figs. 4A** and **B**) available commercially and by using a Seldinger technique. A finder needle attached to a syringe is substituted for the IV cannula catheter and steps of needle cricothyroidotomy are followed. Syringe is removed from the needle and the guidewire is advanced through the needle. The needle is removed once the guidewire is in place. A small stab incision is made using the scalpel in the skin close to the guidewire. Airway catheter along with dilator is inserted over the wire. The dilator and the guidewire both are removed once the airway tube is placed in the trachea. Placement is confirmed through observation of chest rise, auscultation, and assessment of end-tidal CO_2. The tube is secured in place with appropriate tape. The cannula is then connected to high-flow oxygen at 15 L/min (50–60 psi) with a Y-connector. Intermittent insufflation, 1 second on for inspiration and 4 seconds off for exhalation, should be done by placing the thumb over it. In this fashion, patient may be adequately ventilated for 30–45 minutes using this technique. Because of the inadequate exhalation, CO_2 slowly accumulates and thus limits the use of this technique for longer time, especially in head injury patients. Significant barotrauma can occur and may convert simple pneumothorax into tension pneumothorax. Therefore, careful and frequent monitoring must be done till definitive airway achieved either by intubation or tracheostomy.



FIGS. 2A AND B: (A) Positioning the patient to expose the laryngeal prominence; (B) Palpate laryngeal membrane.



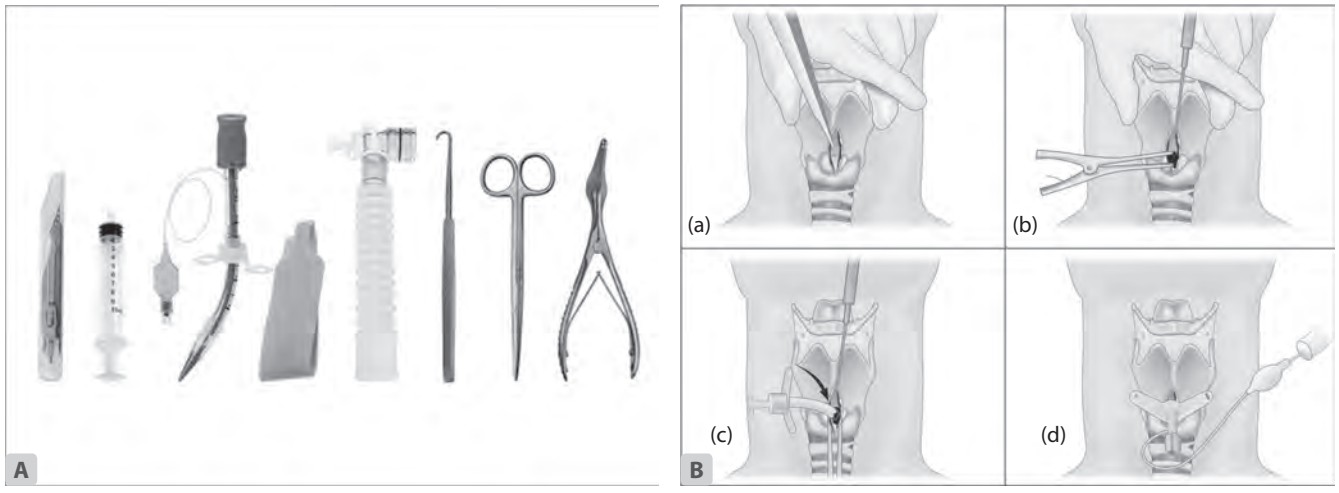
FIGS. 3A TO D: (A) Syringe attached with IV cannula is advanced; (B) Air bubble is seen in syringe; (C) Needle is pulled out and catheter is advanced; and (D) Attached with jet ventilation/Ambu.

FIGS. 4A AND B: Percutaneous cricothyroidotomy by "cricothyroidotomy kit."
Courtesy: Dr Amit D Nabar.

SURGICAL CRICOTHYROIDOTOMY

Requirements of instrument for surgical cricothyroidotomy are as per **Figure 5**.

Follow "step 2" from needle cricothyroidotomy. With the dominant hand, midline vertical incision is made, approximately 3 cm long and skin deep, over the cricothyroid membrane. The cricothyroid membrane is palpated through the incision, using the index finger of the nondominant hand. A horizontal stab incision is made through the membrane. A distinct pop will be felt as the scalpel pierces the membrane and enters the trachea. The tracheal hook is inserted by an



FIGS. 5A AND B: (A) Instruments for surgical cricothyroidotomy; (B) Steps of surgical cricothyroidotomy.

assistant at the superior end of the incision and the skin and membrane retracted cephalad. Using the Trousseau dilator, incision is dilated vertically. With the dominant hand, the tracheostomy tube is inserted between the two blades of the dilator, directing it initially to one side of the patient. Once the tube is through the membrane, it is rotated 90° and inserted caudally. The obturator is removed, and the inner cannula inserted and locked into place. The balloon is inflated with 5–10 mL of air. The tube attached to a catheter mount piece and attached to ventilatory support. Placement is confirmed through observation of chest rise, auscultation, and assessment of end-tidal CO_2. The tracheal hook is removed and the tube is secured in place.

COMPLICATIONS

Bleeding and misplacement of the tube are the most common complication related to cricothyroidotomy in emergency department, acute complications are incorrect placement of tube, subcutaneous emphysema, barotrauma, prolonged procedure time, and injury to surrounding structure. Complications are summarized in **Table 1**.

TABLE 1: Complications of cricothyroidotomy.

Early complications	*Late complications*
• Bleeding • Incorrect placement, resulting in possible creation of a false passage through tissue • Subcutaneous emphysema • Obstruction • Esophageal or mediastinal perforation • Aspiration • Vocal cord injury • Pneumothorax • Laryngeal injury • Posterior tracheal wall perforation • Thyroid perforation • Hypercarbia (needle cricothyroidotomy)	• Dysphonia • Infections • Hematoma • Persistent stoma • Scarring • Glottic or subglottic stenosis • Laryngeal stenosis • Tracheoesophageal fistula • Tracheomalacia

57 CHAPTER

Tracheostomy Related Emergencies

Devendra Richhariya, Bhawana Sharma

INTRODUCTION

Tracheostomies are associated with complication in about 40–50% cases but majority of these complications are minor and in only 1% of tracheostomy patients, catastrophic complication occurs. That's why important for the emergency physician to recognize the signs and symptoms of tracheostomy-related emergencies and provide initial stabilization and, potentially, life-saving interventions. Tracheostomy is performed in upper airway obstruction, control of secretions, possibilities for long-term airway protection and or long-term ventilation, severe obstructive sleep apnea, and head and neck surgery. Percutaneous dilatational approach or open surgical approach are used to place tracheostomies, opening is created into the trachea through the anterior neck where the tracheal mucosa and brought into continuity with the skin, tracheostomies are placed between the second and third tracheal rings. Higher incisions increase the risk of laryngeal injury and lower incisions increase the risk of decannulation and vessel injury. Both two techniques have similar complications rate.

Tracheostomy-related complications can be divided in to three categories. (1) First intraoperative complications, including hemorrhage, air embolism, and damage to the trachea, (2) second intermediate (early postoperative) complications include hemorrhage, tube decannulation, extratracheal air (subcutaneous emphysema, pneumothorax, and pneumomediastinum), and infection and third Late (3) postoperative complications include hemorrhage, tracheal stenosis, tube decannulation, and fistula formation.

For the emergency management purpose, tracheostomy complications can be grouped into emergent life-threatening complications and urgent complications. Emergent life-threatening complications include tube decannulation, tube obstruction, and hemorrhage. Urgent subacute complications include tracheoesophageal fistula (TEF) formation, tracheal stenosis, infection, and tracheocutaneous fistula formation. Comorbid conditions must be considered when making management decisions.

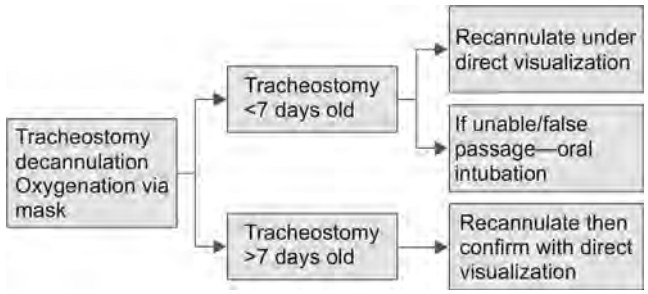
EMERGENT LIFE-THREATENING COMPLICATIONS

Tracheostomy Decannulation

Following tracheostomy placement, tracheostomy tube decannulation can occur at any time. The incidence of tracheostomy displacement varies between 0.35% and 15%. Often decannulations may be handled by the patient or caregiver without any further clinical care, so the incidence may be higher than reported. Lack of mature stoma formation and a narrower tracheocutaneous tract, within the first week of placement, decannulations are most concerning because this increases the risk of airway loss. Accidental decannulation of tracheostomy risk increases in conditions where altered mental status, traumatic brain injury, copious secretions, recent tracheostomy change, increased neck thickness, and pediatric age. Decannulation is reported more in percutaneously placed tracheostomies rather than those placed using an open surgical approach.

Emergency department (ED) management of displaced tracheostomy: When a patient presents to the ED with a displaced tracheostomy tube, two major information must be obtained through history taking. First, time of the tracheostomy placement, and second, time of decannulation of tracheostomy. On examination, possibilities of two variety of presentation, patient may present with the completely displaced tracheostomy from the stoma or partially displaced with the tracheostomy tip present in the soft tissue of the neck.

Action: Replacement of tube is indicated without delay is indicated when decannulation occurs, Stoma (opening) may significantly become narrow in few hours' time even if it is a mature stoma, delayed recannulation makes procedure more challenging and necessitating the use of a smaller tracheostomy tube during replacement. If history of placement of tracheostomy tube is <7 days, replacement of a dislodged tracheostomy is attempted only under direct



FLOWCHART 1: Management of tracheostomy decannulation.

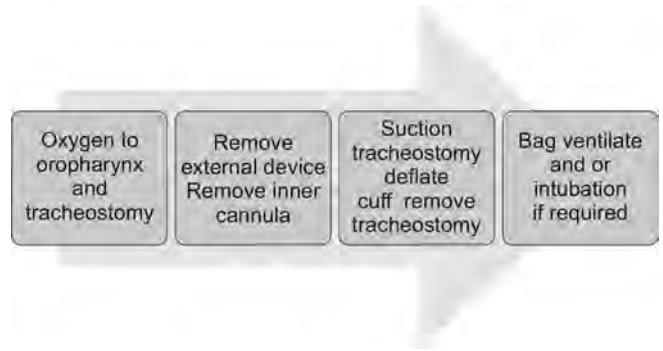


FIG. 1: Management of tracheostomy occlusion.

visualization of fiberoptic endoscopy because risk of creating a false passage into the soft tissue of the neck is very high. If fiberoptic visualization is unavailable or procedure is unsuccessful, oral intubation may be necessary to secure the airway and ventilate the patient (**Flowchart 1**). If history of tracheostomies placement is >7 days, if dislodgement occurs, a new tracheostomy tube is inserted through the stoma and confirmed by fiberoptic visualization. If any resistance is met while inserting the tube, a smaller tracheostomy tube should be selected and insertion reattempted. During unsuccessful procedure of recannulation, and patient fails to oxygenate or ventilate, bag-valve ventilation and oral intubation may be necessary.

Following recannulation, low-volume, gentle bag-valve ventilation can be used to assist ventilation. If subcutaneous emphysema develops, tracheostomy placement must be evaluated through direct visualization due to possible false passage with placement of the tracheostomy tube into the paratracheal soft tissue of the neck. If proper placement is confirmed, the trachea must be subsequently evaluated for injury. Continuous capnometry is used to monitor ventilation during and after recannulation.

Tracheostomy Obstruction

Dried secretions, mucous plugs, clotted blood, partial tube displacement, impingement by the posterior tracheal wall, granulation tissue build up, or displacement of the tracheostomy into a false lumen is the common causes for obstruction of the lumen of a tracheostomy tube. Other risk factors for obstruction include small tracheostomy tube size, single cannula tracheostomy tube, and poor tracheostomy care. Pediatric patients are more at risk for tracheostomy related death. Stepwise approach is required for management of tracheotomy obstruction (**Fig. 1**). An initial simple step is to remove any obstructing material from the external end of the tracheostomy lumen, such as a speaking valve, obturator, decannulation cap, bandages, or humidifying devices. Inner cannula is removed from the double-cannula tracheostomy and suctioning is performed when obstruction is suspected and will relieve most obstructions. Complete obstruction is ruled out if a suction catheter can be passed through the entire length of the tracheostomy till trachea. If a suction catheter cannot be passed, a complete obstruction of the tracheostomy tube is present. Stiff instruments, such as gum-elastic bougies should not be used to assess the patency because they can create a false passage. To improve ventilation and oxygenation patient's assisted with positive pressure ventilation, if necessary. The cuff should also be deflated so that airflow enters from surrounding of tracheostomy tube because flow through the tracheostomy tube lumen is obstructed.

If a new tracheostomy is placed, the balloon is inflated to provide effective positive pressure ventilation. If even after all these measures, patient continues to be distressed from airway obstruction, the tracheostomy tube should be removed and provides high-flow oxygen via both face and tracheostomy stoma and monitored by capnometry, and not necessary to reinsert the tube urgently. The patient with tracheostomy stoma has two airway openings (tracheostomy and oronasopharynx). If the patient is ventilated via the mouth, the tracheal stoma must be occluded with gauze (**Fig. 2A**). If the patient is ventilated via the tracheal stoma, the oral, and nasal pharynx must be occluded. A pediatric face mask or laryngeal-mask airway can be placed over the stoma to generate airway positive pressure when ventilating (**Fig. 2B**). Intubation should be attempted if oxygenation is not maintained by bag-valve ventilation. Endotracheal tube must be advanced beyond the stoma to generate positive pressure in the lower airway after the balloon is inflated. Fiberoptic scope or bougie-guided intubation of the stoma can be attempted if the tracheostomy is more than a week old. A smaller tracheostomy tube or endotracheal tube can be placed directly into the stoma, if oral intubation is anticipated to be difficult. Once the obstruction is partially or completely relieved, the patient's ventilation should be monitored with continuous capnometry and pulse oximetry and assisted with positive pressure ventilation as per clinical situation.

Hemorrhage

Minor to life-threatening tracheostomy bleeding complicates up to 5% of tracheostomies. Bleeding within the first 48 hours after placement is usually related to operative issues, including inadvertent vein puncture, suctioning, and infection. Beyond 48 hours, development of a tracheoinnominate artery fistula (TIAF), most critical and feared hemorrhagic complication. TIAF is a direct connection between the native trachea and the innominate artery branch of the aorta. The innominate artery crosses anterior to the trachea, typically at the level of the ninth tracheal ring; however, there is significant anatomic variation and the innominate artery may cross the trachea superior enough to be anterior to a tracheostomy tube.

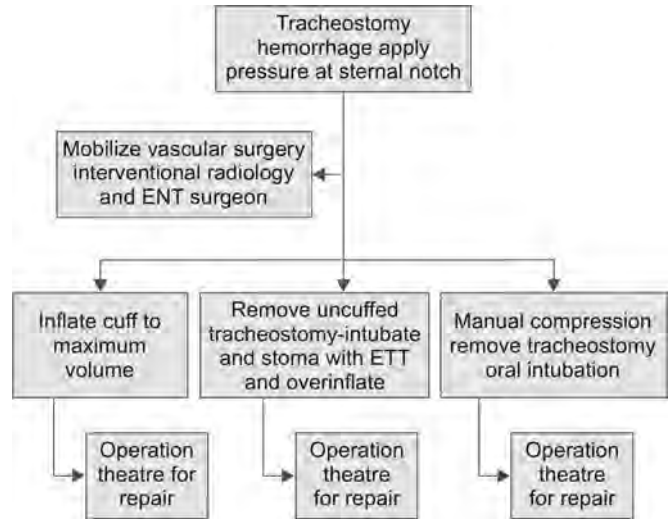
The incidence of TIAF is approximately 0.7% of patients with tracheostomy and the mortality is >90%. Around >70% of TIAF bleeds occurs within 3 weeks of tracheostomy placement but may occur at any time in the form of hemoptysis, or blood seen

FIGS. 2A AND B: (A) Occluding the tracheostomy opening to facilitate bag valve mask (BVM); (B) ventilating through opening with pediatric BVM.

with tracheal suctioning therefore, any hemorrhage occurring within 3 weeks of tracheostomy placement, must be considered a TIAF bleed until proven otherwise. Diagnostic options helpful in evaluation include bronchoscopy, computed tomography or traditional angiography, or local exploration. Risk factors for TIAF include a cuffed tracheostomy tube, low tracheostomy placement, high cuff pressure, high riding innominate artery, excessive neck movement, and tracheostomy infection.

Tracheoinnominate artery fistula should be suspected if catastrophic tracheostomy bleeding occurs and immediate resuscitative measures should be applied to minimize the bleeding and till operative repair is arranged (**Flowchart 2**). External compression of the innominate artery by applying pressure posteriorly at the sternal notch, and internal compression through over inflation of the tracheostomy balloon with up to 50 mL of air is the initial intervention. These interventions are successful in minimizing the bleeding in 85% of the time.

If these measures have failed to control the bleeding, the tracheostomy tube should be removed and endotracheal tube should be placed whose cuff is overinflated with up to 50 mL of air. If this also proves to be unsuccessful, an oral endotracheal tube can be advanced beyond the stoma to secure the airway with the addition of a finger inserted into the tracheostomy for digital compression of the innominate artery anteriorly against the manubrium. Digital compression must be maintained until definitive repair is undertaken. These measures are applied in an attempt to decrease the amount of blood loss while getting the patient to the operating room or interventional radiology suite for definitive management.



Tracheostomy hemorrhage apply pressure at sternal notch
Mobilize vascular surgery interventional radiology and ENT surgeon
Inflate cuff to maximum volume
Remove uncuffed tracheostomy-intubate and stoma with ETT and overinflate
Manual compression remove tracheostomy oral intubation
Operation theatre for repair
Operation theatre for repair
Operation theatre for repair

FLOWCHART 2: Management of tracheostomy hemorrhage.

URGENT COMPLICATIONS

Tracheoesophageal Fistula

A TEF is a communication between the posterior wall of the trachea and the anterior wall of the esophagus. Tracheostomy balloon causes prolonged pressure on the posterior membranous wall of the trachea results in ischemic necrosis, tissue breakdown, and subsequent fistula formation. Risk factors include high airway pressures, prolonged presence of a cuffed tracheostomy tube, high cuff pressures, excessive tracheostomy movement, steroid use, type 1 diabetes mellitus chronic hypoxia, poor nutritional status, hypotension, anemia, sepsis, the presence of a nasogastric tube, and gastroesophageal reflux disease (GERD).

Manifestations of TEFs are persistent tracheal air leaks, abdominal distention, pulmonary aspiration injury, cough with swallowing, copious bronchopulmonary secretions, and respiratory distress. In patients with tracheostomy, the TEF is generally located 1–2 cm distal to the tracheal stoma at the level of the balloon and can be large, measuring 4–5 cm. Diagnosis is made by bronchoscopy or, if not available, esophagogram.

Emergency department management includes discontinuation of oral feeding, and elevation of the patient's head to 45 and stop contamination of the airway through tracheal suctioning. Drain the gastric contents of the stomach through gastric tube if present, and it should be removed to prevent pressure necrosis and worsening of the fistula. Any other complications, such as pneumonia, should be treated. Long-term conservative management includes placing of the

tracheostomy balloon to a more distal position and nutrition via jejunostomy tube, minimally invasive treatment includes tracheal and esophageal stents, or surgery.

Tracheal Stenosis

Most patients experiencing some degree of tracheal narrowing after prolonged intubation or tracheostomy, only 3–12% of cases of tracheal stenosis require any intervention and very few requiring urgent intervention. Various risk factors are identified related to tracheal stenosis, one of them is formation of granulation tissue and fibrosis of peristomal and tracheal tissues. Trauma during procedure itself or ischemia from balloon over inflation leads to tracheal inflammation and ulceration. Other risk factors include surgical site infection, GERD, obesity, and hypotension. Tracheal stenosis frequently occurs at the site of the stoma, the level of the tracheostomy tube tip, the site of the balloon, or in a suprastomal position. Stenosis will not cause symptoms until the diameter of the tracheal lumen is reduced by >50%. Early symptoms include difficulty clearing secretions, cough, and exertional dyspnea. Dyspnea at rest and stridor are associated with a tracheal diameter of 5 mm. Tracheal stenosis can occur while a patient is still mechanically ventilated or years after decannulation, but most will present within 2 months of decannulation. Stenosis can make tube exchanges difficult due to narrowing of the space and bleeding risk. Early stenosis with exposed granulation tissue without overlying epithelium can bleed easily with minor trauma. Stenosis can be treated with dilation, excision with end-to-end anastomosis, or laser excision of granulation or fibrous tissues.

Infection

Patients are at risk of surgical site infection because of rich environment of blood and secretions at the surgical site place. Bacterial colonization of the skin and aerodigestive tract gives rise to common early infections such as cellulitis and tracheitis. Strict wound care with frequent dressing changes is the cornerstone of preventing infection after tracheostomy.

These infections are minor and more commonly observed after open tracheostomy but severe infections, including mediastinitis and necrotizing fasciitis, are possible. Presentations of serious infections osteomyelitis and septic arthritis of the sternoclavicular joint present late.

The presence of a cuffed tracheostomy tube disrupts swallowing, and increases the risk of aspiration while overinflated tube cuff can compress the esophagus, leading to aspiration. This aspiration is often asymptomatic or silent and therefore unrecognized by patients and caregivers. Aspiration of infected secretions can result in pneumonia or lung abscesses. These infections are most commonly attributed to *Staphylococcus aureus*, *Pseudomonas*, and mixed flora. Pneumonias and severe skin and soft tissue infections should be treated aggressively. Despite the frequency of infectious complications, the role of perioperative antibiotics in tracheostomy remains controversial.

Cutaneous Fistula

After decannulation, most stomas close in approximately 6 weeks. Persistent epithelialization of the stoma track can result in fistula formation. If the stoma persists after 3–6 months, a tracheocutaneous fistula is diagnosed. Persistent tracheocutaneous fistulas can lead to skin irritation and infection due to draining secretions, weak cough, and aspiration leading to recurrent pneumonias, poor phonation, poor cosmesis, and submersion intolerance. The most notable risk factor is prolonged tracheostomy tube placement with one small series noting tracheostomy placement for at least a year in all observed cases. Other risk factors include steroid use, advanced age, and malnutrition. Management options include tract cauterization or excision with healing by secondary intention or surgical closure.

MYIASIS (MAGGOTS) OF TRACHEOSTOMY WOUND

Myiasis is caused by dipterous larvae (maggots) a parasitic infestation of live human tissues (vertebrate animal) or cavities. Myiasis is the disease in which dipterous larvae invade organs and tissue, make them necrotic and then leave the necrotic tissue for viable tissue, causing extension of the lesion by local tissue destruction.

- *Causative agents*: Myiasis is caused by dipterous larvae which can be classified into two groups, (1) obligate parasites, specifically producers of myiasis, can develop only on live hosts and (2) facultative parasites, their larvae feed primarily on cadavers or vegetables, but can sporadically infest human or animal tissues.
- *Risk factors*: Human myiasis is extremely rare in western countries but Maggot infestation in tracheostomy wound is quite rare even in tropical country such as India. Myiasis is common in natural orifices such as ear, nose, and oral cavity, but myiasis of tracheostomy wound site is a very rare entity. Most important risk factors for the development of myiasis of tracheostomy wound are poor hygiene. Underdeveloped countries where malnutrition and unsanitary condition are common in people are more vulnerable to disease such as myiasis. Myiasis is also frequent in elderly and abandoned individuals, and mental institutions presenting poor hygiene habits.
- *Pathogenesis*: The eggs are deposited by the female flies over the unbroken suppurating lesions or open wounds. Depending on the number of viable eggs that are actually deposited by the female fly, the same number of larvae hatches and grows in any lesion. Upon hatching, the maggots with their sharp mouth hooks penetrate deep into tissue and cause necrosis of the tissue. With the mechanism of the progressive necrosis, larvae invade the deeper tissue until a cavernous lesion is formed, while the larvae aggregate and remain active. The cavernous lesion is characterized by tense and edematous surrounding tissue with pungent odor. The vital tissues can be damaged by larvae and they can cause life-threatening hemorrhage. The severity of the lesion depends on the time interval from the onset of infection and the diagnosis of the lesion. This is very important to diagnose and identify the condition in early stage with a smaller number of larvae, crucial for limited tissue damage. But if the lesion is presented at later stage or delayed, it will result in greater number of larvae with extensive tissue necrosis.
- *Treatment*: Mechanical removal of the larvae is the traditional treatment of myiasis. Antilarval measures include use of turpentine oil or mixture of turpentine oil and chloroform followed by removal of the larvae. But

also use of topical and systemic antibiotic as coadjuvants in the treatment improves the favorability of prognosis in severe cases. Clearing the maggots with ether meticulously, tracheostomy care and treatment of underlying disease is very vital. To classify the generic group, it is also important to send the larvae for culture. Keep in mind that with proper care, the condition can be controlled and cured. Special care at home as well as at hospital is required for tracheostomy wound site. Patient should be educated about proper tracheostomy care, regular cleaning habits and keeping the area covered are helpful in preventing of this problem.

Emergency physician should be aware of proper knowledge of the surrounding airway and disease process which is essential to treat such a case. Regular sterile dressing, proper nutrition, and through understanding of the importance of wound management by the patient and patient party helpful in preventing this condition.

Stepwise Approach for Tracheostomy Wound Myiasis

- *Step 1*: The wound site should be cleaned carefully using 10% povidone-iodine solution. Flushing is not done in uncuffed tracheostomy tube could not be changed to cuff due to chance of aspiration of infiltrating maggots surrounding the tracheostomy tube.
- *Step 2*: Normal saline soaked sterile gauge piece is wrapped around the tracheostomy tube to prevent maggot movement toward trachea thus reducing chance of maggot aspiration.
- *Step 3*: Careful apply the turpentine oil. The maggots will crawl toward the skin (the turpentine oil creates an anaerobic atmosphere for larvae forcing them to crawl out).
- *Step 4*: The maggots should be removed using nontoothed forceps carefully. The maggots should place in bowl containing ether solution.
- *Step 5*: The tracheostomy wound is then covered with povidone iodine-soaked gauge piece. The patient should be admitted, regular dressing is done maintaining the above mentioned five steps.
- *Step 6*: The patient should be discharged with counseling regarding importance of proper and regular tracheostomy tube care.

Prevention

Myiasis can be prevented by practicing good personal hygiene, primary care of wound, controlling fly population, and maintenance of sanitation of the surroundings. Apart from these, patient's relatives should be educated about the postoperative care, by teaching them the dressing and wound care and the importance of it, so that such manifestation of larvae could be prevented. Any symptoms relating to infestation should be reported to the hospital as the earliest, so that the lesion can be treated with minimal tissue damage rather than extensive necrosis when presenting at later stage.

SUMMARY

The emergency provider must be prepared to deal with both catastrophic and urgent tracheostomy-related emergencies. Life-threatening complications, including accidental decannulation, obstruction, and hemorrhage, are rare but require immediate action. Having a predetermined, stepwise approach to these complications will help guide management when such patients arrive in the ED. Subacute complications, such as TEF formation, tracheal stenosis, infection, and cutaneous fistula formation, may occur at any time, ranging from the postoperative period to years after a tracheostomy was placed or even following decannulation. The emergency provider must maintain a high index of suspicion for a tracheostomy-related complication when a patient with a present or prior tracheostomy presents with fever, dyspnea, or hemoptysis.

58
CHAPTER

Chest Pain Evaluation in Emergency Department

Devendra Richhariya

INTRODUCTION

Acute chest pain is one of the most common reasons for emergency hospital visits accounting for approximately 8 million visits per annum in the United States. The main difficulty arises in differentiating the acute coronary syndrome (ACS) patients and other life-threatening causes of chest pain with other nonlife-threatening noncardiovascular causes of chest pain. It has been seen that the mortality rates increase by two-fold in acute myocardial infarction patients which were discharged prematurely from the hospital as compared to those admitted. Also, in patients with low risk of complications the cost of further investigations and hospital admission needs to be weighed apart from the small risk associated with the diagnostic procedures.

Recent advances in the medical field have improved the accuracy and efficiency in the evaluation of patients with chest pain. Development of new cardiac biomarkers (acute MI), radionuclide studies for low-risk patients, multislice CT scan for coronary artery disease (CAD), pulmonary embolism, and aortic dissection has improved the management of these patients. Also, the setting of chest pain units and pain pathways for evaluating the low-risk patients helps in the better outcome of the patients.

CAUSES OF CHEST PAIN

The causes of chest pain vary from life-threatening conditions needing urgent medical care to those that are relatively benign and nonlife-threatening (**Table 1**). Studies have shown that approximately one-third to one-half of patients have musculoskeletal chest pain, 10–20% have a gastrointestinal cause, 10% have stable angina, 5% have respiratory conditions, and approximately 2–4% have acute myocardial ischemia (including myocardial infarction).

Cardiac Causes

Myocardial Ischemia

Angina pectoris is defined as chest pain attributable to myocardial ischemia. Symptoms in chronic stable angina include heaviness, tightness, or constriction in the center or left side of the chest which gets precipitated on exertion and relieved by rest. Chest pain due myocardial ischemia can also be experienced in other locations also as shown in **Figure 1**. Other associated symptoms include provocation with emotional stress or cold and radiating to the neck, jaw, and shoulder. Sometimes patient does not present with classical angina but angina like symptoms such as dyspnea, nausea and vomiting, diaphoresis, presyncope, or palpitations. These set of patients are mostly women, diabetics and elderly population. Differentiating features of cardiac (ischemic) and noncardiac (nonischemic) pain are summarized in **Table 2**.

Patients presenting with ACS (myocardial infarction and unstable angina) have anginal symptoms at rest, or new onset angina that is more frequent, prolonged in duration and occurs with less exertion. These patients should be referred

TABLE 1: Common, life-threatening and nonlife-threatening causes of chest pain.

Common causes of chest pain	*Life-threatening causes*	*Nonlife-threatening causes*
• *Cardiac*: Coronary artery disease aortic valve disease, mitral valve disease, pericarditis, and pulmonary hypertension aortic stenosis • *Vascular*: Aortic dissection aortic aneurysm • *Pulmonary*: Pulmonary embolism, pneumothorax, and pneumonia pleuritis • *Musculoskeletal*: Costochondritis arthritis and muscular spasm • *Gastrointestinal*: Peptic ulcer disease, bowel diseases, cholecystitis pancreatitis, hiatus hernia	• *Acute coronary syndromes* • *Pulmonary embolism* • *Aortic dissection* • *Myocarditis* (most common cause of sudden death in the young) • *Tension pneumothorax* • *Acute chest syndrome* (in sickle cell disease) • *Pericarditis* • *Boerhaave's syndrome* (perforated esophagus)	• *Gastrointestinal*: Biliary colic, gastroesophageal reflux, peptic ulcer disease • *Pulmonary*: Pneumonia, pleurisy chest wall syndromes • *Musculoskeletal pain*: Costochondritis, thoracic radiculopathy • *Psychiatric*: Anxiety Shingles

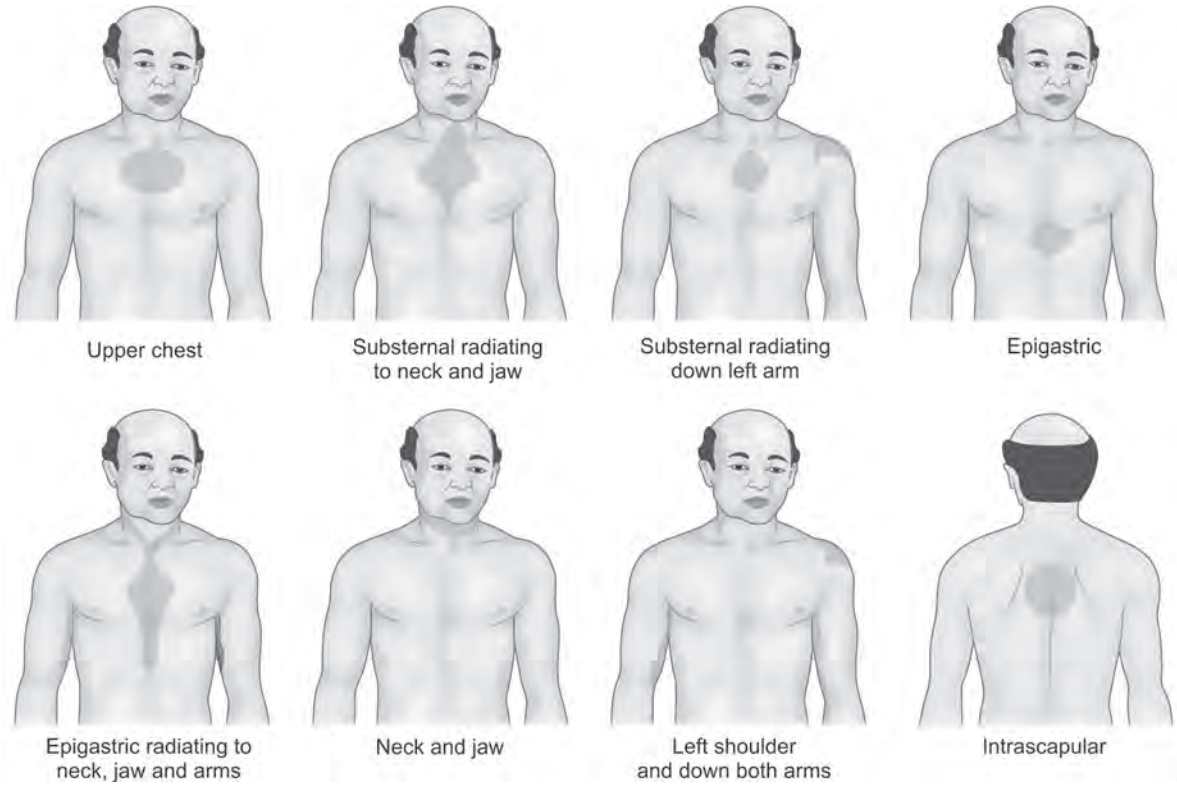

FIG. 1: Various locations of the pain induced by myocardial ischemia.

TABLE 2: Differentiating features of cardiac and noncardiac pain.

Cardiac (myocardial ischemia—coronary occlusion)	***Noncardiac chest pain***
• *Pain*: Severe, sudden onset, substernal, crushing, tightness, radiate to shoulder neck, back jaw, and arm may not relieve by nitroglycerin • *Associated features*: Dyspnea syncope tachycardia diaphoresis, extreme weakness nausea vomiting	• *Pain*: peripherally, localized, nonradiating, sharp, or stabbing may be provoked by posture respiration and palpitation • *Associated features*: Respiratory gastrointestinal or psychological features

to an emergency department and managed on a priority basis. Coronary heart disease is the most common cause of myocardial ischemia. Other less common causes include coronary dissection and vasospastic angina (Prinzmetal's angina).

Nonischemic Cardiac Causes of Chest Pain

- *Aortic dissection*: This condition is rare but a true surgical emergency needing immediate care. Typical symptoms include acute onset of chest and back pain that is severe, sharp, and tearing in nature radiating anywhere to the chest or into the abdomen.
- *Heart failure*: Patients with heart failure may present with chest discomfort, usually associated with dyspnea, orthopnea, cough, and peripheral edema.
- *Pericarditis*: Acute pericarditis refers to inflammation of the pericardium due to variety of causes. Patients often complain of pleuritic chest pain increasing on deep inspiration and relieved by sitting up and leaning forward. It is diagnosed based on history, physical examination, and electrocardiogram (ECG) findings. Etiologies include infections, drugs, autoimmune disorders, and malignancy.
- *Stress cardiomyopathy*: Stress (takotsubo) cardiomyopathy or apical ballooning syndrome occurs in the setting of physical or emotional stress or critical illness. Its clinical presentation is similar to that of acute myocardial infarction and needs to be suspected in patients with no traditional risk factors for CAD and classical echo findings.
- *Mitral valve disease*: Patients with mitral stenosis uncommonly experience chest pain or heaviness. This is most often due to pulmonary arterial hypertension and right ventricular hypertrophy seen in these patients. Patients with mitral valve prolapse may also experience chest pain, is usually mild, but often troubling.

Pulmonary Causes

Life-threatening pulmonary causes of chest pain include pulmonary embolism and tension pneumothorax.

- *Pulmonary embolism*: The most common symptoms of pulmonary embolism include dyspnea, pleuritic chest pain, cough, and sometimes hemoptysis. Often patients may have symptoms of deep venous thrombosis. Most common sign is sinus tachycardia. A high index of suspicion should be kept in mind while considering this diagnosis as it can be life-threatening if left undiagnosed. So past history of major surgery, malignancy, prolonged hospitalization, and immobilization should be enquired into.

- *Pneumothorax*: Patients with spontaneous pneumothorax present with sudden onset of pleuritic chest pain and dyspnea. A diagnosis of tension pneumothorax is considered if the patient is hemodynamically unstable. Primary spontaneous pneumothorax is usually seen in young, tall, and thin individuals with no underlying lung disease. A secondary spontaneous pneumothorax occurs as a complication of underlying lung disease [e.g., chronic obstructive pulmonary disease (COPD)].
- *Pneumonia*: Patients may have chest pain, often pleuritic but associated with fever and productive cough.
- *Malignancy*: Patients may complain of chest pain, typically on the same side as the primary tumor. Other symptoms include cough, hemoptysis, dyspnea, and weight loss.
- *Pulmonary hypertension*: Patients with pulmonary hypertension may have chest pain on exertion in addition to exertional dyspnea and syncope.

Gastrointestinal

- *Esophageal rupture/perforation*: Spontaneous rupture of esophagus (Boerhaave's syndrome) may results from a sudden increase in intra esophageal pressure usually seen after vomiting.
- *Gastroesophageal reflux disease (GERD)*: It is the most common clinical condition mimicking angina pectoris. Sometimes patients may describe it as squeezing or burning pain, radiating to the back, neck, jaw, or arms. Pain can last for minutes to hours, and resolves spontaneously or with antacids. It may be seen after meals, during sleep.
- *Esophagitis*: Patients with esophagitis may present with sudden onset retrosternal chest pain. It may be associated with odynophagia. It can be due to candidiasis, cytomegalovirus (in HIV-AIDS), or radiation injury.
- *Others*: Hiatus hernias may cause chest pain in addition to symptoms of reflux. Esophageal motility disorders/esophageal spasm generally manifests with dysphagia, but sometimes patients may complain of chest pain.

Musculoskeletal

Commonly seen in patients who present to the primary care physician with chest pain.

- *Isolated musculoskeletal chest pain syndrome*: Patients usually have local or regional chest wall tenderness without any other symptom. The most common causes are costochondritis and lower rib pain syndromes.
- *Rib pain*: Rib fractures are associated with pleuritic chest pain that is localized and reproducible with palpation. Patients often describe an associated injury/trauma, though some may occur without trauma. Other systemic disorders such as osteoporosis, metastasis, and infarction from sickle cell anemia can also cause acute rib pain.

Psychiatric

Chest pain is a common complaint in a wide variety of psychiatric disorders such as panic attack, depression, and somatization disorder. So a good clinical history and atypical symptoms in young individuals should raise a suspicion of underlying psychiatric illness. However, patients with underlying psychiatric illness may have coexisting CAD; hence a sound clinical judgment is needed.

Others

- *Substance abuse*: Cocaine abuse is commonly associated with myocardial ischemia. Other cardiac complications which can be seen include aortic dissection, coronary artery aneurysm, myocarditis and cardiomyopathy, and arrhythmias. Methamphetamine intoxication mimics cocaine and can cause similar cardiac complications.
- *Herpes zoster*: Sometimes chest pain may be the presenting symptom of herpes zoster, preceding the rash but is localized to a particular dermatome. Postherpetic neuralgia may also present with chest pain.
- *Domestic violence*: Patients may complain of chest pain or have chest pain in the setting of psychiatric conditions after suffering from intimate partner violence. In a community-based population, chest pain was one of the many physical symptoms associated with domestic violence.

EVALUATION

A detailed clinical history, physical examination, and relevant blood tests help in determining the probable cause of chest pain and the urgency of management. Stepwise approach is adopted to evaluate the chest pain in emergency (**Fig. 2**). History and physical examination are important part of chest pain evaluation and summarized in **Box 1**. Unstable patients or patients with high suspicion of ACS or ECG suggestive of ST elevation myocardial infarction (STEMI) should be treated with reperfusion therapy and chest pain with inconclusive ECG should be evaluated with serial ECG cardiac enzyme low molecular weight heparin and later disposition should be planned on the basis of risk stratification (**Flowchart 1**). Other life-threatening condition (e.g., aortic dissection, pulmonary embolism, and Boerhaave's syndrome) should be referred to the emergency department and managed on a priority basis.

DIAGNOSTIC APPROACH

The following is a diagnostic approach toward patients presenting with chest pain in the emergency department with priority for life-threatening conditions. Various screening and early diagnostic tools should be adopted in order to manage life-threatening conditions as early as possible (**Table 3**). Patients with life-threatening causes of chest pain should be

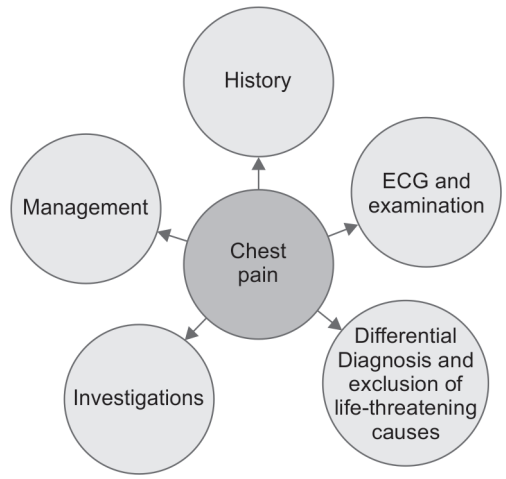

FIG. 2: Stepwise approach for evaluation of chest pain.

BOX 1: History and physical examination in chest pain evaluation.

***History*:**

- Patient presenting with chest pain should be evaluated with a detailed description of the pain and other associated symptoms should be noted
- *Description of chest pain*: It often helps in differentiating cardiac from noncardiac chest pain. Symptoms associated with a relatively high risk of myocardial infarction include radiation to an upper extremity, associated with diaphoresis or nausea and vomiting. However, no symptom alone or in combination helps in identifying patients in whom the diagnosis can be excluded safely
- *Quality*: Chest pain can be pleuritic, positional, sharp or dull, ripping or tearing, or tender on palpation. It is also important to enquire whether, the quality of the pain is similar to a previous episode if any. In a known case of CAD, pain similar to previous episodes is related to myocardial ischemia
  - A pleuritic chest pain gets worse on deep respiration. Causes include pericarditis, pulmonary embolism, pneumothorax, pleuritis, and pneumonia
  - Positional pain which improves on sitting and leaning forward suggests pericarditis
  - Ripping or tearing pain point toward aortic dissection
- *Location and radiation*: Ischemic pain is often diffuse and poorly localized. Well-localized pain associated with finger tenderness is more likely to be musculoskeletal in nature. Ischemic pain often radiates to the neck, throat, lower jaw, teeth, upper extremity, or shoulder
- *Temporal factors*: Acute onset of chest pain suggests pneumothorax, aortic dissection, esophageal rupture/perforation, or pulmonary embolism. However, the onset of ischemic pain is more gradual (over a period of few minutes) and gradually increasing in intensity over time
- Chest discomfort that lasts only for seconds or is constant over weeks is unlikely to be ischemic in origin. Myocardial ischemic pain usually lasts not >20–30 min, though it may be prolonged in the setting of a myocardial infarction
- *Exacerbating factors*: Chest discomfort on exertion is a classic symptom of angina. Sometimes esophageal pain can also present in a similar pattern. Other factors that may provoke ischemic pain include cold, emotional stress, meals, or sexual intercourse. Discomfort occurring with eating is suggestive of gastrointestinal etiology. Pain worsened on swallowing is likely to be esophageal in origin
- *Relieving factors*: Pain that subsides with cessation of activity strongly suggests an ischemic origin. Pericarditis pain typically improves with sitting up and leaning forward. Pain palliated by antacids or food is likely to be gastroesophageal in origin. However, pain which responds to sublingual nitroglycerin is usually associated with cardiac etiology but may be due to esophageal spasm as well
- *Other associated symptoms* may help in distinguishing the various etiologies of chest pain. However, sometimes even these symptoms may not reliably distinguish between cardiac and gastrointestinal origins of chest pain
- *Presyncope* can be seen in patients with myocardial ischemia. However, it is also associated with other pathologies such as aortic dissection, a hemodynamically significant pulmonary embolus, or critical aortic stenosis

Continued

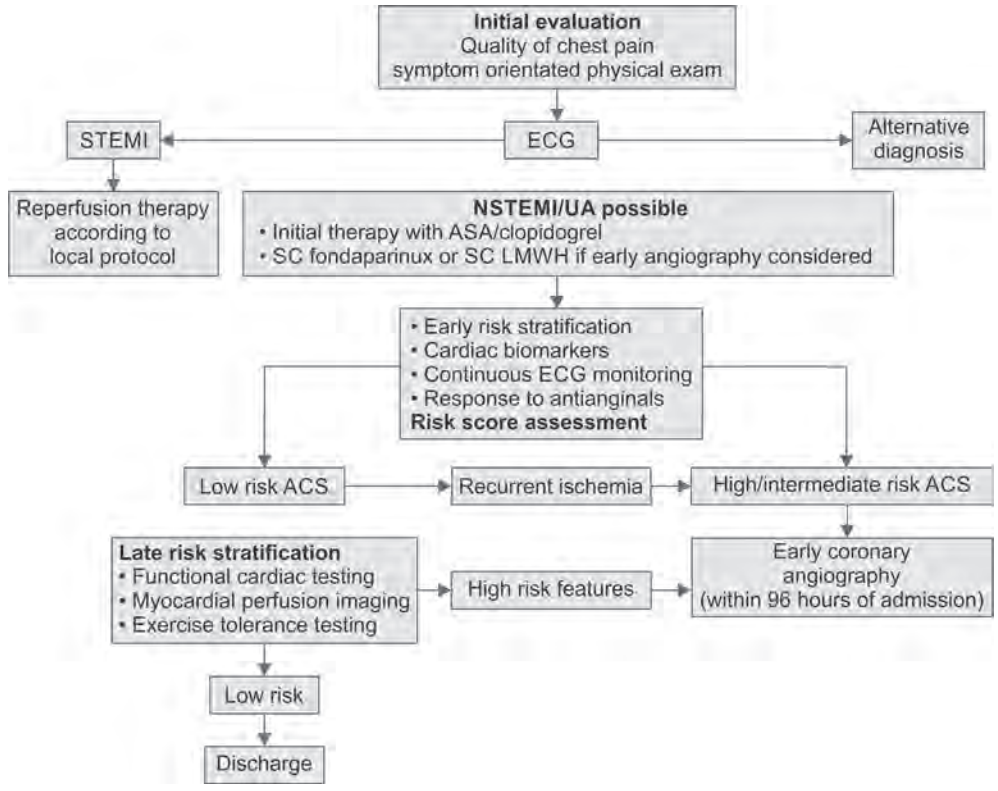
Continued

- *Palpitations* are often the complaint in patients with ischemia due to ventricular ectopic or atrial fibrillation
- Exertional dyspnea may be considered as anginal equivalent but it is also associated with other cardiac (e.g., aortic stenosis and atrial fibrillation) and pulmonary (e.g., asthma or chronic obstructive lung disease and pulmonary hypertension) causes of chest pain
- *Cough* is associated with infection, neoplasm, pulmonary embolism, and GERD
- *GERD* is associated with heartburn, regurgitation, and dysphagia. Belching, difficult, or painful swallowing is suggestive of esophageal disease, although belching and indigestion may also be seen in patients with myocardial ischemia. Nausea and vomiting are often seen in the setting of myocardial ischemia in addition to gastrointestinal problems
- *Musculoskeletal pain* in the neck, thoracic spine, or shoulder may cause referred pain to the chest. Chronic widespread musculoskeletal pain is associated with fibromyalgia
- *Presence of fever* leads to infective or autoimmune etiologies for chest pain. Fatigue, weight loss, and other constitutional symptoms raise concerns for malignancy or rheumatologic etiologies
- *Psychiatric symptoms* associated with pain may be due to panic disorder. Patients with depressed mood, decreased appetite, or sleep disturbances may have underlying depression
- *Other relevant medical history*: Diabetes, hypertension, smoking, and dyslipidemia are traditional risk factors for CHD. Prolonged immobilization, recent surgery, and trauma all increases the probability of pulmonary embolism. Hence knowledge about such risk factors provides important information regarding likelihood of a particular disease

***Physical examination*:**

- *Vital signs*: Presence of hemodynamic instability is an indication for immediate referral to the emergency department. Presence of hypoxemia points toward pulmonary or cardiac etiologies of chest pain whereas fever raises suspicion for infectious or autoimmune disease. In patients suspected of aortic dissection, blood pressure should be checked in both the arms and lower limbs
- *Cardiac examination*: A complete examination should be performed to evaluate for rate, rhythm, murmurs, and extraheart sounds. In pericarditis, one should examine in both supine and sitting and leaning forward position. This assesses for a pericardial rub which may only be present in the sitting position
- *Pulmonary examination:* It should be done to evaluate for symmetrical breath sounds, wheezing, crackles, and any evidence of consolidation
- *Musculoskeletal examination*: Chest pain reproducible with palpation may indicate musculoskeletal pain. Hyperesthesia associated with a rash is often due to herpes zoster. The presence of subcutaneous emphysema suggests Boerhaave's syndrome or pneumothorax
- *Abdominal exam*: A careful examination of the abdomen is required to assess for any referred pain, with attention to the right upper quadrant, epigastrium, and the abdominal aorta

(CAD: coronary artery disease; CHD: coronary artery disease; GERD: gastroesophageal reflux disease)



(ACS: acute coronary syndrome; ECG: electrocardiogram; SC: subcutaneous; STEMI: ST elevation myocardial infarction)

FLOWCHART 1: Evaluation and management of chest pain in ED.

TABLE 3: Screening and early diagnostic tools for acute coronary syndrome.

Pretest probability		*Early diagnostic tools for acute coronary syndrome*	
Demographic risk (CAD risk factors)	***Incident risk (typical Symptoms)***	***ECG***	***Cardiac enzyme***
• Diabetes hypertension • Hyperlipidemia smoking • Family history of CAD in a first degree relative: ○ Age >45 years for men ○ Age >55 years for women ○ Male Gender	• Chest pain, pressure, or discomfort • Arm pain, neck/jaw pain • Atypical symptoms shortness of breath • Fatigue • Nausea • Vomiting • Dizziness • Upper abdominal pain	• ST segment elevations that meet STEMI criteria • New ST depressions • New T-wave inversion in a coronary distribution • ST and T-wave abnormalities in a nonspecific (noncoronary) distribution • Normal ECG	• Elevated troponin Normal troponin but an elevated CK-MB ratio • Normal troponin and normal CK-MB ratio elevated CK-MB with a normal CK-MB ratio only

(CAD: coronary artery disease; CKMB: creatine kinase-MB; ECG: electrocardiogram; STEMI: ST elevation myocardial infarction)

referred immediately to the emergency department. These include patients with:

- Hemodynamic instability
- Sudden onset of chest pain and/or suspected life-threatening etiology such as pulmonary embolism, aortic dissection, esophageal rupture, and tension pneumothorax.
- Suspected ACS based on history (angina at rest, prolonged, or progressive) or ECG changes. Appropriate initial interventions should also be started such as 325 mg of aspirin tablet, sublingual nitroglycerin, and intravenous morphine.

ELECTROCARDIOGRAM

An ECG should be obtained for all the patients with new onset of chest pain or any pain that is different from previous episodes of noncardiac pain. ECG is very helpful in the evaluation of patients with suspected myocardial ischemia as well as in making a diagnosis of many other etiologies. Patients with ECG findings suggestive of ACS should be referred to the emergency room for further evaluation and management. Those patients with a history suggestive of ACS but a normal ECG should have serial ECGs done and monitored in the

emergency department. A normal ECG helps in ruling out ACS but findings must be interpreted in the context of the clinical history and physical examination. Sometimes ECG also helps in making a diagnosis of nonischemic chest pain such as acute pericarditis (diffuse ST elevation with PR depression), pulmonary embolism (sinus tachycardia, RBBB, RAD, and S1Q3T3 pattern). So, in an emergency department, an ECG should be obtained in all the patients presenting with chest pain.

OTHER STUDIES

Laboratory tests and other studies such as chest radiograph and cardiac enzymes are determined on initial evaluation and vary depending upon the need. Many patients will not need any additional tests for their chest pain evaluation. When there is a possibility of ACS, cardiac enzymes (CK-MB, Trop-I) should be tested. Chest X-ray if pneumonia, tension pneumothorax is the possibility. Perform 2D echo to rule out cardiac tamponade and aortic dissection. Multislice CT for pulmonary embolism and aortic dissection can be considered.

SUMMARY

The most common cause of chest pain in primary care practice is musculoskeletal pain and gastrointestinal conditions. Initial evaluation of chest pain starts with a detailed clinical history and physical examination. It helps in assessing the probability of various causes of chest pain and the need for further testing. ECG will be required in many patients suspected of myocardial ischemia. Patients with hemodynamic instability or life-threatening pathology (e.g., pulmonary embolism, aortic dissection, esophageal rupture, tension pneumothorax, and ACS), should be referred to the emergency department and managed on a priority basis. Patients with suspected ACS due to classical history or ECG changes should be given 325 mg aspirin tablet to chew. Symptoms consistent with stable angina should be further evaluated for myocardial ischemia. The appropriate diagnostic test will depend on the most likely etiology. In patients with a negative work-up for myocardial ischemia or in whom clinical suspicion is low, further evaluation depends upon the most likely diagnosis that emerges from the initial evaluation.

59
CHAPTER

Palpitation

Roberta Petrino, Aldo Tua

INTRODUCTION

The term palpitations are referred by the patient when he/she feels a sense of abnormality of the heart beating in terms of rate or regularity. The heart is defined as skipping, frisking, fluttering, racing, or jumping. Frequently, the abnormality is lasting for a prolonged period and thus causes anxiety or anguish.

ETIOLOGY

The causes of palpitations may be several and different. Any situation that can cause acceleration or deceleration of the heart beating, or a change in the regularity can determine the unpleasant feeling referred as palpitation. Causes of palpitations can be of cardiac or noncardiac etiology. About 40% of the causes are of cardiac origin, one-third is of psychiatric origin, while the remaining is of other or unknown origin. In **Table 1**, there are summarized the most common causes of palpitations. *Cardiac etiology* is generally due to an impairment of the conduction system that causes brady or tachyarrhythmias with the mechanisms such as altered automatism, reentry of a premature beat, and postpotential excitation due to cell membrane ion channels disturbances. *Psychiatric causes* of palpitations may be anxious state, panic attack, and conversion crisis. Palpitations in these cases normally are more frequent, last longer than for cardiac causes and may be accompanied by different symptoms. In any case, it is necessary to rule out any cardiac cause before accepting the diagnosis of a psychiatric disorder, thus a 12-lead electrocardiogram (ECG) is mandatory and eventual other investigations. Other etiologies include:

- *Physiological*: Exercise, pregnancy, excitement, and emotional trauma
- *Hyperkinetic circulatory state*: Fever, hyperthyroidism, anemia, and hypoglycemia
- Vasovagal syndrome
- *Drugs*: Aminophylline, atropine, antiarrhythmic, tricyclic antidepressants, and calcium channel blockers
- *Toxic*: Cocaine, alcohol, amphetamines, and tobacco
- Systemic mastocytosis
- Da Costa's syndrome or effort syndrome or neuro-circulatory asthenia

TABLE 1: Etiologies of palpitations.

Arrhythmic causes	*Nonarrhythmic cardiac causes*	*Noncardiac causes*
• Supraventricular tachycardia • Ventricular tachycardia • Atrial flutter • Atrial fibrillation • Supraventricular and ventricular extrasystoles • Sick sinus syndrome • Bradyarrhythmias • Brugada syndrome • Arrhythmogenic right ventricular dysplasia	• Mitral valve prolapses • Aortic stenosis or insufficiency • Pulmonary embolism • Atrial myxoma • Congenital heart disease • Arterial hypertension • Pericarditis • Myocarditis • Pacemaker malfunction	• Exercise • Anxiety, fear, stress, and panic attack • Emotional trauma • Fever • Hyperthyroidism • Hypoglycemia • Anemia • Pregnancy • Poisoning and drug abuse with cocaine, amphetamines, and other drugs • Alcohol and caffeine abuse

PATHOPHYSIOLOGY

- *Palpitation intermittent*: Normally due to extrasystole (**Fig. 1**). The patient feels the beat after the extrasystole because the major end-diastolic filling after the pause and the increased strength of contraction.
- Palpitations that appear only after exercise or excitement or emotional stress—normally, the heart rate is not faster than 120 bpm and regular. Palpitation is due to catecholaminergic stimulus and transitory hyperdynamic cardiovascular state.
- *Palpitation continuous and regular*: Generally due *to supraventricular tachycardia (SVT) or atrial flutter or ventricular tachycardia* (**Figs. 2** to **4**). The pathogenesis of the former is a reentry mechanism, around the atrioventricular node or through an atrioventricular accessory pathway. Atrial flutter is normally occurring in patient with a cardiac scar or cardiomyopathy and

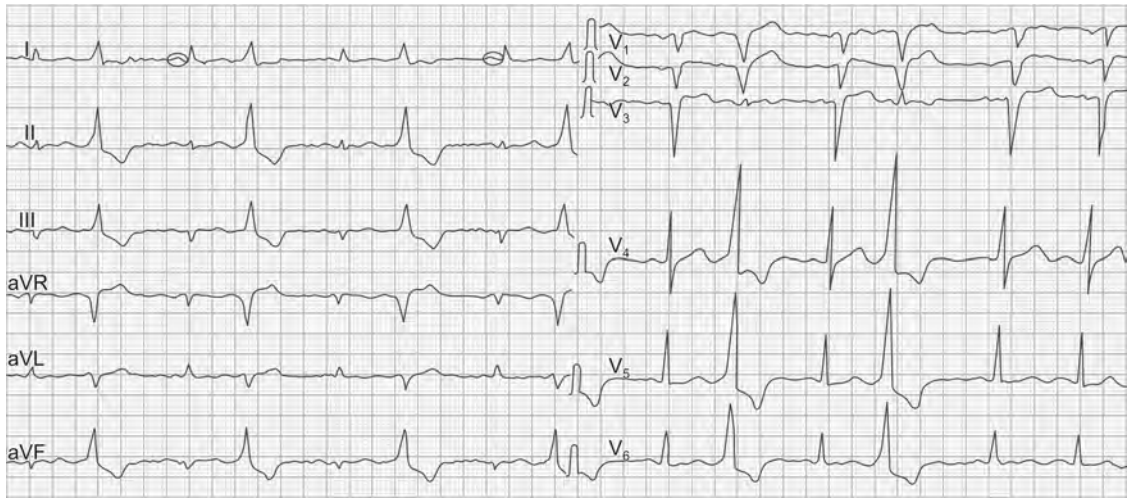

FIG. 1: 12-lead ECG showing ventricular extrasystole bigeminies.

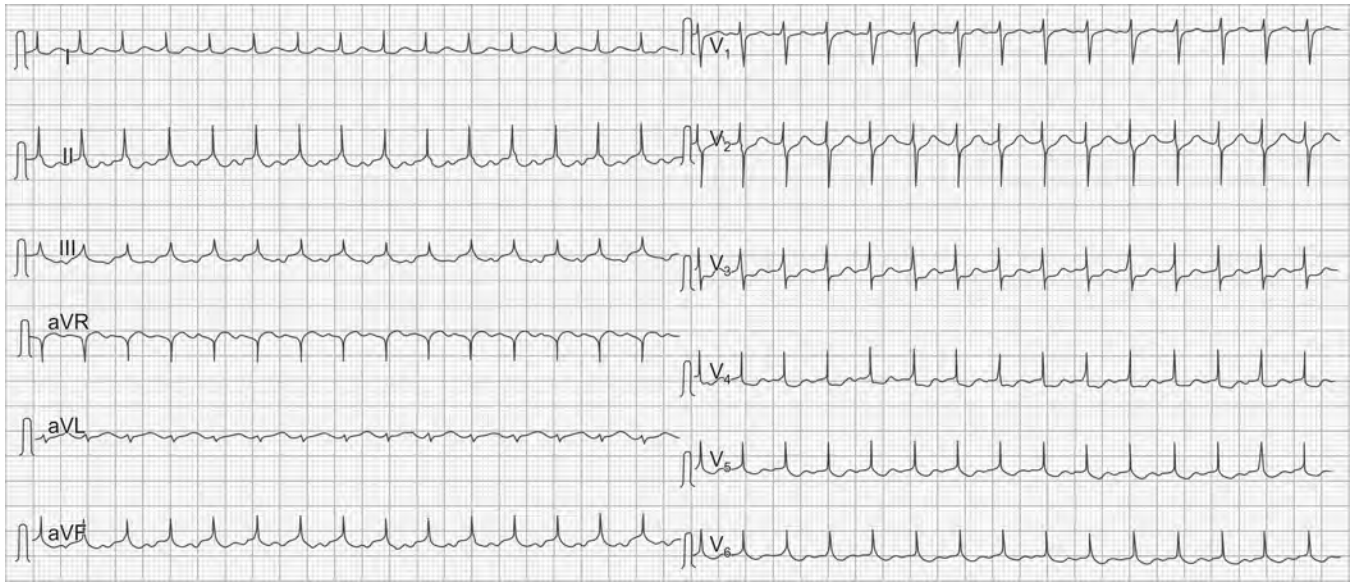

FIG. 2: 12-leads ECG showing a supraventricular tachycardia.

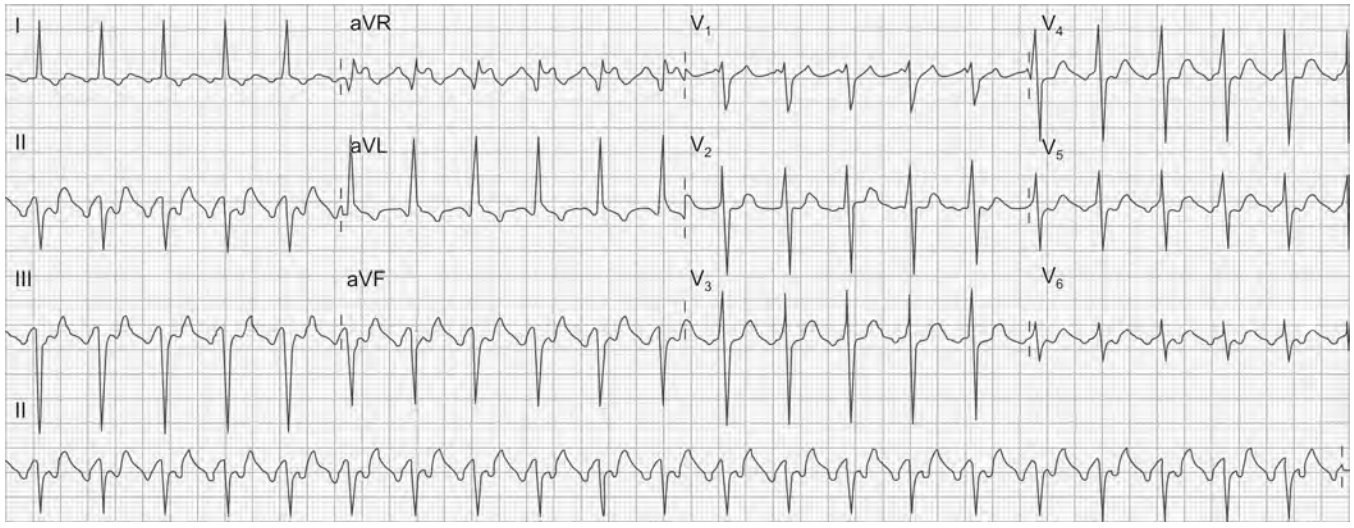

FIG. 3: 12-lead ECG showing an atrial flutter with conduction 2:1.

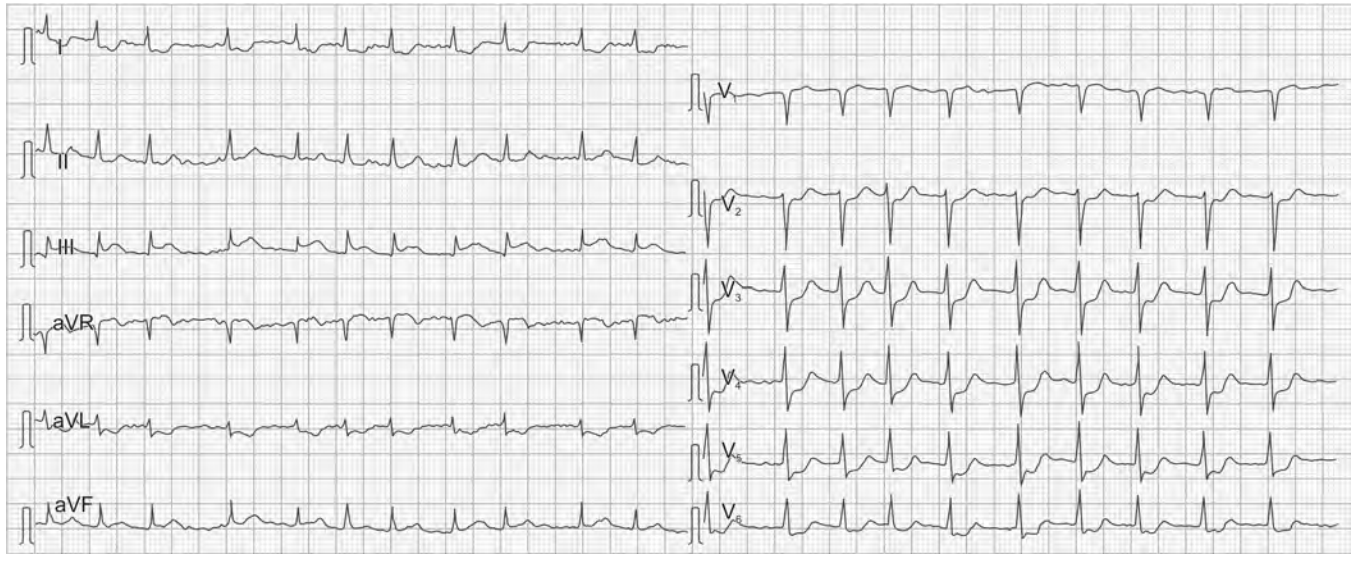
FIG. 4: 12-lead ECG showing a ventricular tachycardia.



(ECG: electrocardiogram; STEMI: ST segment elevation myocardial infarction)

FIG. 5: 12-leads ECG showing an atrial fibrillation and an inferior STEMI.

is sustained by reentry mechanism around the scar or around anatomic or functional atrial circuits. Ventricular tachycardia is the most threatening as it may evolve toward pulseless tachycardia or ventricular fibrillation is normally due to ischemia, dilative cardiomyopathy, hypokalemia, or other arrhythmogenic congenital or acquired diseases.

- *Palpitation continuous irregular*: It may be due to *atrial fibrillation* (**Fig. 5**), but also to atrial flutter with variable ventricular conduction, multifocal atrial tachycardia (MAT) or frequent extrasystoles. Pathogenesis of atrial fibrillation is several mini reentry mechanisms due generally to atrial walls distension and dilation. Very important to keep in mind the need for anticoagulation to prevent thrombus formation in the atria due to the absence of an efficacious atrial systole. MAT may be seen in chronic respiratory failure.
- Palpitation is associated with:
  - *Chest pain*: Possible myocardial infarction with arrhythmia
  - *Syncope*: Low cardiac output with arrhythmia and hypoglycemia
  - *Dyspnea*: Heart failure and chronic obstructive pulmonary disease (COPD) exacerbation
  - *Sweating*: Vasovagal syndrome, anxiety, and hypoglycemia

- *Polyuria*: SVT
- *Diarrhea*: Thyrotoxicosis

- *Positional palpitation*: It may be due to the presence of an intracardiac (atrial myxoma) or mediastinal mass that in certain positions triggers the arrhythmia.

CLINICAL PRESENTATION

As already described above, palpitation may be continuous or intermittent, may start and stop abruptly, and may be associated with other symptoms such as chest pain, dyspnea, fever, sweating, syncope, polyuria, anxiety, or agitation. Very often when the patient comes to the ED palpitation is extinguished and is necessary to make a hypothesis according to the patient history and the associated symptoms. Whenever possible, it is important to ask the patient to tap on the table the rhythm and frequency of the palpitation. In **Table 2**, there is the correlation of the description of the palpitation and the possible cause. The patient may be in shock or hemodynamically unstable or may present palpitation only in orthostatic or lying position. Very often the patients are young and otherwise healthy so easily labeled as "anxious."

RED FLAGS

When palpitation is recurrent, persistent, and is provoked by *exertion*, or accompanied by light—*headedness, syncope, chest pain, and dyspnea,* a careful workup is mandatory and if the diagnosis is not evident at the beginning a period of observation and monitoring is necessary. Preceding episodes of syncope can be associated with long QT syndrome, idiopathic or acquired, that may develop torsade des pointes. A syncope may also happen with the onset of an atrioventricular advanced block or a ventricular tachycardia. The onset of chest pain and palpitation is always alarming as it can be due to a ventricular tachycardia or another arrhythmic complication of a coronary syndrome.

TABLE 2: Description of palpitation and possible cause.

Description	*Suggestion*
Beat skipping and thumps	Extrasystole
Worsen at rest	Extrasystole
Fast and regular	Supraventricular or ventricular tachycardia
Sudden onset	Supraventricular or ventricular tachycardia
Ends with vagal maneuvers	Reentry supraventricular tachycardia
Fast and irregular	Atrial fibrillation or flutter with varying block
Nonfast and irregular	II-degree AV block or extrasystole
Hard and regular	Awareness of sinus rhythm (hypertension, anxiety, and cocaine)
Dizziness, heart failure, syncope, and shock	Ventricular tachycardia

EVALUATION

History

The patient should be asked about the onset of palpitation, the duration, and the associated symptoms. The rate of heartbeat and regularity is an important information, like the onset with a syncope, or other symptoms, and whether the patient was in activity or at rest. In particular, palpitation occurring during exertion or just after, it is a warning sign for possible cardiomyopathy or conduction disturbance. Doctors should enquiry about the interruption of the palpitation—if it is sudden or triggered by vagal maneuvers such as Valsalva or diving reflex, a paroxysmal SVT is likely.

The previous medical history in fundamental to disclose preexisting cardiac, respiratory, or metabolic diseases such as thyroid diseases, to:

A = Allergies: Investigate on known allergies and manifestations

M = Medications: Investigate on drugs taken by the patients in particular cardiovascular medications such as antiarrhythmics, diuretics, hypotensive, antithyroids or thyroid-stimulants, and drugs acting on the central nervous system.

P = Past medical history: To investigate on any past or chronic disease, with particular attention to cardiac diseases, previous arrhythmias, syncope, and cardiac arrest; history of drug and alcohol abuse. Family history of sudden cardiac arrest, genetic cardiac disease and psychiatric problem.

L = Last meal: To investigate on the kind of food or beverages taken in the previous hours or days.

E = Events: To investigate on the present symptoms and all the events that may be linked with them, in particular ask whether, palpitation is felt as alteration of the heart rate, of the heart rhythm or to a sensation of awareness of the heartbeat.

It is also important to know whether the patient is in a difficult or stressful period, is in sleep deprivation or with a fever.

Physical Examination

The patient should be evaluated according to ABCD approach.

- *Airway*: If the patient is able to speak fluently the airway is clear. Disclose a possible allergic-anaphylactic reaction that may cause glottis edema.
- *Breathing*: Take respiratory rate and oxygen saturation, look for signs of cardiac decompensation, or respiratory failure, the presence of rales, wheezes, and rhonchi on auscultation that may be the cause or the consequence of a tachyarrhythmia.
- *Circulation*: Blood pressure and heart rate give immediately the idea of a cardiac arrhythmia and of the stability of the patient. In this phase, it is essential to make a 12-lead ECG directly at the triage, because it permits immediately to find the cause of palpitations in a wide majority of cases, or at least to disclose life-threatening situation such as ventricular tachycardia or hemodynamically unstable tachyarrhythmia, myocardial infarction, or evident signs of electrolyte disorders, like hyperkalemia.
- *Disability*: Once excluded an obvious cardiac cause of palpitation, it is necessary to evaluate all the other signs

and symptoms that may lead to the diagnosis, like signs of hyperthyroidism, evidence of intoxication, psychosis, anxiety, panic attack, etc.

Interpretation of Findings

If at the first clinical evaluation, an unstable cardiac or respiratory disease is evident, it will be necessary to start immediately the proper treatment and monitoring. An eventual arrhythmia that may be related to palpitation may need to be treated with the condition (e.g., high-rate atrial fibrillation in pulmonary edema) or may be a consequence of the disease (e.g., MAT in COPD exacerbation with respiratory failure) and will resolve once the situation is getting better. When at the ECG, it is clear that the pure cause of palpitation is an acute arrhythmia; the best option is to treat it immediately as described later in the text. If the clinical examination excludes a cardiac or another medical problem, the probability of a psychiatric disorder is high, so a proper specialist consultation is recommended.

INVESTIGATIONS

As already reported, a 12-lead ECG is mandatory and needs to be available as soon as possible. Some laboratory tests are recommended, including blood cell count, to exclude anemia or leukocytosis, creatinine, electrolytes, arterial blood gas analysis, to evaluate respiratory failure, hypercarbia, metabolic acidosis, and carbon monoxide poisoning. If the ECG is negative, but the patient is describing episodes of syncope, dyspnea, or chest pain, a period of observation or monitoring in the ED is recommended, and very often is possible to scavenge a new arrhythmic episode or another cardiac problem like ischemia.

If the patient is discharged should be referred to the cardiologist to apply a Holter ECG recording or an implantable loop recording. An echocardiogram is recommended either before discharge or soon after. In **Table 3**, there are the ECG criteria for cardiologist urgent or deferred involvement.

TABLE 3: Indication for urgent o nonurgent expert opinion of a cardiologist according to the ECG finding.

ECG finding	*Acute onset*	*Unknown*
STEMI, coronary syndrome	Urgent	Urgent
Atrial fibrillation and atrial flutter	Urgent or deferred (if treated by the EP)	Nonurgent
Left ventricular hypertrophy and left bundle branch block	Urgent if acute cardiac decompensation	Nonurgent. Echocardiogram mandatory
Second degree atrioventricular block	Urgent for Mobitz II	Nonurgent for Mobitz I
Third degree atrioventricular block	Urgent	Urgent
Atrioventricular accessory pathway (Wolff–Parkinson–White pattern)	Urgent if associated with tachyarrhythmia	Nonurgent

(ECG: electrocardiogram; STEMI: ST segment elevation myocardial infarction)

TREATMENT

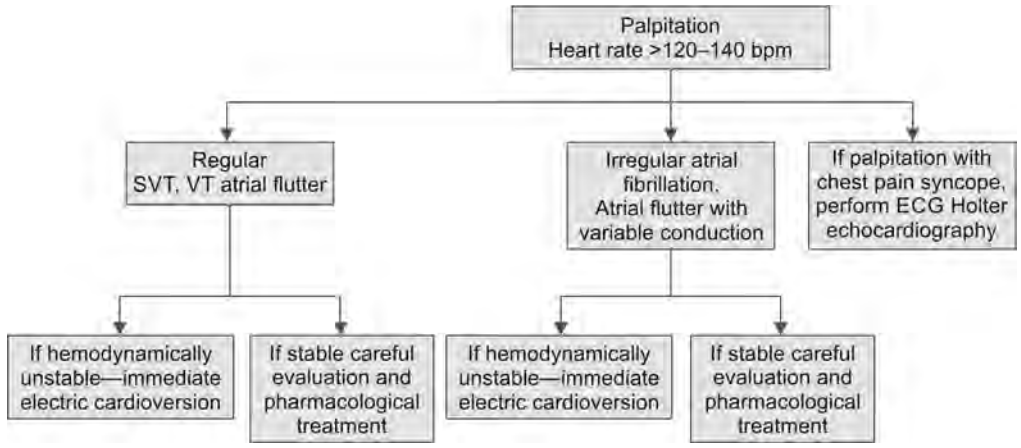
Arrhythmias

- *Extrasystoles* are normally not treated unless really disturbing the patient. In this case, a beta-blocker or some magnesium is indicated.
- *Atrial fibrillation:* According to the most recent guidelines, it is necessary to identify the time of onset because if it is <48 hours, it is possible to attempt a cardioversion, if not it is necessary to do a "rate control" approach and postpone the cardioversion after a period of anticoagulation. According to patient choice, it will be possible to do an electrical cardioversion that needs sedation, or a pharmacological cardioversion with flecainide, if the patient has not structural cardiac disease or amiodarone if there is a cardiac disease or decompensation. A hemodynamically unstable atrial fibrillation as any other unstable tachyarrhythmia requires an urgent electrical cardioversion. According to the CHA2DS1-VASc score for the risk of thrombotic stroke, an oral anticoagulation therapy should be initiated. The patient needs to be always referred to the cardiologist, in the ED or at discharge.
- *Supraventricular tachycardia*: Reentry SVT often is self-limited or may be interrupted by vagal maneuvers. If these are not efficacious, the drug of choice is adenosine, 6 mg IV flush that can be repeated at 12 mg. A period of asystole after the drug is possible but the very short half-life of adenosine makes it a very safe option. The third choice is a nondihydropyridine calcium channel blocker like verapamil, but it must be avoided in patients with a Wolff–Parkinson–White syndrome.
- *Ventricular tachycardia* is generally treated with electrical cardioversion or, in a stable situation, can be treated with amiodarone or lidocaine.
- *Arrhythmias due to electrolytes alterations or drug* poisoning need to be treated by treating the underlying cause.
- *Symptomatic bradycardias* require the use of transthoracic or transvenous cardiac pacing, and a washout of the drugs that may have provoked the bradyarrhythmia.
- *Any other structural cardiac disease or any noncardiac disease* will be treated properly or referred to a specialist evaluation.

In a majority of cases, palpitation does not need pharmacological treatment but only reassurance of the patient and can be resolved by lifestyle modification.

SUMMARY

Palpitation is a common symptom that leads the patient to the emergency department. It is generally described as the sense of abnormality of the heart beating in terms of rate or regularity. About 40% of the cases or of cardiac origin, 30% have a psychiatric cause and 30% of other medical causes. Any acute arrhythmia may cause palpitation, for this reason a 12-lead ECG is mandatory every time a patient refers palpitation at the triage. Approach to palpitation is summarized in **Flowchart 1**.



Palpitation
Heart rate >120–140 bpm
Regular
SVT, VT atrial flutter
Irregular atrial fibrillation, Atrial flutter with variable conduction
If palpitation with chest pain syncope, perform ECG Holter echocardiography
If hemodynamically unstable—immediate electric cardioversion
If stable careful evaluation and pharmacological treatment
If hemodynamically unstable—immediate electric cardioversion
If stable careful evaluation and pharmacological treatment

(ECG: electrocardiogram; SVT: supraventricular tachycardia)

FLOWCHART 1: Showing approach to the patient with palpitation.

At the first evaluation, it is necessary to exclude all the possible life-threatening conditions that may cause or present with palpitation such as unstable ventricular or supraventricular arrhythmia, cardiac ischemia, structural arrhythmogenic cardiac disease, poisoning, electrolyte disorders, or advanced AV block. If not evident immediately, a proper period of monitoring and observation is mandatory. Particular attention must be given when palpitation is provoked or followed by chest pain, dyspnea, lightheadedness, or syncope that may be the alarm sign of ischemia or a structural heart disease. A careful evaluation of previous medical history, with recording of all the drugs and structural cardiac diseases, is of utmost importance, as well as the habit to consume alcohol or illegal drugs. An acute arrhythmia or any other critical illness related to the symptom must be stabilized and addresses immediately, while in all the other cases it will be indicated a follow-up with some investigations such as Holter ECG, or loop recording to scavenge eventual arrhythmic episodes. It is important to recognize the noncardiac causes of palpitations, such as thyrotoxicosis and hypoglycemia, and when all the organic causes have been excluded to address the patients toward a psychiatric evaluation.

60
CHAPTER

Syncope

Brajesh Kumar Mishra

INTRODUCTION

Syncope is a common, disabling, and often challenging symptom. It can cause fall and injury, and can be the warning sign before sudden cardiac death. Syncope is defined as transient loss of consciousness (TLOC) due to transient global cerebral hypoperfusion; it has three important features rapid onset, short duration, and complete recovery. Differentiation of syncope from other causes of TLOC such as seizure and "syncope mimics" (pseudo seizure, nonsyncopal TLOC, and psychological disorder) is very important for emergency physician while evaluating such type of patient.

EPIDEMIOLOGY

Transient loss of consciousness events of suspected syncope are highly prevalent in the general population. It affects about 50% of human being in their life time. First episode occurs generally around the age of 15 year, it is more common in female population, around age of 65 years. Syncope rises sharply as age increases. Syncope contributes to about 1% of total in hospital admission and 3% of emergency evaluation, although this is just tip of iceberg because <50% of patient of syncope visits emergency department (ED) or consults their doctor.

PATHOPHYSIOLOGY

Overall mechanism in syncope is transient cerebral hypoperfusion because of decreased cardiac output. Commonly, neutrally mediated syncope occurs when ventricular filling is decreased by venous pooling. It leads to a fall in cardiac output and BP activation of arterial baroreceptors, result rise in catecholamine levels, combined with reduced venous filling, and volume-depleted ventricle. Activation of "C fibers" receptors found in the atria, ventricles and pulmonary artery can result in "paradoxical" loss of peripheral sympathetic tone and an increase in vagal activity, which ultimately causes vasodilation and bradycardia leading to syncope or presyncope. Various risk factors are responsible for syncope are summarized in **Box 1**.

BOX 1: Important cardiac risk factors for syncope.

- Severe structural heart disease (low heart function, previous heart attack, and heart failure):
  - Clinical or ECG suggestive of arrhythmia
  - Syncope during physical exercise
  - Palpitations during syncope
  - Family history of sudden death
  - Non sustained VT
  - Bifascicular block or QRS >120 ms
  - Severe sinus bradycardia (<50 bpm) in the absence of medications or physical training
  - Preexcitation
  - Prolonged or very short QT interval
  - Brugada ECG pattern (right bundle branch block with ST elevation in leads V_1–V_3)
  - Arrhythmogenic right ventricular dysplasia ECG pattern (T wave inversion in leads V_1–V_3 with or without epsilon waves)
  - ECG suggestive of hypertrophic dilated cardiomyopathy
- Clinical evidence or suspicion of a pulmonary embolus (clinical setting, sinus tachycardia, and shortness of breath)
- Severe anemia

CLASSIFICATION

Syncope can be classified according to etiology or mechanism. Classification of syncope according to etiology modified by ESC guidelines versus classification according to mechanism modified by International Study on Syncope of Uncertain Etiology (ISSUE) classification is given in **Table 1**.

LIFE-THREATENING CAUSES OF SYNCOPE

Very important to identify the Life-threatening etiology such as acute coronary syndrome (ACS), aortic dissection, leaking abdominal aortic aneurysm (AAA), subarachnoid hemorrhage

TABLE 1: Etiological classification of syncope.	
Reflex syncope (neurally mediated)	• Vasovagal • Situational • Carotid sinus syncope • Atypical forms
Orthostatic hypotension	• Primary autonomic failure • Secondary autonomic failure • Drug-induced volume depletion
Cardiac Arrhythmia	• Bradycardia • Tachycardia (atrial fibrillation, ventricular tachycardia • Structural heart disease (aortic stenosis and atrial myxoma)

(SAH), ruptured ectopic pregnancy, and gastrointestinal (GI) bleed which may present as syncope in about 15% of cases—missed diagnosis in these conditions can lead to medicolegal action inpatients presenting as syncope. The physician evaluating a patient with TLOC should be alert for the possibility of this disease in addition to cardiovascular diagnosis of ominous significance.

- *Cardiac syncope*—cardiac causes which are associated with syncope include arrhythmia, ischemia, structural/valvular abnormalities (e.g., aortic stenosis), cardiac tamponade, and pacemaker malfunction. Brady and tachycardia are second the most common reason of syncope after reflex syncope.
- *Hemorrhage*—large blood loss because of acute severe bleed can manifest as syncope. Important potential causes include—trauma, GI bleed, leaking aortic aneurysm, ruptured ovarian cyst, ectopic pregnancy rupture, and ruptured spleen.
- *Massive pulmonary embolism (PE)*—hemodynamically significant PE is an uncommon but well-documented cause of syncope.
- *Subarachnoid hemorrhage*—patients presenting with syncope following a headache require evaluation for a possible SAH.

COMMON CAUSES OF SYNCOPE

Neurocardiogenic Syncope

Often referred to as vasovagal or vasodepressor syncope, neurocardiogenic syncope is the most commonly reason of syncope, accounting for 25–65% of cases. In this condition, the cardiovascular reflexes mechanism that controls the circulation become improper in response to a triggering factor, which results in vasodilation with or without bradycardia and a drop in BP leading to global cerebral hypoperfusion. Patients diagnosed with neurocardiogenic syncope have a benign course with no increase in mortality or morbidity. Three types of responses are seen: (1) A cardioinhibitory response which is characterized by asystole, (2) A vasodepressor response presents as fall in BP, and (3) A mixed response with features of both. Significant bradycardia and/or hypotension accompany the acute loss of consciousness. Potential triggers are numerous and often determination of the underlying cause is made in the outpatient setting. Most patients with neurocardiogenic syncope experience a prodrome, which may include dizziness or lightheadedness, a sense of warmth, pallor, nausea/vomiting, abdominal pain, and diaphoresis, prior to their loss of consciousness. Examples include micturition or defecation syncope, situational syncope (e.g., while having blood drawn), or cough-mediated syncope.

Carotid Sinus Hypersensitivity

Carotid sinus hypersensitivity is a variant of neurocardiogenic syncope, resulting from pressure at the carotid sinus. External pressure to the neck can induce this reflex response. Common causes include shaving, a tight collar, and turning of the head.

Orthostasis

Orthostatic syncope comprises between 5% and 24% of syncope cases and can be defined by a fall in blood pressure of 20 mm Hg or more, or a reflex tachycardia of >20 bpm. Orthostasis is most often caused by a loss of intravascular volume, from any number of causes, or by failure or instability of the autonomic nervous system. Nevertheless, clinicians should remain cautious because orthostasis can occur with cardiac syncope. Syncope from orthostatic hypotension is a diagnosis of exclusion in the ED, reserved for low-risk patients who have symptoms consistent with the diagnosis. Orthostatic hypotension can be an isolated disease (Bradbury-Eggleston syndrome) or can be a part of systemic disease like Parkinsonism or Shy–Drager syndrome. Postural orthostatic tachycardia syndrome (POTS) is characterized by symptoms of orthostatic intolerance because of milder form of chronic autonomic incompetence. Orthostatic vital signs are neither sensitive nor specific in assessing volume status or diagnosing syncope. Many patients become symptomatic if their systolic blood pressure drops below 90 mm Hg, but a large portion of the population who meets the definition of orthostasis does not have syncope. Elders, pregnant women, and patients taking drugs with vasodilating effects are predisposed to develop symptomatic orthostasis.

Medications

The effects of medications account for 5–15% of syncopal events due to volume depletion or as a result in vasodilatation. Elderly patients are affected more due to the hypotensive effects of drugs because of renal sodium wasting, reduced baroreceptor sensitivity, decreased cerebral blood flow, and an impaired thirst mechanism that develops with aging. Medications often implicated include calcium channel blockers, beta-blockers, alpha-blockers, nitrates, antiarrhythmics, digoxin, diuretics (affecting volume status and electrolyte concentrations), erectile dysfunction medications, and medications affecting the QTc interval (e.g., antipsychotics and antiemetics). Alcohol can also cause symptomatic orthostasis by impairing vasoconstriction.

OTHER CAUSES OF SYNCOPE

Neurologic Syncope

True syncope is defined by an immediate, spontaneous return to baseline function following loss of consciousness, without new focal neurologic findings. Therefore, true neurologic causes leading to syncope are rare. Examples of neurologic syncope

include SAH, transient ischemic attack (TIA), subclavian steal syndrome, and migraine headache. Stroke and TIAs generally cause focal neurologic deficits that do not recover rapidly or completely.

Psychiatric Syncope

Anxiety and panic disorders can cause situational syncope. Emergency clinicians must be cautious when attributing syncope to psychiatric causes. Patients with hypoxia, inadequate cerebral perfusion, or other medical conditions may appear confused or anxious. Patients with psychiatric syncope are generally young, without cardiac disease, and complain of multiple episodes.

Metabolic

Metabolic causes of syncope include hypoxia, hypoglycemia, and hyperventilation. These comprise <5% of cases of syncope.

Rare Causes

Rare causes of syncope include atrial myxoma, Takayasu's arteritis, systemic mastocytosis, and carcinoid. Anaphylaxis can involve syncope and loss of consciousness, and both patients and witnesses sometimes overlook or forget the more subtle, earlier symptoms, such as flushing, itching, hives, cough, bronchospasm, or abdominal cramping. In addition, these less dramatic symptoms may have resolved by the time the patient is evaluated.

OBJECTIVES FOR EVALUATION

There are two main objectives for evaluation of a patient with syncope in ED:

1. To identify the syncope so that an effective specific treatment strategy can be given.
2. To assess the prognosis in view of death, severe adverse events, and syncope recurrence

During ED evaluation, the differential diagnosis of syncope is extensive, main focus remains on the treatment of underlying cause when this is obvious. However, the cause of syncope often remains unclear. First challenge during evaluation of syncope is differentiate it from seizure (**Table 2**). Epilepsy, stroke, and head trauma may present with TLOC and syncope like situations. Taking careful history alone can narrow down the diagnosis. History of previous seizure, head injury, tongue bite, the presence of a tonic-clonic activity, abnormal posturing, incontinence of bowel or bladder, missed antiepileptic medication, and postictal confusion gives clue about seizure. While syncope associated with sweating or nausea and rapid return of orientation upon awakening.

Evaluation

The utmost important parameters in evaluation of syncope are a careful history, physical examination, supine and upright BP, and a 12-lead electrocardiogram (ECG), followed by additional testing in selected patient subgroups, including carotid sinus massage, echocardiography, ECG monitoring, and tilt-table testing. A thorough history and clinical examination

TABLE 2: Differentiation of syncope caused by neurally mediated hypotension, arrhythmias, seizures, and psychogenic causes.

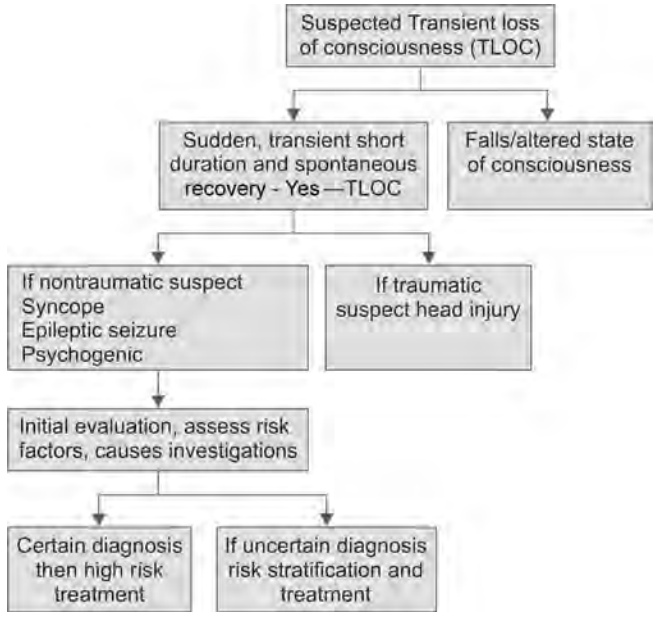
	Neurally mediated hypotension	***Arrhythmia***	***Seizures***	***Psychogenic***
Demographics and clinical settings	• Female > Male • Younger age (<55 years) • >2 episodes • Standing • Warm room • Emotional upset	• Male > Female • Older age groups • Fewer episodes (<3), during exertion or supine position • Family history of sudden death	• Younger age <45 years • Any setting	• Female > Male • Younger age • Occurs in the presence of gathering, often many episodes in a day, no identifiable trigger
Premonitory symptoms	Longer duration >5 sec with palpitation, blurred vision, nausea, warmth, diaphoresis, lightheadedness	• Shorter duration (<6 sec) • Palpitation less common	Sudden onset or brief aura	Usually absent
Observation during events	Pallor, diaphoresis, dilated pupil, slow pulse, low BP, incontinence may occur, brief clonic movement may occur	Blue not pale, Incontinence can occur, brief clonic movement can occur	Blue face, no pallor frothing from mouth prolonged syncope, tongue bite, eye deviation, Incontinence more likely, increase in heart rate and blood pressure	• Normal color • No diaphoresis • Eye closed • Normal heart rate and blood pressure • No incontinence, Prolonged duration
Residual symptoms	• Residual symptoms common • Prolonged fatigue common • Oriented	Residual symptoms uncommon unless prolonged unconsciousness, Oriented	Residual symptoms common, aching muscle, disoriented, fatigue headache, slow recovery	Residual symptoms uncommon Oriented

are by far the most important components of the evaluation of a patient with TLOC, which contribute to diagnosis in 25% of patients. During history, special attention should be given to age and sex, surrounding circumstances, position, premonitory symptoms, index event witness, recovery, past medical history, medication, and family history. Based on this initial evaluation, patients can be divided into those with established syncope and those with nonsyncopal transient LOC. Patients with syncope can be further classified into two groups: (1) Those with a certain diagnosis and clear treatment plan and (2) those with an uncertain diagnosis. For the latter, attention should be on risk stratification of patients. The patients which require hospitalization and/or an intensive timely outpatient cardiovascular evaluation should be identified. These patients may require exercise stress testing, cardiac catheterization, and electrophysiology (EP) testing. Conversely, patients who are presenting with only a single episode of syncope and are determined to be at low risk for a cardiovascular event or death may require no further evaluation. Patients who fall between these two extremes can undergo further testing selected on the basis of results of the initial evaluation. There are subtle features in history and investigation which can assist clinicians in identifying high risk patient with risk to life in comparison to low-risk patient who can be discharged safely. Approach to evaluation of syncope is summarized in **Flowchart 1**.

INVESTIGATION

Laboratory Test

Blood tests helpful in only <2% of cases of syncope. Routine laboratory blood tests are helpful in identifying anemia and electrolyte abnormalities. Acute drop in hemoglobin can suggest bleeding. Arterial blood gas (ABG) can reveal hypoxia suggestive of PE. Elevation of cardiac biomarkers may suggest ACS, PE, arrhythmia, and cardiac decompensation. Electrolyte imbalance contributing to TLOC can also be detected.



Suspected Transient loss of consciousness (TLOC)
Sudden, transient short duration and spontaneous recovery - Yes—TLOC
Falls/altered state of consciousness
If nontraumatic suspect
Syncope
Epileptic seizure
Psychogenic
If traumatic suspect head injury
Initial evaluation, assess risk factors, causes investigations
Certain diagnosis then high risk treatment
If uncertain diagnosis risk stratification and treatment

FLOWCHART 1: Approach to patients with transient loss of consciousness (TLOC) and syncope.

Electrocardiogram

The initial ECG can contribute to diagnosis in 5% of patients and suggests a probable diagnosis in another 5% of patients. ECG showing sinus bradycardia, sinus pauses, Mobitz type II atrioventricular (AV) block, high-grade AV block, or congenital heart block (CHB) suggests bradyarrhythmia as culprit. Right bundle branch block (RBBB), left bundle branch block (LBBB), and bifascicular block will require further evaluation. Extensive massive myocardial infarction can suggest ACS as a cause. PE may manifest as sinus tachycardia, RBBB, and S1Q3T3 pattern. RBBB in V_1–V_3 with ST elevation may suggest Brugada syndrome similarly Epsilon wave suggests arrhythmogenic right ventricular (RV) dysplasia. Preexcitation or Wolff-Parkinson-White (WPW) can also be detected with ECG. Abnormality of QT interval can lead to diagnosis of long or short QT interval. Ventricular tachycardia (VT) or nonsustained VT (NSVT) can also confirm diagnosis. ECG monitoring can also be done with Holter, telemetry, or loop recorder for better yield. Current guidelines recommend that an implantable event recorder should be tried when the mechanism of the syncope is unclear even after a complete evaluation.

Carotid Sinus Massage

This test is indicated in patient with syncope >40 year of age with unexplained reason; however, it is contraindicated in patient with history of recent stroke (within 3 month) or patient with carotid bruit. A pause of >3 seconds and fall in BP of >50 mm Hg is considered as criteria for hypersensitive carotid sinus syndrome.

Head-up Tilt Table Test

Tilt table test is done in patient with recurrent unexplained syncope when the cardiac evaluation and carotid sinus massage is noncontributory. This test demonstrates patient susceptibility for reflex syncope and helpful in initiating treatment in these undiagnosed cases. It also helps in differentiating all the three types of neurogenic syncope: (1) Cardioinhibitory; (2) Vasodepressor and; (3) Mixed response. It also helps in differentiation of orthostatic (immediate blood pressure falls and no bradycardia) vasovagal (delayed blood pressure fall and bradycardia) and reflex syncope, as well as psychogenic, pseudo seizure, and reflex syncope.

Ambulatory Blood Pressure

Monitoring is an important test to diagnose syncope in elderly population because of recurrent hypotension because of autonomic failure.

Echocardiography

It is an important inexpensive noninvasive test. It confirms the cardiac diagnosis when there is suspicion of structural heart disease—left ventricular (LV) or RV dysfunction, valvular heart disease, pericardial effusion, cardiac tumor, myxomas, outflow tract obstruction, or hypertrophic cardiomyopathy (HCM). Yield of the test increases if there is history suggestive of cardiac diagnosis or abnormal ECG. The yield may go up to 27–40%.

Coronary Angiography or CT Angiography and EP Study

It is helpful in suspected ischemia or ischemia-related arrhythmia. Electrophysiological study is helpful in establishing a diagnosis of sick sinus syndrome, carotid sinus hypersensitivity, heart block, SVT, and VT. EP testing should be performed in patients when the initial evaluation suggests an arrhythmia as a cause of the syncope. Dedicated syncope unit has shown better overall diagnosis and management of syncope patient. Initial evaluation gives a diagnosis in 21%, further workup reveals a diagnosis in 61% but in 18% diagnosis still remains uncertain.

TREATMENT

Treatment of a patient with syncope has three aims:

1. Prolong survival
2. Prevent traumatic injuries
3. Prevent recurrences

The syncope treatment is based on the etiology and mechanism of the syncope. Current guidelines recommend that patients with syncope be hospitalized when there is known or suspected cardiac diagnosis, ECG suggestive of arrhythmic syncope, syncope with severe injury or during exercise, patients with a history of sudden unexplained death in family.

Nonpharmacological General Measures

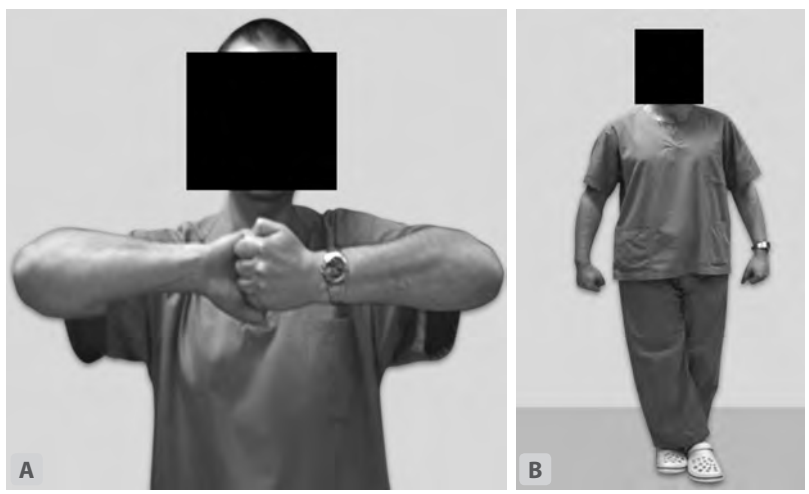
Single episodes of reflex syncope do not require any treatment, patients should be educated about common precipitating factors such as dehydration, prolonged standing, alcohol, and medications such as diuretics and vasodilators. Patients should also be taught to sit or lie down at the beginning of symptoms and to initiate physical counter pressure maneuvers (**Fig. 1**). One recent study reported that a standard education protocol decreased traumatic injuries and recurrences of syncope significantly· expansion of volume by salt supplementation is also commonly recommended. Intake of approximately 500 mL of water immediately increases orthostatic tolerance to tilt in healthy subjects and may be of value as prophylaxis for syncope in blood donors. Orthostatic hypotension patient may be benefited by various nonpharmacological measures such as tilt table training, increased salt intake, physical counter pressure maneuvers, abdominal binder and compression stocking, midodrine, and fludrocortisone are another alternative in these scenarios.

Pharmacological Treatment

If syncope is refractory to nonpharmacological measures then drugs such as alpha agonist midodrine, droxidopa, and pyridostigmine can be considered for frequent hypotensive episodes. Drugs with less proven efficacy such as β-blockers and fludrocortisone are also in use for reflex syncope. Despite the widespread use of agents such as midodrine and fludrocortisone, these drugs proven ineffective in many prospective randomized clinical trials. Even though β-blockers metoprolol, propranolol, and nadolol were previously considered by many to be first-line therapy, recent studies have reported contrary (not better than placebo).

Role of Pacemakers

Role of pacemakers in patients with neurally mediated syncope is debatable. Although the 2008 guidelines for device-based therapy state that pacemaker implantation has a IIb indication for the treatment of patients with highly symptomatic, neurally mediated syncope associated with bradycardia documented spontaneously, or at the time of tilt-table testing. Management of syncope because of specific clinical entity requires the appropriate treatment for specific diagnosis, as for example a patient with syncope related to AV conduction block would require a pacemaker in most situations. However, a patient with syncope secondary to heart block on the background of an inferior wall myocardial infarction will not usually require a permanent pacemaker because the heart block usually resolves spontaneously after revascularization. Similarly, heart block resulting from neurally mediated syncope does not generally require pacemaker implantation. Management of a patient of WPW syndrome presenting with syncope typically involves catheter ablation. Management of a patient with syncope due to VT or in the setting of ischemic or nonischemic cardiomyopathy would probably include implantation of an implantable defibrillator. However, ICD implantation may not be required for patients with VT/VF occurring within 48 hours of an acute myocardial infarction. For other types of syncope, treatment may involve cessation of likely culprit drugs,



FIGS. 1A AND B: Counter-pressure maneuvers: (A) Arm tensing; (B) Leg crossing.

increased salt intake, education and counseling of the patient. In the case of syncope because of neurological or GI disease, respective super specialty must be involved.

RISK STRATIFICATION FOR SYNCOPE IN EMERGENCY DEPARTMENT

In emergency department, risk stratification evaluation of patients presenting with syncope is an important step in management. There are several predictors and scoring system used for risk stratification of syncope patient as, for example, OESIL Study, STePS study, San Francisco rule, Rose rule EGSYS Score, etc. The EGSYS Score: During follow-up at a mean of 20 months, patients with an EGSYS score ≥ 3 predict higher mortality than patients with score <3 (**Box 2**).

FUTURE PERSPECTIVE

Syncope will be an important clinical problem in coming years because of increasing life expectancy and more frequent occurrence of cardiac disease in this subset. Over the next 5 years, additional studies will confirm the clinical and economic value of syncope evaluation units. This will lead to more widespread use of syncope evaluation units, much like chest pain emergency rooms which are now routinely used to evaluate patients with chest pain. Clinical genetic testing is now available on a routine clinical basis for many of the inherited cardiac conditions that may be accompanied by syncope, including long-QT syndrome, arrhythmogenic right ventricular dysplasia (ARVD), and HCM. Therefore, it also seems likely that genetic testing will grow in diagnostic importance in the evaluation of patients with syncope.

BOX 2: The EGSYS score long-term predictor.

- Palpitation preceding syncope (4 points)
- Heart disease and abnormal ECG (3 points)
- Syncope during effort (3 points)
- Syncope during supine (2 points)
- Precipitating and predisposing factor — (minus 1 point)
- A prodrome of nausea and vomiting— (minus 1 point)

Note: Score ≥3 predict higher mortality.

SUMMARY

The evaluation and management of syncope in emergency department are very challenging. First, "syncope" is only one of many causes of TLOC. Second, symptoms are variable, and the patient is usually asymptomatic at the time of evaluation. Third, events are often unwitnessed; or even when witnessed; questions about reliability exist. Finally, there is often an urgent need to carry out diagnostic procedures. Initial risk stratification in emergency department is more likely to give a correct diagnosis. Before prescribing investigation, it is important to spend enough time on history. Despite the difficulties, a thorough evaluation of the cause of syncope is necessary in all patients. The emergency physician must carefully consider whether detected abnormalities are compatible with the clinical circumstances. The goal in every case should be to determine the cause with sufficient confidence to provide a reliable assessment of prognosis and treatment options.

61
CHAPTER

Interpretation of ECG

Kartikeya Bhargava

INTRODUCTION

The electrocardiogram (ECG) is often the first investigation in any patient presenting with symptoms related to cardiovascular disease. Rather, it is seen as an extension of a good history and physical examination in view of its almost universal availability. Emergency physicians are usually the first ones and often the only ones to analyze the ECG performed in a patient presenting in an emergency department. Hence, it is imperative that they should have proficiency in reading and analysis of ECGs so as to arrive at a diagnosis rapidly and take appropriate clinical decisions regarding treatment. The present chapter is not supposed to be a comprehensive review of ECG diagnosis, rather it tries to summarize ECG findings to assist interpretation in a typical patient presenting in the emergency department with symptoms of cardiovascular disorders such as chest or epigastric pain, palpitations, syncope or presyncope, breathlessness, etc. The findings on ECG in certain systemic or noncardiac conditions that can assist in the clinical diagnosis and therapy are also mentioned. *The various groups of cardiovascular conditions in which ECG is of diagnostic value* are listed in **Box 1**.

A systematic approach to read and analyze the ECG is essential to arrive at an accurate diagnosis and the steps (not necessarily in the order given) that can be used in this approach are mentioned in **Box 2**. However, it is important to realize that in an emergency, especially if the patient is hemodynamically unstable, a rapid diagnosis may be needed based on the most significant finding correlated with patient's symptoms and a stepwise approach can be deferred to a later time.

The following sections discuss various ECG patterns grouped according to the ECG findings that may be seen in patients presenting in the emergency department. The description of each finding and its clinical correlation with the cardiovascular disorder is not comprehensively presented but can be found elsewhere in this book.

CARDIAC ARRHYTHMIAS

One of the most common uses of ECG is a diagnosis of an abnormal rhythm. The arrhythmias include disorders with abnormally fast rhythm (tachyarrhythmia) or abnormally slow rhythm (bradyarrhythmia). Sometimes, though an abnormal rhythm may not be present at the time of presentation, but an abnormal finding during sinus rhythm ECG may point to a specific rhythm disorder during the time of symptoms. For example, presence of ventricular preexcitation during sinus rhythm may suggest episodes of supraventricular tachycardia (SVT) in a patient with palpitations. Similarly, presence of left bundle branch block (LBBB) in a patient with history of syncope may suggest intermittent complete atrioventricular (AV) block.

TACHYARRHYTHMIAS

Any rhythm with a rate >100/min qualifies to be called as tachycardia. These can be classified based on the QRS duration and regularity of the ventricular rhythm as shown in **Flowchart 1**. The patients with tachyarrhythmias usually present with complaints of palpitations, presyncope or syncope, breathlessness, and/or chest discomfort. Though, the details regarding the diagnosis of these are beyond the scope of this chapter, a few comments are outlined below for the aid of emergency physician:

BOX 1: Cardiovascular conditions where ECG is likely to be useful.

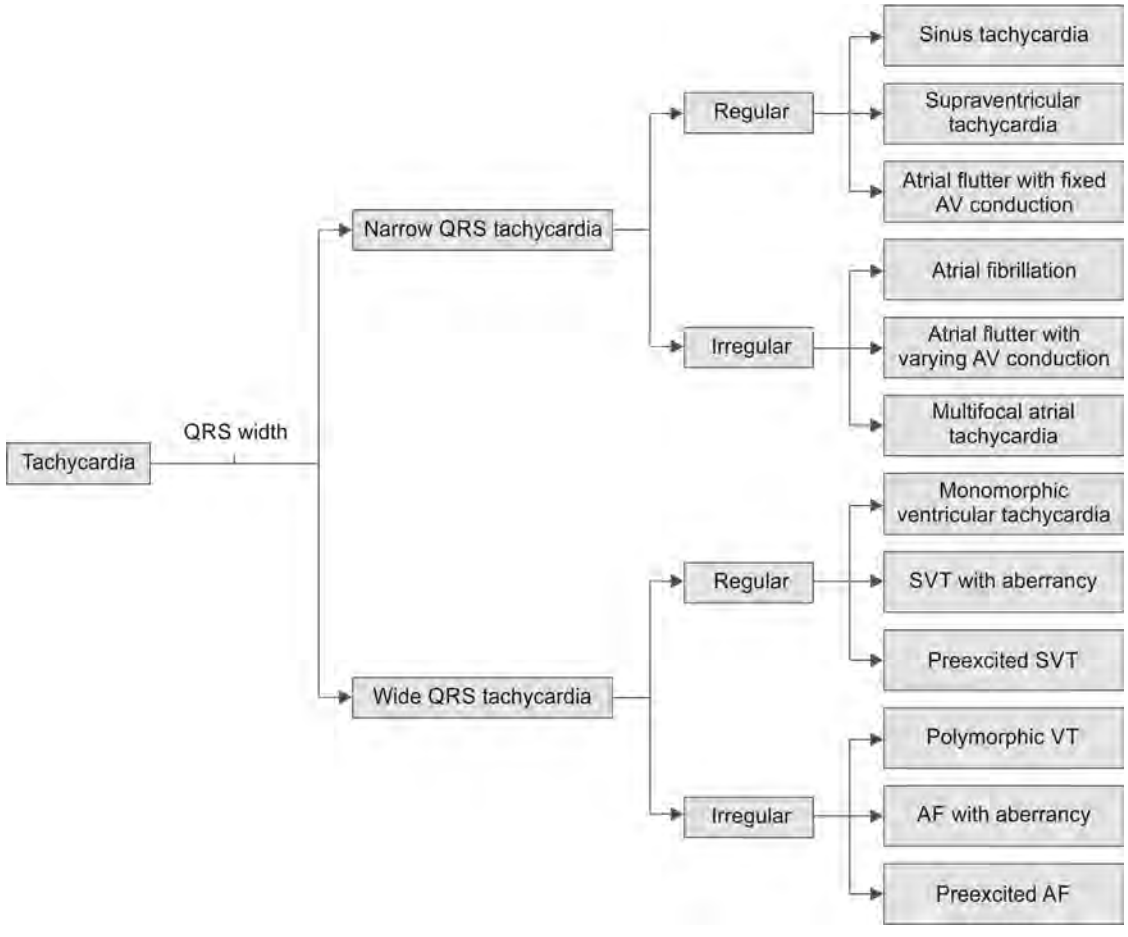
- *Arrhythmias*: Bradycardia-tachycardia, WPW syndrome, Long QT syndrome, and others
- *Acute coronary syndrome*: STEMI, NSTEMI, and noncoronary causes of ST elevation
- *Miscellaneous nonarrhythmic cardiac emergencies*: Aortic dissection, acute pulmonary embolism, and acute pericarditis
- *ECG in systemic conditions presenting in emergency*: Electrolyte imbalance—hypokalemia, hyperkalemia, hypocalcaemia, hypercalcemia, hemorrhagic stroke, pericardial effusion, myxedema cor pulmonale due to COAD, drug effects and toxicities

(ECG: electrocardiogram; COAD: chronic obstructive airway disease; STEMI: ST elevation myocardial infarction; WPW: Wolff–Parkinson–White)

BOX 2: Steps in systematic analysis of ECG.

- *Rate and rhythm*: Rate is estimated by 1,500/small square between two consecutive R wave. If distance between R-R and P-P is same then rhythm is regular
- Relationship between *P waves and QRS complexes, PR interval*: Every P wave is followed by QRS complex, PR interval extends from end of the P wave to beginning of the QRS complex (PR duration 0.12-0.20 second)
- *QRS duration, morphology and amplitude*: Presence of bundle branch block (BBB) or intraventricular conduction defect (IVCD), and ventricular preexcitation; pathological Q waves; left or right ventricular enlargement or hypertrophy, fragmentation, and notches
- *ST segment and T wave abnormalities*: ST segment elevation or depression; early repolarization pattern; T wave inversion, flattening, tall and pointed patterns, etc.
- *QRS axis* in the frontal plane and fascicular blocks
- *P wave morphology*: Site of atrial origin, left or right atrial enlargement/hypertrophy patterns
- *Intervals:* PR interval, QT interval, PP, and RR intervals
- *Miscellaneous*: Paced ECG interpretation, disease specific diagnostic patterns—acute pulmonary embolism, arrhythmogenic right ventricular dysplasia (ARVD), electrolyte imbalance, etc.
- *Correlate with patient signs and symptoms*

- *Sinus tachycardia* is identified by gradual onset (history), normal or reduced PR interval, and a P wave morphology suggestive of sinus node origin (negative in lead aVR, positive in leads I, II, III, aVF, and biphasic in lead V1). It is usually secondary to some other underlying cause that can be physiological (anxiety, fever, and pregnancy) or pathological (pulmonary embolism, myocardial ischemia, etc.).
- *Paroxysmal SVT (PSVT)* starts abruptly and presents with symptoms of palpitations. It shows regular RR intervals with rate varying from 140 to 220 beats/min. The various subtypes of PSVT (**Figs. 1** to **3**) can also be inferred from the ECG based on the location of the P waves in the cardiac cycle, however, since the acute treatment of different sub forms of the PSVTs is more or less same, their identification is not of paramount importance in the emergency. The QRS complexes during SVT are usually narrow, however, preexisting BBB or transient aberrant conduction can result in wide QRS complexes during SVT. The clue lies in the fact that the QRS morphology is typical of either right or left BBB in SVT with aberrancy.
- *Atrial flutter* can be recognized by rapid atrial rate (220–350 beats/min, usually 300 beats/min) with P waves of single morphology occurring in a saw-tooth pattern without any isoelectric line between them. The ventricular rate and rhythm depend on the AV conduction pattern and can be rapid or controlled and regular or irregular.



FLOWCHART 1: Classification of tachyarrhythmias.

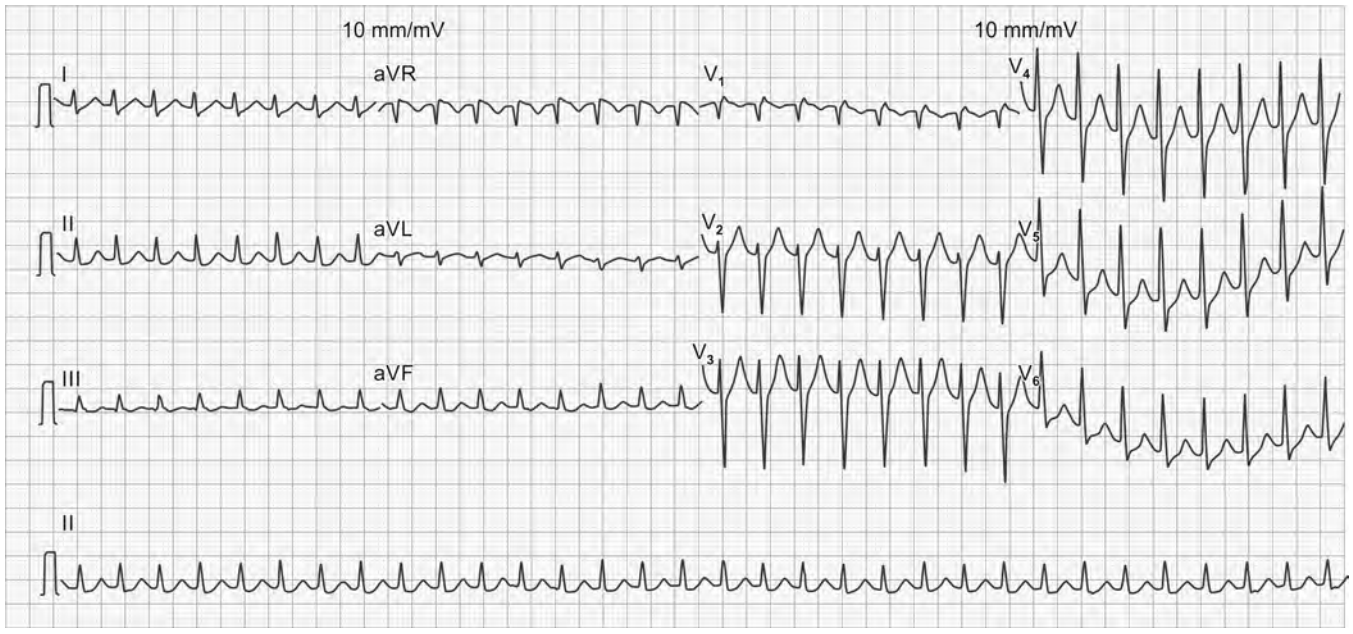


FIG. 1: Paroxysmal supraventricular tachycardia (PSVT) due to atrioventricular nodal reentrant tachycardia (AVNRT). A regular narrow QRS tachycardia with QRS morphology that is normal is diagnostic of PSVT. Note the lead V_1 shows a small positive deflection similar to r′ after the S waves that suggest presence of P waves occurring just at the end of the QRS complex. These P waves may also be visible as small negative deflections in leads II, III, and aVF immediately at the end of QRS. This location of P waves during PSVT indicates a diagnosis of AVNRT—the most common mechanism of PSVT.

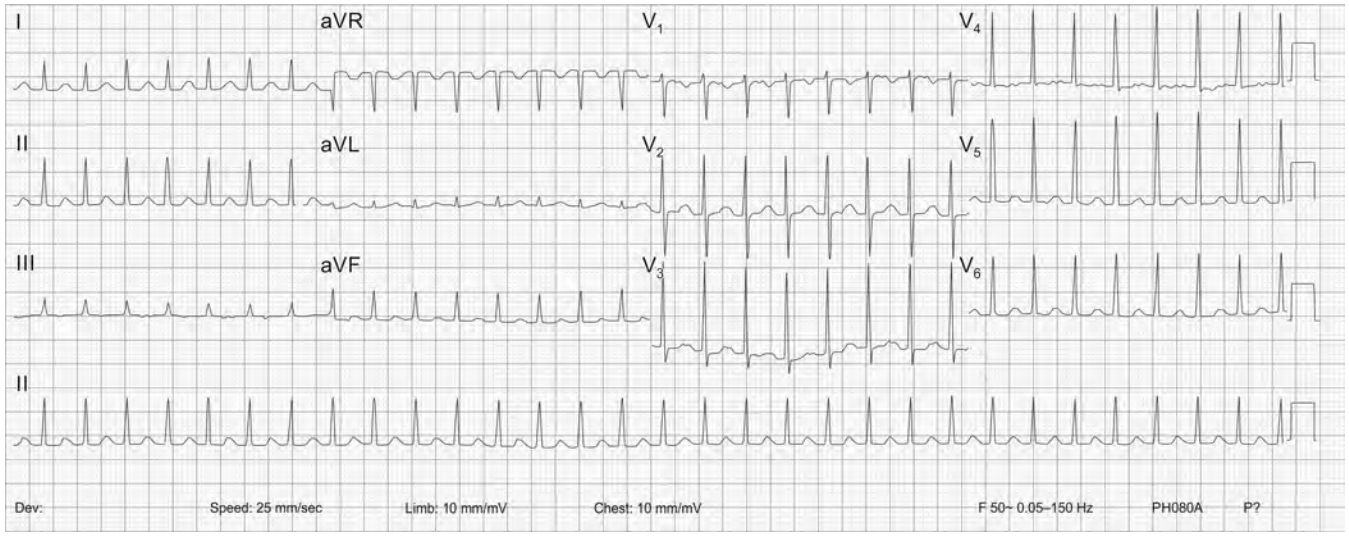

FIG. 2: Paroxysmal supraventricular tachycardia (PSVT) due to atrioventricular reciprocating tachycardia (AVRT). Another example of regular narrow QRS tachycardia where the P waves are seen in the ST segment. The most common mechanism of this pattern is AVRT wherein the reentrant circuit involves antegrade conduction over the normal AV node—His-Purkinje system and retrograde conduction over an accessory pathway. A similar pattern of ECG can also occur in a focal atrial tachycardia, however, that is much less common.

- *Atrial fibrillation* presents with rapid irregular ventricular rhythm with P waves that is either not visible or exist as small, nonuniform undulations (fibrillatory waves). The QRS complexes are usually narrow but can be wide if there is aberrant intraventricular conduction (transient BBB), preexisting BBB (**Fig. 4**) or ventricular preexcitation. The clue to recognition of atrial fibrillation is markedly irregular RR intervals.
- *Monomorphic ventricular tachycardia (MMVT)* presents as a regular wide QRS tachycardia. It is the most common cause of wide QRS tachycardia in clinical setting and its diagnosis is even more likely if the patient has structural heart disease or prior myocardial infarction (MI) (**Figs. 5** to **7**). The ECG pointers to a diagnosis of MMVT as against the other differential diagnosis of SVT with aberrancy include AV dissociation, fusion and capture beats, wider QRS [(>140 ms with right bundle branch block (RBBB) type and >160 ms with LBBB type)], precordial concordance (**Fig. 5**), and northwest axis of the QRS in the frontal plane. Though, many algorithms exist to help in differentiation of MMVT

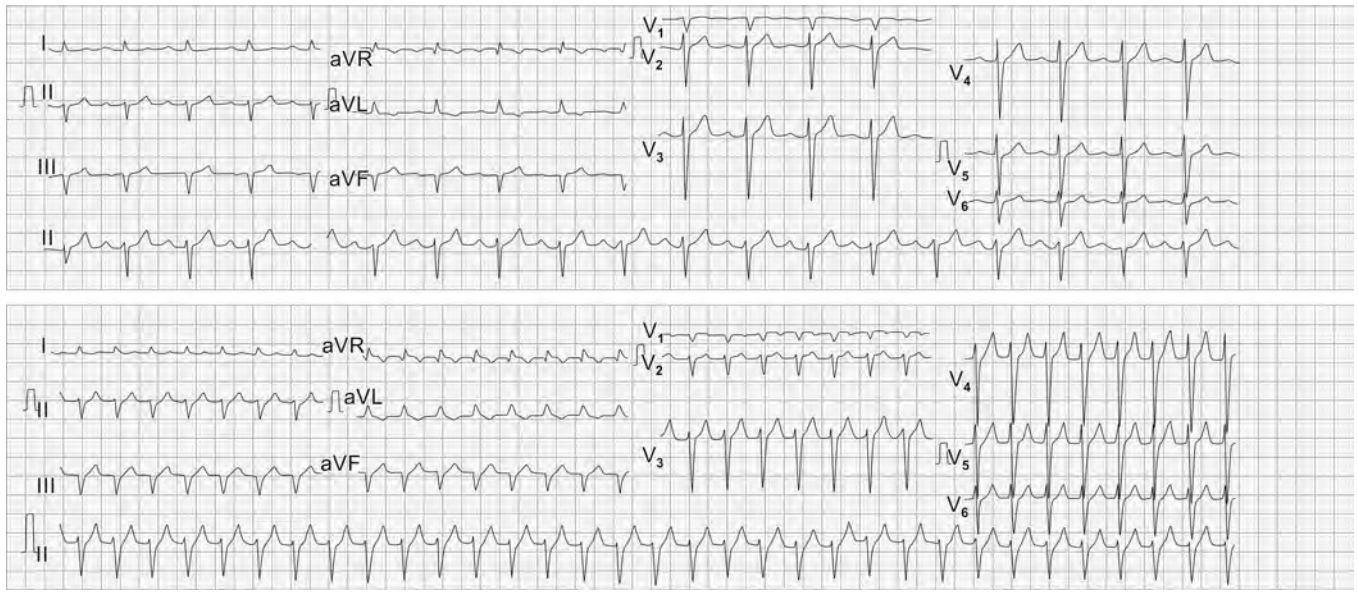

FIG. 3: ECGs of sinus rhythm (top panel) and paroxysmal supraventricular tachycardia (PSVT) (bottom panel) showing identical QRS morphology. Note that in both panels, the 12-lead ECG is displayed at half voltage (5 mm/mV) resulting in small QRS amplitude. The rhythm strips in both panels display lead II at standard 10-mm/mV voltage. The sinus rhythm ECG was recorded immediately after termination of PSVT with injection of metoprolol that also explains prolonged PR interval during sinus rhythm. The P waves are not visible during the regular narrow QRS PSVT suggesting atrioventricular nodal reentrant tachycardia (AVNRT) as the likely diagnosis.

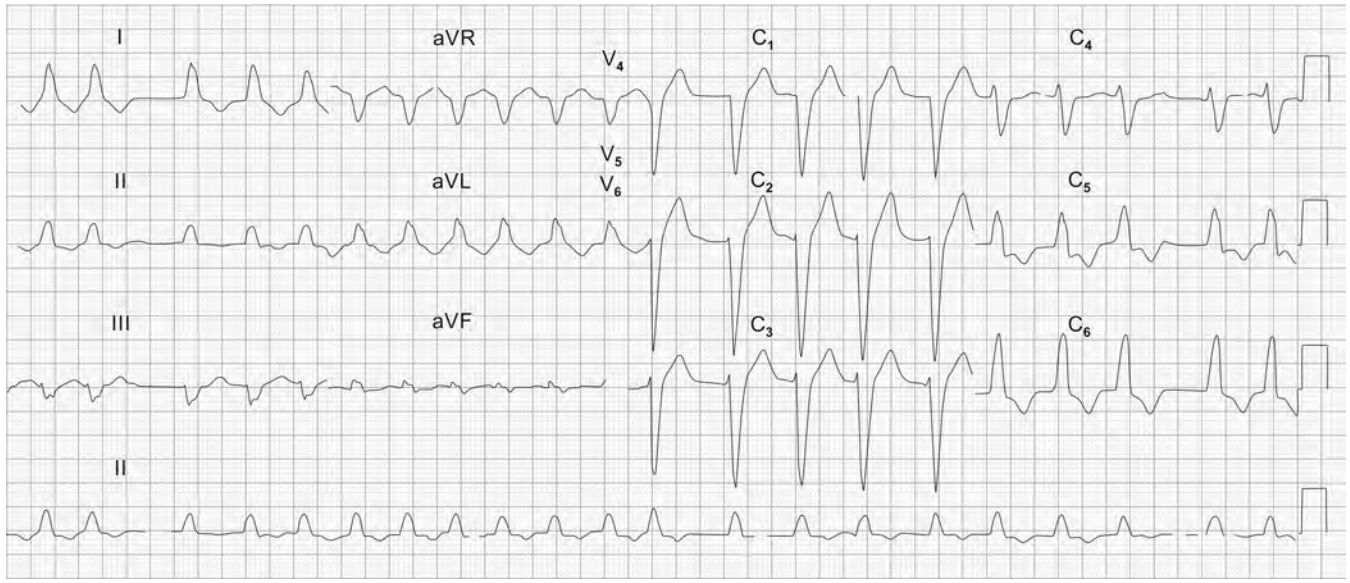

FIG. 4: Atrial fibrillation with aberrant conduction. Irregular wide QRS complex tachycardia with predominantly negative QRS complexes in lead V_1 [left bundle branch block (LBBB) type] with no identifiable P waves indicating a diagnosis of atrial fibrillation. The typical LBBB morphology of the QRS suggests aberrant intraventricular conduction rather than ventricular tachycardia. Also, marked irregularity of RR intervals clinches the diagnosis of AF.

from SVT with aberrancy; the history of prior infarction, QRS morphology not resembling typical LBBB or RBBB, and QRS morphology different from baseline indicate a diagnosis of ventricular tachycardia.

- *Preexcited SVT*—any SVT can present as a wide QRS complex tachycardia in patients with ventricular preexcitation or Wolff–Parkinson–White (WPW) syndrome. The QRS morphology does not resemble that during sinus rhythm or typical BBB but suggests the location of commonly found accessory pathways. The sinus rhythm ECG (of prior times or recorded after termination of SVT) shows typical preexcitation pattern with short PR interval, delta waves, and wide QRS complexes.
- *Polymorphic ventricular tachycardia (VT)* presents as an irregular tachycardia with wide QRS complexes with marked variation in the morphology of the QRS complexes from beat to beat. If the tachycardia is sustained, the patient is usually hemodynamically unstable. It can exist in the presence of normal QT interval, but is more common with QT interval prolongation, when it is known as *Torsades*

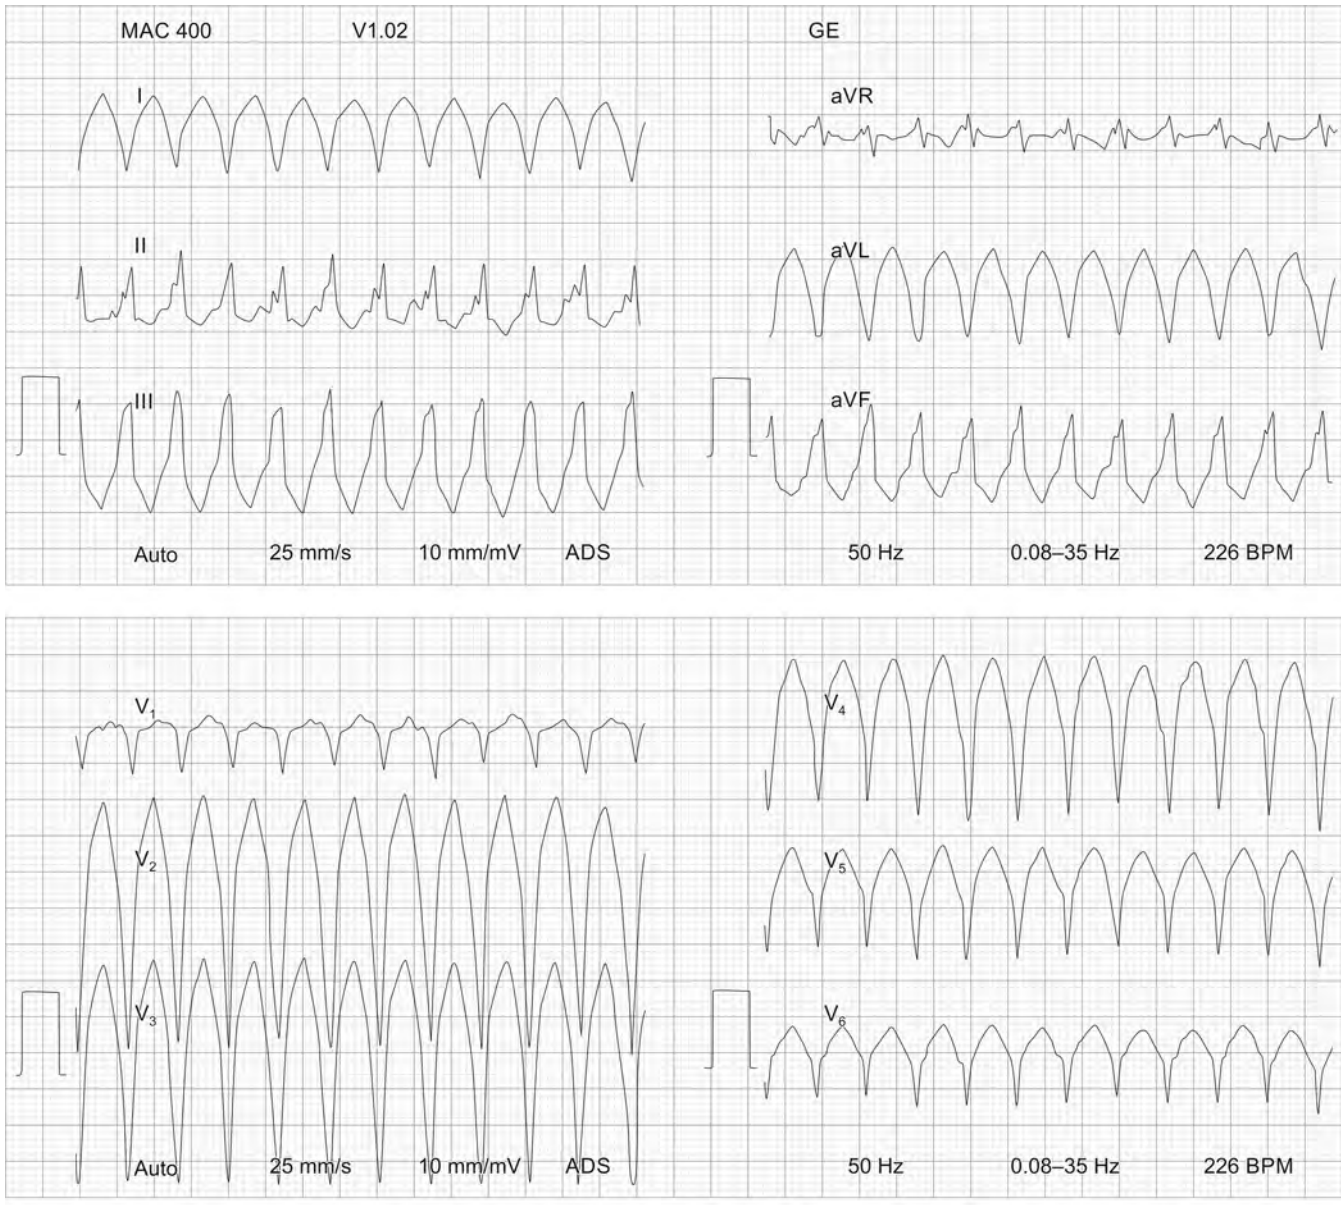

FIG. 5: Ventricular tachycardia (VT) in a patient with prior myocardial infarction (MI). A regular wide QRS tachycardia with predominantly negative QRS complexes in V_1 [left bundle branch block (LBBB) type] is displayed. The clues to the diagnosis of VT include history of prior MI, atrioventricular dissociation (best seen in V1), negative concordance of QRS in the precordial leads, axis-morphology discordant pattern (LBBB morphology with right axis deviation of QRS in the frontal plane) and QRS morphology not resembling typical LBBB.

de pointes due to appearance on the ECG as if the QRS complexes are twisting around a point or line.

BRADYARRHYTHMIA

The normal heart rate in an adult person at rest varies from 60 to 100 beats/min. Any rhythm where the heart rate is <60 beats/min is known as bradyarrhythmia. *AV block of second or higher degree even with a ventricular rate > 60 beats/min is classified as bradyarrhythmia*. These rhythm disorders can occur due to either sinus node dysfunction (disorder or impulse formation or conduction) or AV block (disorder of impulse conduction). The patients with bradyarrhythmia usually present with complaints of syncope or presyncope, weakness or fatigue, and/or breathlessness on exertion. Though**,** *commonly these rhythm disorders occur as a result of degenerative diseases of the electrical system*, at times *reversible causes such as drugs, electrolyte imbalance, or acute myocardial ischemia or infarction* (**Fig. 8**) may be the causative mechanism:

- Sinus node dysfunction can present as sinus pauses, sinus arrest with junctional or ventricular escape beats and rhythm, sinus bradycardia, or sinoatrial exit block (**Fig. 9**). Other ECG manifestations that may be found in patients with so called sick sinus syndrome include AV block, BBB, atrial fibrillation, and episodes of bradycardia alternating with tachycardia (tachybrady syndrome).
- Atrioventricular block presents as delay in conduction (prolonged PR interval, first degree AV block) or block

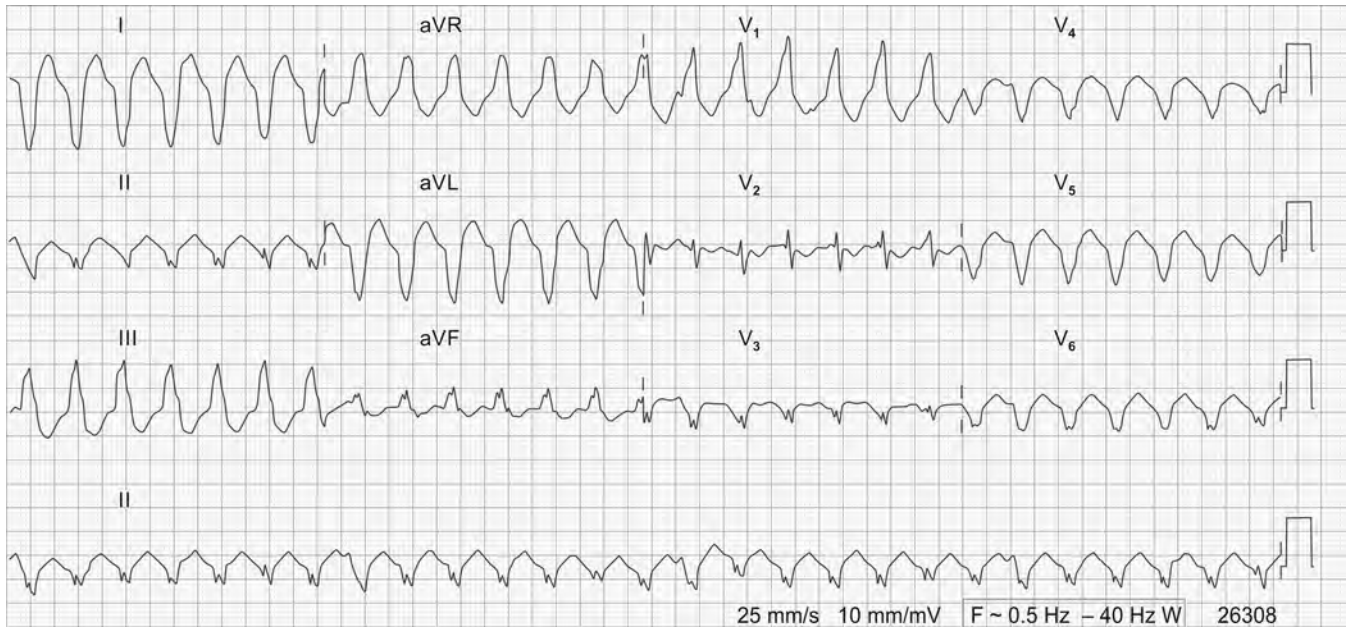

FIG. 6: Ventricular tachycardia (VT) in a patient with idiopathic dilated cardiomyopathy. A regular wide QRS tachycardia with predominantly positive QRS in lead V_1 [right bundle branch block (RBBB) type] is shown. The clues to the diagnosis of VT include atrioventricular dissociation (best seen in rhythm strip of lead II), markedly wide QRS complexes, Q waves in lead V_6 and QRS morphology not resembling typical RBBB among many others. Note that the QRS looks deceptively narrow in lead V_2 and an erroneous diagnosis of supraventricular tachycardia can be made if this lead is chosen as the only monitoring lead and a 12-lead ECG is not recorded.

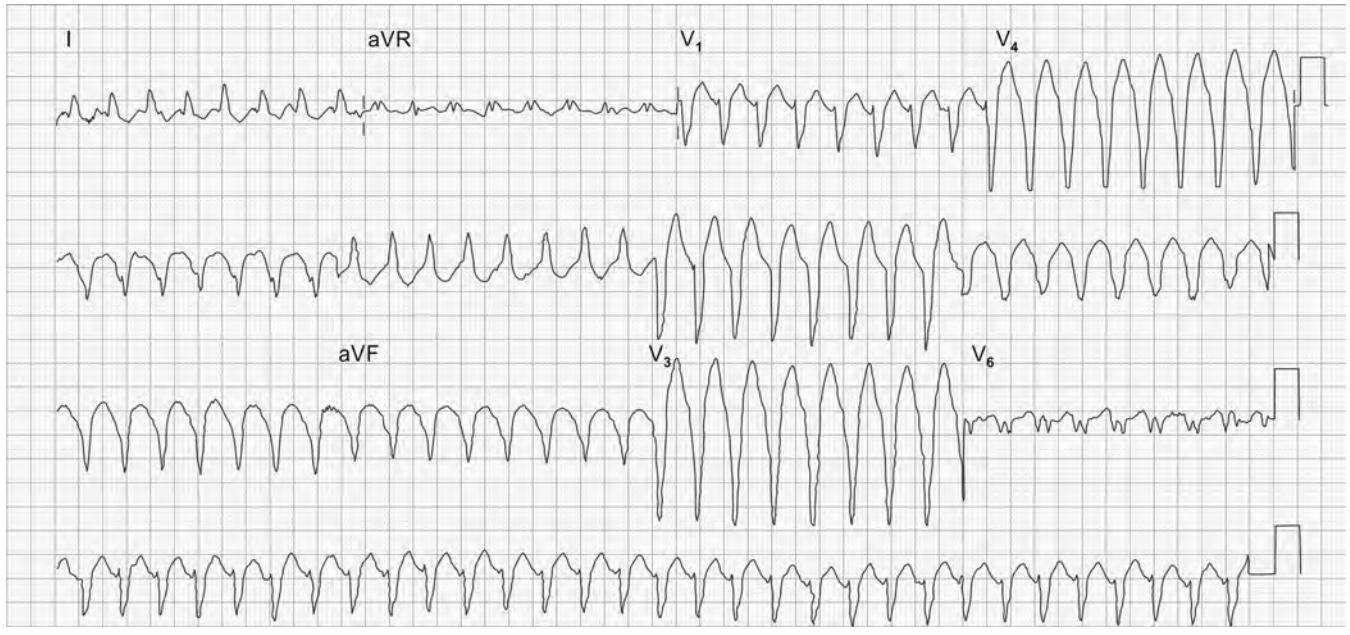

FIG. 7: Ventricular tachycardia (VT) in a patient with arrhythmogenic right ventricular dysplasia (ARVD). A regular wide QRS tachycardia with left bundle branch block (LBBB) type pattern and left axis of the QRS in the frontal plane is shown. The presence of AV dissociation (seen best in rhythm strip of lead V1) and negative precordial concordance clinches the diagnosis of VT. Note that during LBBB type VTs, left axis deviation of QRS complex is suggestive of ARVD as the underlying diagnosis, whereas a right axis deviation is more common with idiopathic outflow tract VTs.

of some (second degree, **Fig. 10**) or all (third degree or complete AV block, **Fig. 11**) atrial impulses to the ventricles. The need for temporary and permanent pacemaker implantation depends on the presence and severity of symptoms, presence of reversible causes, ventricular rate, QRS width, and underlying heart disease.

ST-T CHANGES

ST Segment Deviation

ST segment is the deflection from the end of QRS complex to the onset of T wave and is normally isoelectric. Deviation

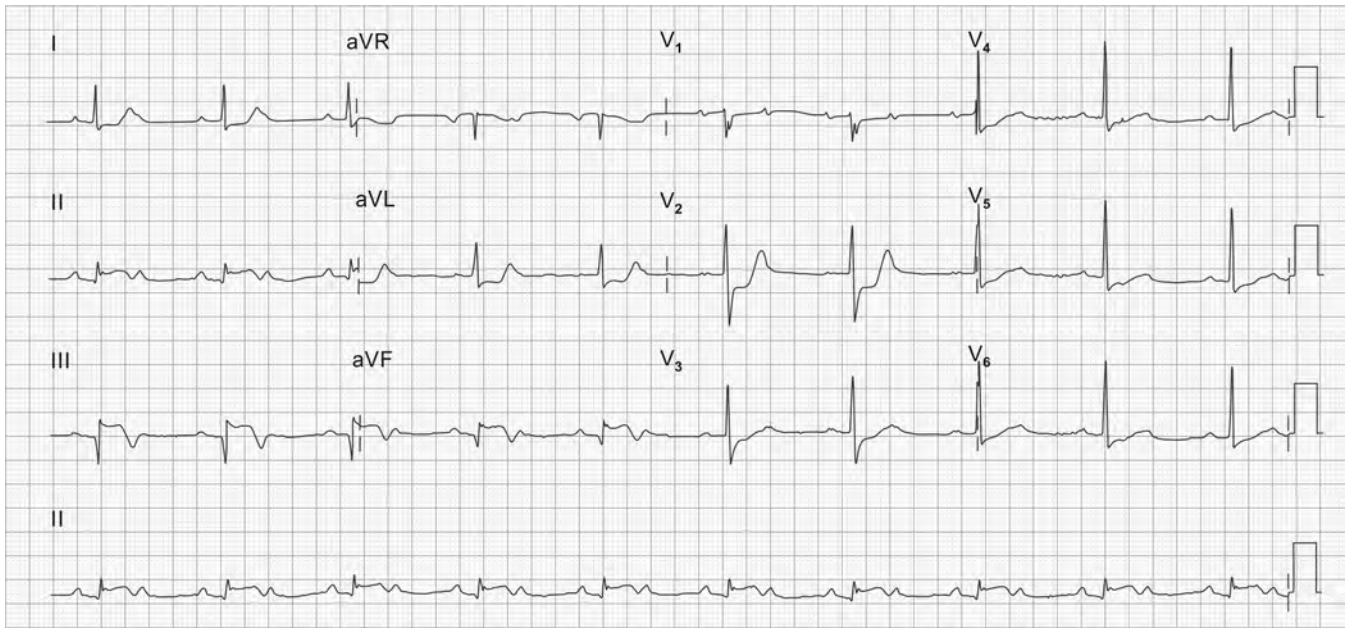

FIG. 8: Acute inferior-posterior myocardial infarction (MI). Sinus rhythm with 2–1 atrioventricular block with narrow QRS complexes in the conducted beats is seen. The leads II, III, and aVF show ST segment elevation with prominent Q waves indicating acute evolving inferior wall MI. Notice that large R wave in lead V_2 with marked ST depression suggests presence of concomitant posterior wall MI. ST segment elevation that is greater in lead III than in lead II indicate involvement of the right coronary artery and presence of AV block suggests a proximal location of the culprit lesion.

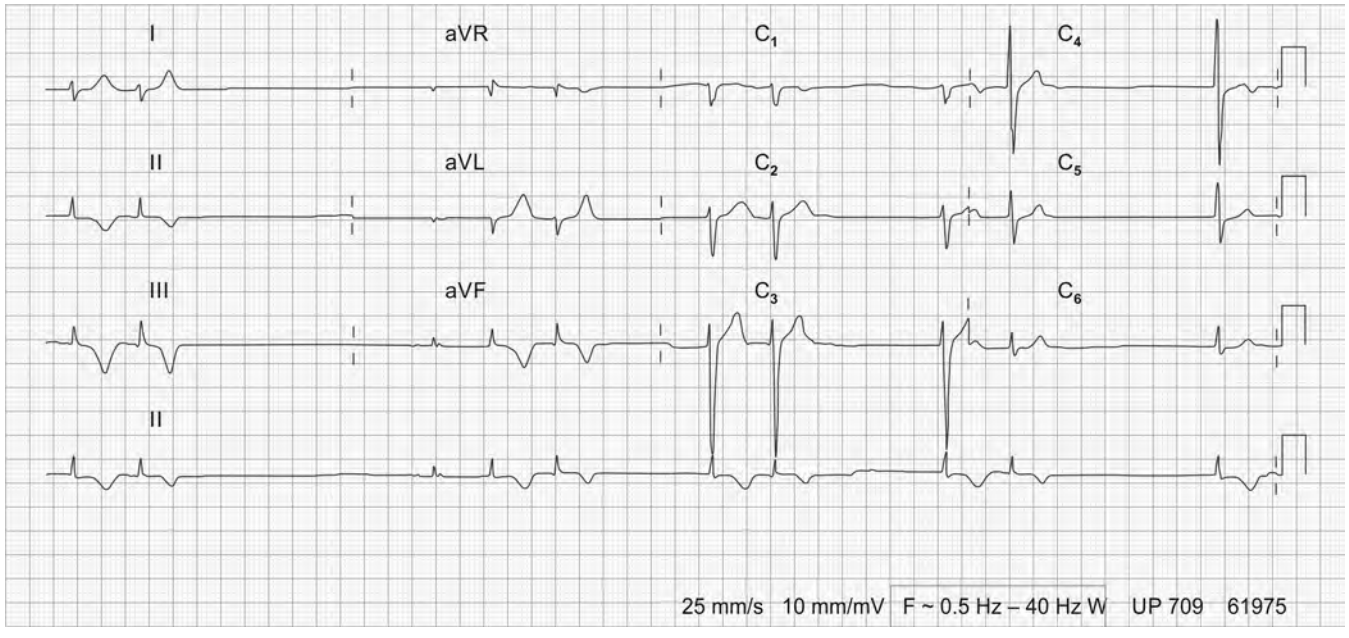

FIG. 9: Sinus node dysfunction. An ECG showing sinus pauses and junctional escape beats and rhythm in a patient with sinus node dysfunction is displayed. Also, note that marked T wave inversion in inferior leads that could be either due to underlying heart disease (for example, myocardial ischemia) or due to cardiac memory as a result of prior persistent ventricular escape rhythm. Also present in this tracing is possibly left posterior fascicular block (right axis deviation of QRS; qR pattern in leads II, III, and aVF; and rS pattern in leads I and aVL).

of the ST segment upward (ST elevation) or downward (ST depression) in various ECG leads is an important sign of many heart diseases the most important of which is coronary artery disease. In fact, presence or absence of ST segment elevation is a means of classifying acute MI into ST elevation MI (STEMI) or non-ST elevation MI. Few important points are provided below in reference to ST segment deviation and its utility in the emergency:

- The ECG leads can be grouped according to the location of the ventricles that they overlie. These are known as contiguous leads and include:
  - *Inferior wall*—Leads II, III, and aVF
  - *Anterior wall*—Leads V_1 to V_6
  - *Antero-lateral wall*—V_4 to V_6, I, and aVL
  - *Antero-septal wall* —V_1 to V_3, aVR

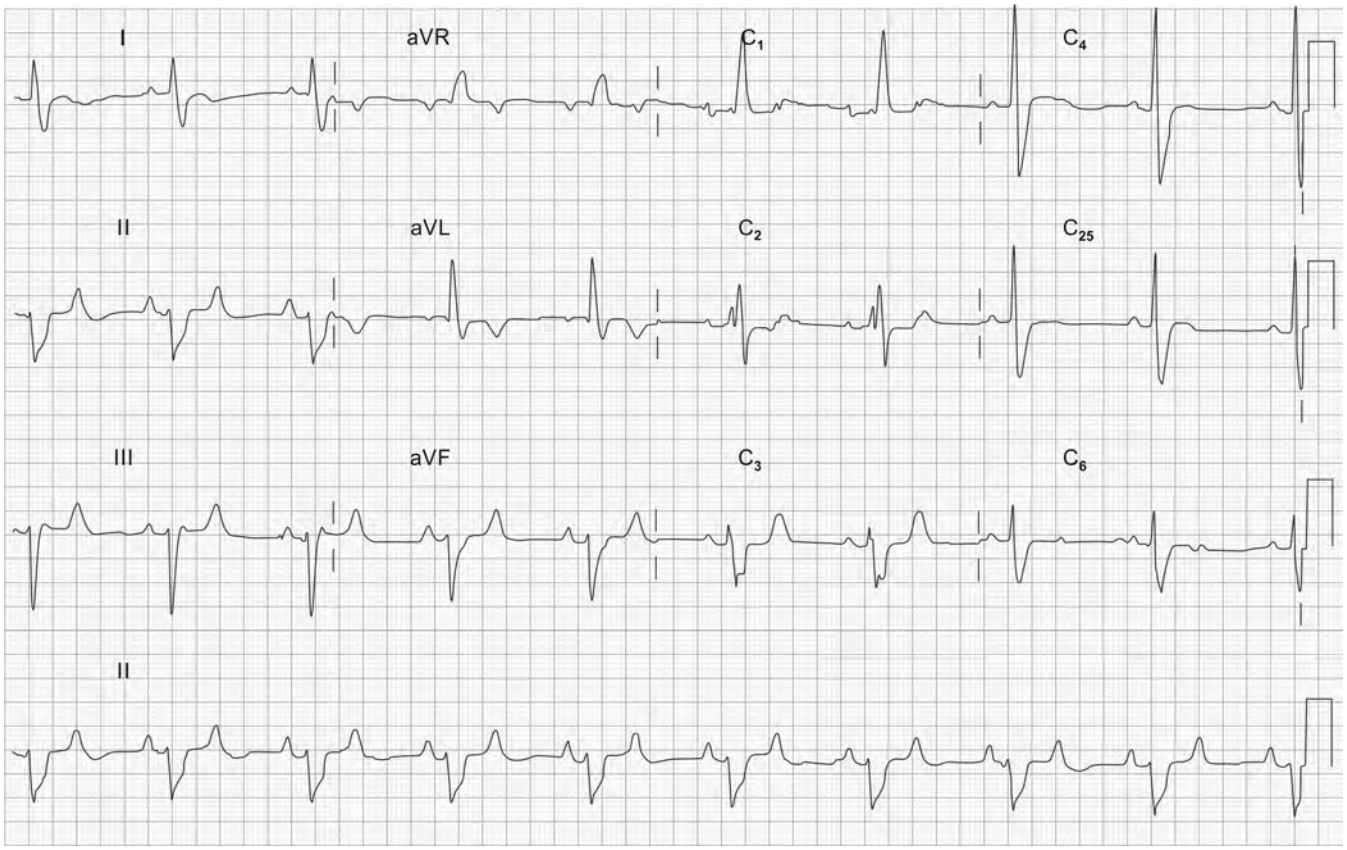

FIG. 10: *Two to one AV block*. Sinus tachycardia with 2 to 1 AV block with RBBB and LAFB in the conducted beats is seen. Notice that there are two P waves for each QRS complex, and the PR intervals of the conducted beats are constant as are PP and RR intervals. A wide QRS complex in the conducted beat (RBBB in this case) suggests infra-Hisian location of the AV block and need for permanent pacemaker implantation even in the absence of bradycardia-related symptoms.

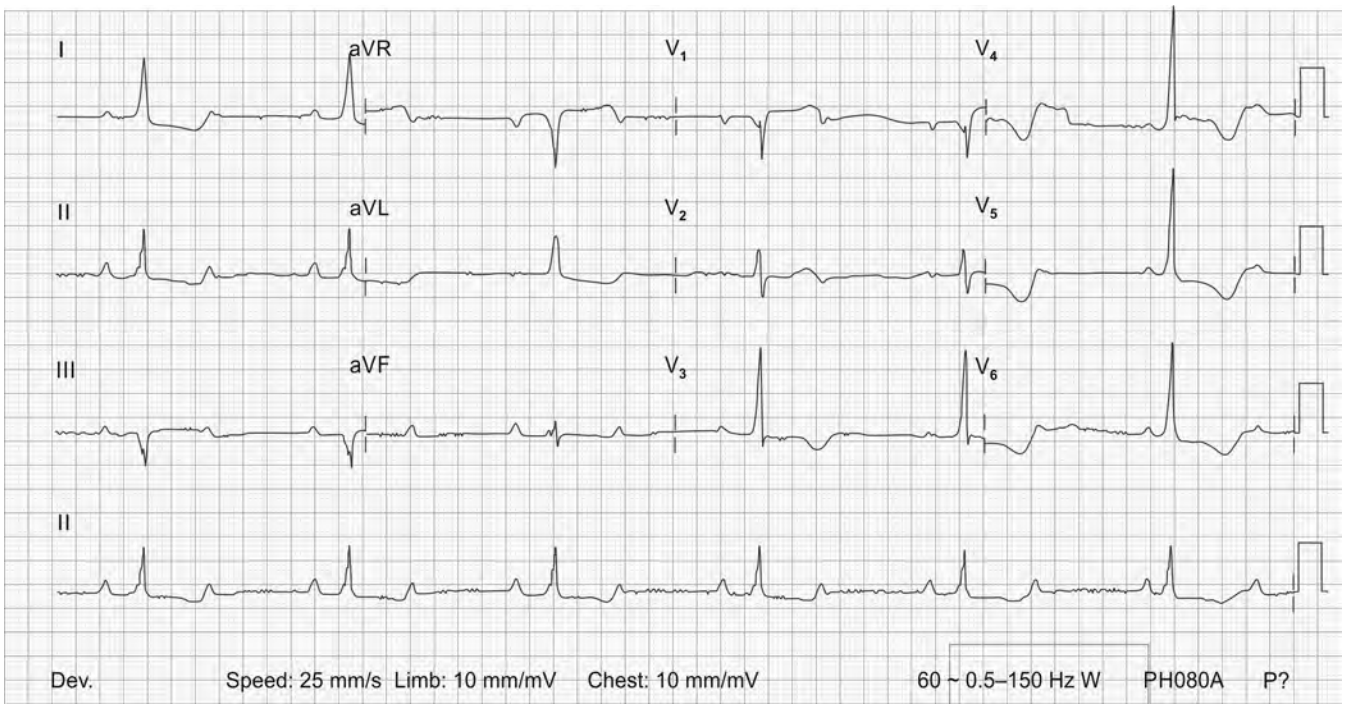

FIG. 11: *Complete AV block*. Sinus rhythm with complete AV block and a slower wide QRS (ventricular) escape rhythm is seen. Note that the P waves occur at a much faster rate, and have no association with the QRS complexes (AV dissociation). The clue to the presence of AV dissociation is varying apparent PR intervals in the presence of constant RR and PP intervals.

- *Right ventricle*—right-sided precordial leads V_1 to V_6
- *Posterior wall*—Leads V_7 to V_9.

- ST elevation of 1 mm (0.1 mV) or greater in two or more contiguous leads in a patient with chest discomfort is indicative of STEMI (**Figs. 8** and **12**). A prompt recognition of STEMI suggests the need of emergency reperfusion therapy in the form of either primary angioplasty or thrombolysis.
- ST elevation and depression both are suggestive of myocardial ischemia. ST elevation has localizing value but ST depression does not. Hence, ST elevation in leads II, III, and aVF indicates acute inferior wall MI. ST depression in these leads may indicate myocardial ischemia but not necessarily in inferior wall of the left ventricle.
- Serial changes in ECGs taken over time have more importance than fixed changes.
- The ECG not only has value in diagnosis of MI but also helps in localization of infarct, culprit artery localization, estimation of infarct size, timing of infarction, risk stratification, and prognostication.
- Various other causes of ST elevation apart from STEMI exist and should be considered if diagnosis of MI is doubtful. These are listed in **Box 3**.
- ST segment depression indicates myocardial ischemia especially if it is >1 mm, present in two or more contiguous leads, of horizontal or down-sloping (rather than upsloping) nature or if associated with marked T wave changes.
- ST segment depression of <1 mm especially if present in the absence of typical chest discomfort is commonly nonspecific and is seen in a variety of clinical conditions.

T Wave Changes

The T wave represents part of the recovery period of the ventricles (repolarization). The T wave is normally upright in leads I, II, and V_4 to V_6; inverted in aVR; usually upright in aVF and can be variable in III, aVL, and V_1. The T wave changes can often be nonspecific and should always be interpreted along with the ST segment abnormalities and clinical setting. The common T wave abnormalities are described in **Box 4**.

BOX 3: Noninfarction causes of ST segment elevation.

- Acute pericarditis
- Coronary artery spasm
- Left ventricular aneurysm
- Left bundle branch block
- Left ventricular hypertrophy
- Early repolarization syndrome
- Hypertrophic cardiomyopathy
- Acute pulmonary embolism

BOX 4: T wave abnormalities.

- T wave inversion associated with ST segment deviation and/or abnormal Q waves—myocardial ischemia or infarction, digitalis effect, or toxicity (**Fig. 13**)
- Diffuse deep T wave inversion (usually nonspecific and seen in variety of conditions)—myocardial ischemia, evolving MI, apical or hypertrophic cardiomyopathy, cardiac memory, electrolyte imbalance, and cerebrovascular accidents
- Asymmetric T inversion in lateral precordial leads—left ventricular hypertrophy
- Asymmetric T inversion in right precordial leads—right ventricular hypertrophy and acute pulmonary embolism
- Peaked T waves in precordial leads—hyperkalemia
- Peaked T waves in V_1 and V_2 with positive QRS complexes—*posterior wall MI*

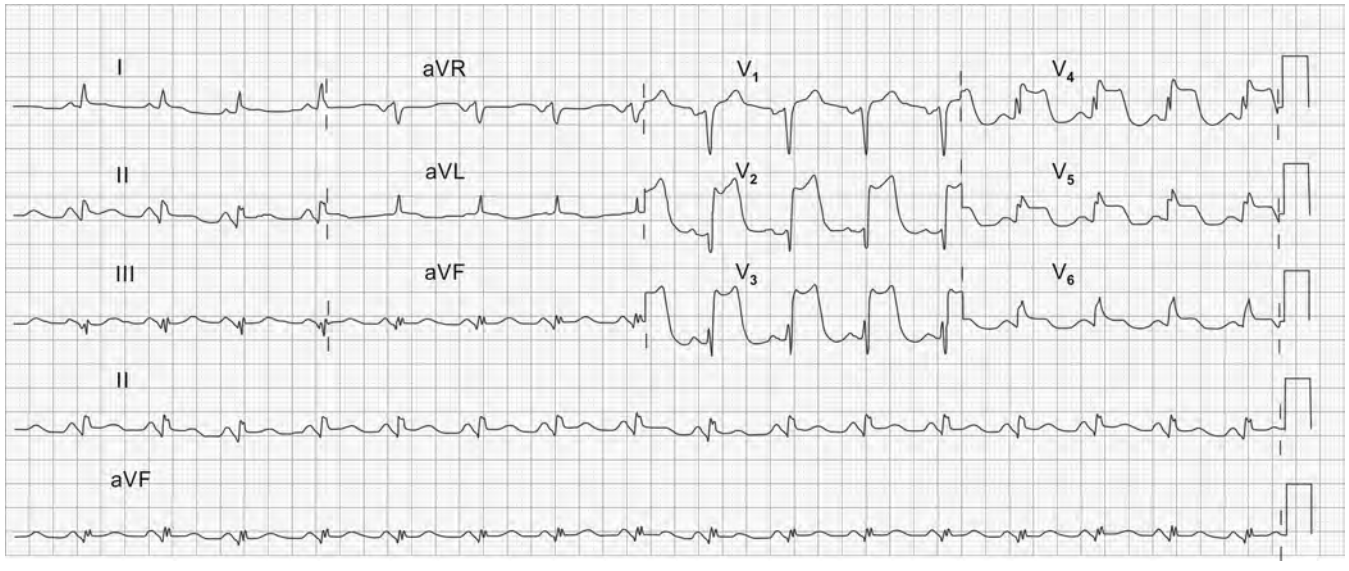

FIG. 12: *Acute anterior wall myocardial infarction (MI)*. Marked ST elevation is seen in precordial leads V_2 to V_6 indicating acute anterior wall MI and involved of left anterior descending (LAD) coronary artery. Notice, that the inferior leads also show ST segment elevation. This pattern suggests that the site of culprit lesion in the LAD artery is distal to the origin of the septal and diagonal branches. Hence, ECG not only helps in diagnosis but indicates the culprit vessel and localizes the site of lesion.

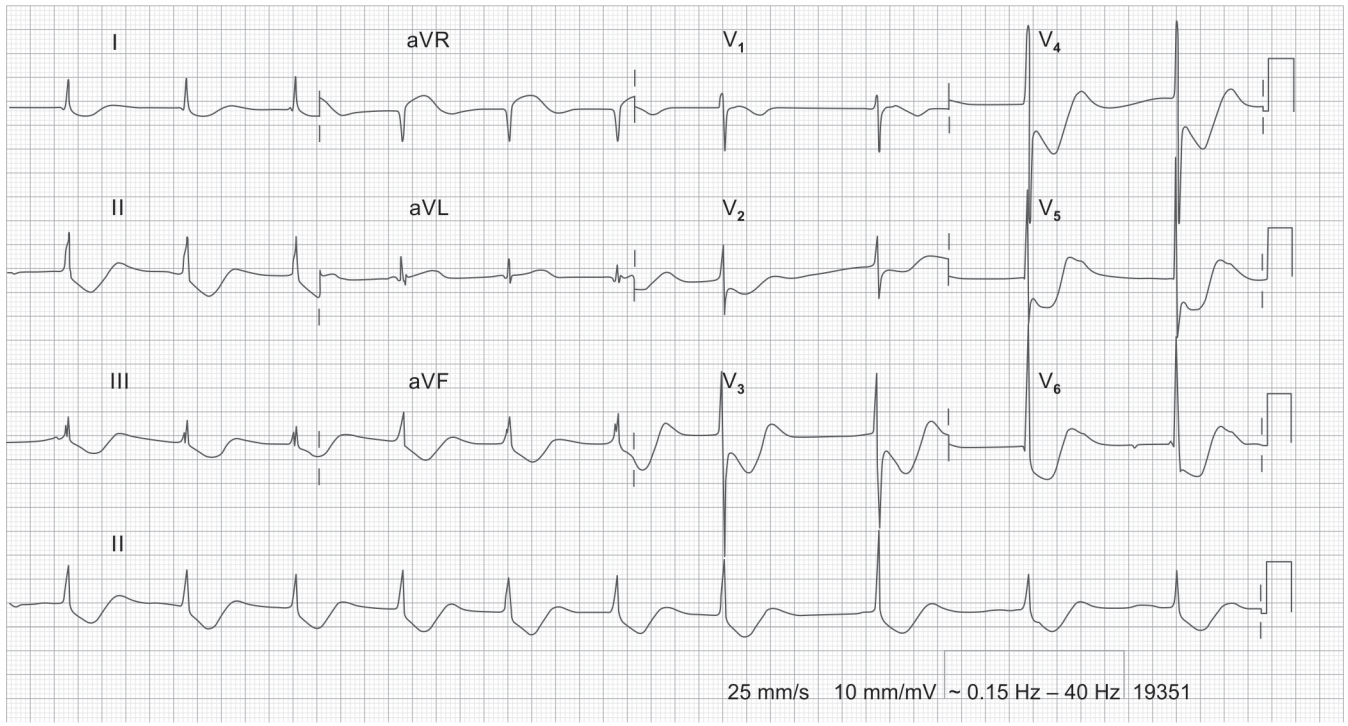

FIG. 13: *Digitalis toxicity. This is an ECG of a patient with permanent AF and digitalis toxicity*. The P waves are absent and the ventricular rhythm is irregular with narrow QRS complexes. Importantly there is marked ST segment depression with T wave inversion in most leads. Note, that the J point (end of QRS) is also markedly depressed in leads V_3 to V_6 that differentiates it from digitalis *effect* wherein the ST depression and T wave inversion are present without J point depression. Note is also made of large amplitude R waves in V_5 and V_6 due to underlying left ventricular hypertrophy.

QRS MORPHOLOGY AMPLITUDE DURATION AND AXIS PATTERN

The normal coordinated simultaneous activation of both right and left ventricle is responsible for *normal QRS complex that is narrow (QRS duration < 100 ms), has normal axis in the frontal plane, and has normal amplitude in various leads (in absence of normal left and right ventricular thickness)*.

Delay or block in conduction of left or the right bundle branches results in sequential activation of the ventricles with resultant right or left BBB pattern. The block in conduction of the left anterior and posterior fascicles (*see* **Fig. 9**) does not result in QRS widening but causes change in the QRS axis in the frontal plane. The diagnostic criteria for left and right BBB and fascicular blocks are summarized in **Box 5**. A diagnosis of BBB especially LBBB (**Fig. 14**) or bifascicular block in a patient presenting with history of syncope or presyncope may suggest intermittent complete AV block as the cause and requirement of additional evaluation and possible pacemaker implantation. All physicians should have an imprint of typical LBBB and RBBB patterns inscribed in their minds for an accurate diagnosis of many arrhythmias.

Similarly, presence of an antegrade conducting accessory pathway *(WPW syndrome)* (**Fig. 15**) results in preexcitation of the ventricle in which it is inserted resulting in sequential activation of ventricles. The QRS complex in this situation of ventricular preexcitation occurs as a result of fusion of activation of ventricles by the accessory pathway and the

BOX 5: Diagnostic criteria for left and right BBB and fascicular blocks.

Left bundle branch block (LBBB):
- QRS duration > 120 ms
- Wide notched R waves in V_5, V_6, I, and aVL
- Small or absent initial r wave in right precordial leads V_1 and V_2 followed by deep S waves
- Absent septal Q waves in left-sided leads V_6 and lead I
- Prolonged intrinsicoid deflection (>60 ms) in V_5 and V_6

Right bundle branch block (RBBB):
- QRS duration > 120 ms
- Wide notched R waves (rsr′, rsR′, or rSR′ patterns in right precordial leads—V_1 and V_2
- Wide and deep S waves in left precordial leads—V_5 and V_6
- Bifascicular block—RBBB and LAFB/RBBB and LPFB

Left anterior fascicular block (LAFB):
- Left axis deviation (QRS axis in the frontal plane –45 to –90°)
- rS pattern in leads II, III, and aVF
- qR pattern in lead aVL
- QRS duration < 120 ms

Right anterior fascicular block (RAFB):
- Right axis deviation (QRS axis in frontal plane > 120°)
- qR pattern in leads II, III, and aVF
- rS pattern in leads I and aVL
- QRS duration < 120 ms

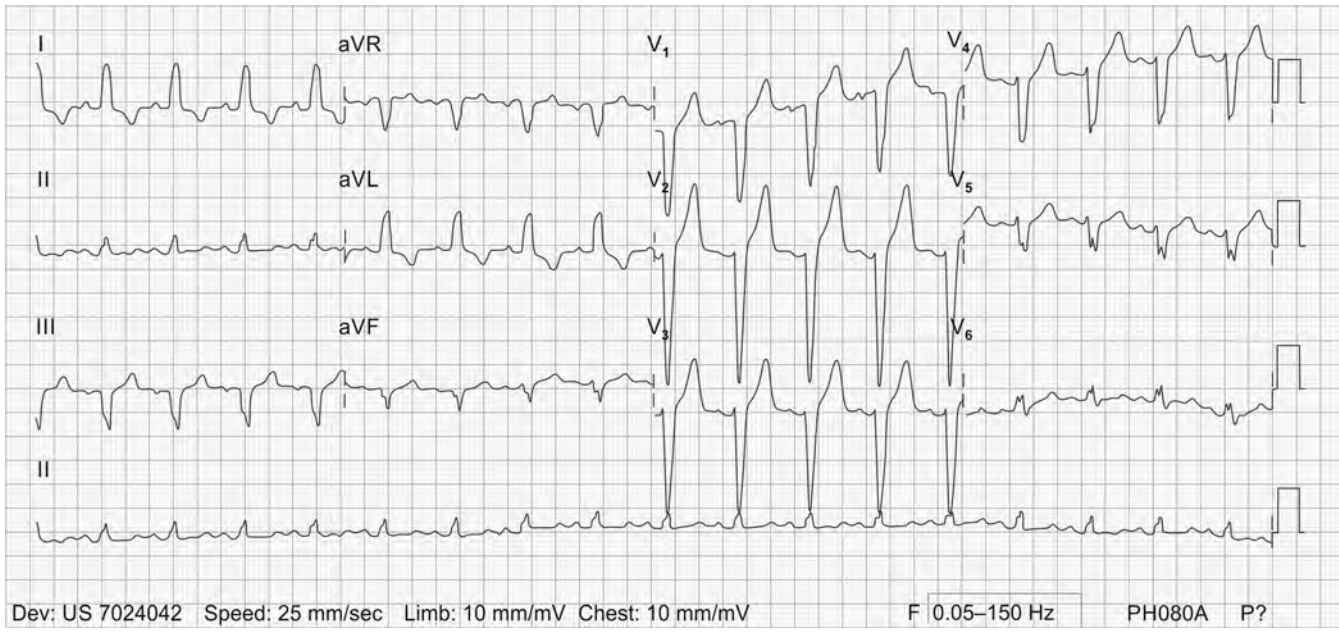

FIG. 14: *Left bundle branch block (LBBB)*. Sinus tachycardia is present with wide QRS complexes that have predominantly negative QRS in lead V_1, notching in V_4 to V_6, absent (very small) r in lead V_1 and absent q waves in leads V_6, I, and aVL. These are typical features of LBBB.

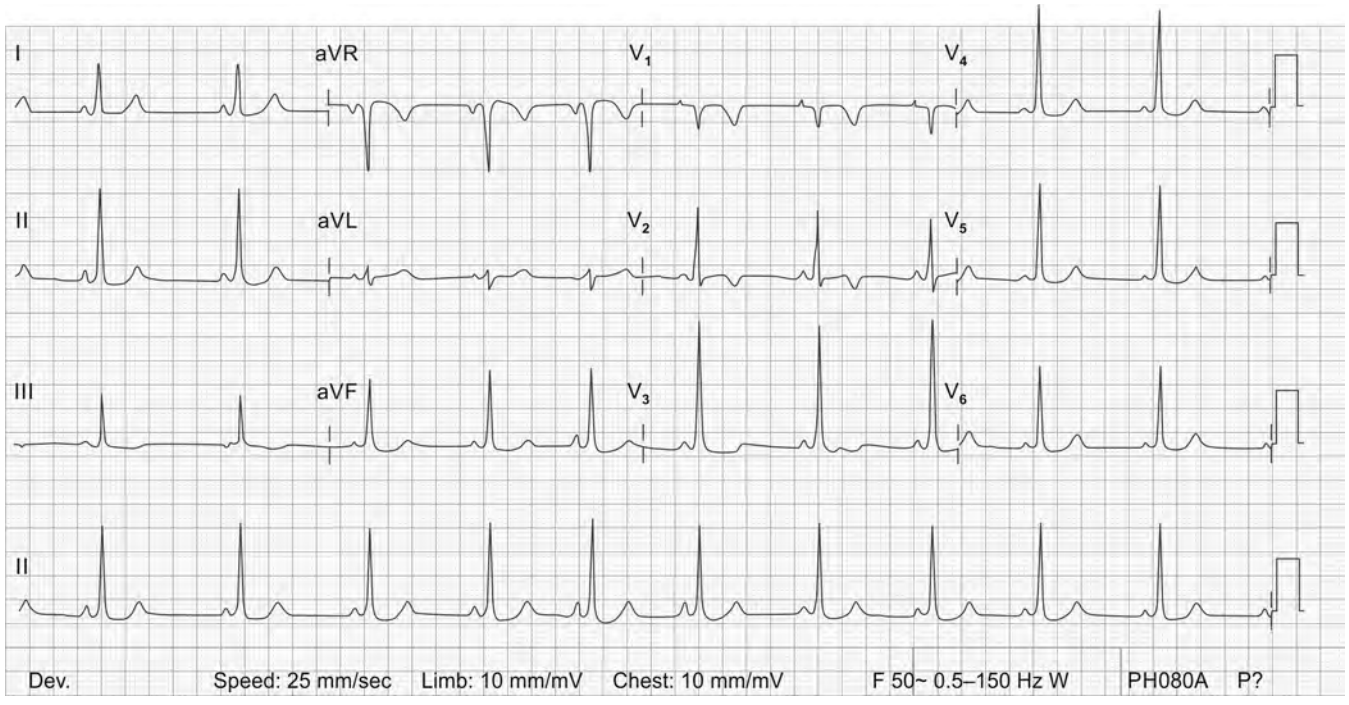

FIG. 15: *Wolff–Parkinson–White (WPW) syndrome*. Sinus rhythm with short PR interval, delta waves and wide QRS complexes are present indicating ventricular preexcitation due to an accessory pathway. The negative delta and QRS in lead V_1 suggest a right sided pathway. The presence of symptoms or documented arrhythmias related to accessory pathways in a patient with ventricular preexcitation makes a diagnosis of WPW syndrome. Note is made of marked irregularity in sinus rhythm that is as a result of sinus arrhythmia due to respiratory variation.

normal AV node—His-Purkinje system and is wide with an initial delta wave. Recognition of WPW syndrome or ventricular preexcitation during sinus rhythm in a patient with episodic palpitations may indicate PSVT as a cause of palpitation.

MISCELLANEOUS ECG FINDINGS IN EMERGENCY

Many other findings in the ECG may be present that may provide an important clue to the diagnosis in the emergency setting. These include:

- Wide QRS complexes with absent P waves—hyperkalemia (**Fig. 16**)
- Low voltage ECG—pericardial effusion, hypothyroidism, thick chest wall, obesity, emphysema, and incorrect standardization
- Electrical alternans—cardiac tamponade
- Prolonged QT interval—congenial long QT syndrome, drug- induced QT prolongation, hypocalcemia, and hypomagnesemia
- Osborn wave—abnormal wave seen at the end of QRS seen classically in hypothermia.

SUMMARY

The ECG plays an important role in the initial diagnostic evaluation of all patients presenting with symptoms related to cardiovascular disorders or at times systemic illnesses in the emergency. Emergency physicians cannot afford to miss the finding of ST segment elevation, the hallmark of diagnosis of acute MI as it may result in disastrous consequences. Studies have shown that emergency physicians are usually good and accurate at diagnosing MI from the ECG, but are not up to the mark in diagnosis of cardiac arrhythmias. A systemic nine-step approach to ECG interpretation as outlined below can be useful to arrive at a quick and accurate diagnosis in most patients presenting in the emergency in emergency department (**Box 6**).

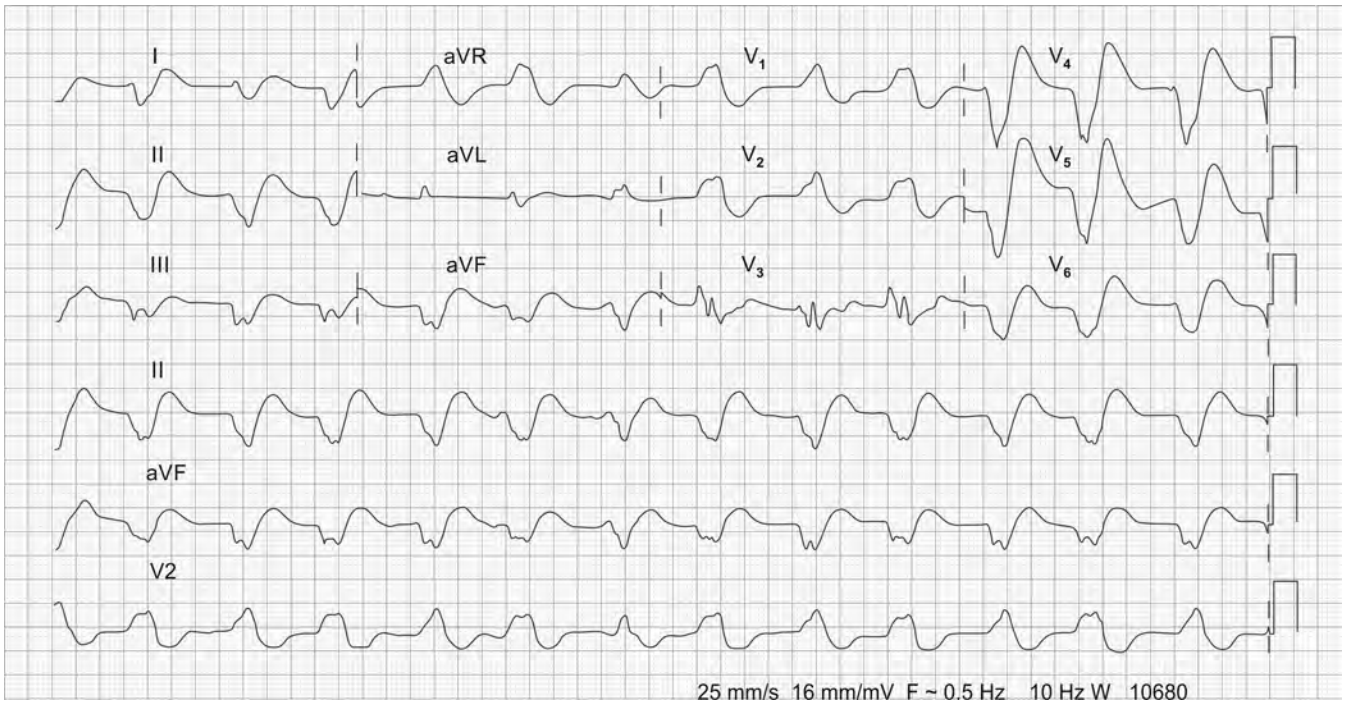

FIG. 16: *Hyperkalemia*. A regular rhythm with markedly wide and bizarre QRS complexes that are not preceded by P waves—sinoventricular rhythm. The T waves start immediately after the end of QRS complexes with almost absent ST segment. These are ECG features of severe hyperkalemia.

BOX 6: 9 Steps approach of ECG interpretation.

1. *Is the rhythm regular*? QRS segment of the ECG is observed to determine to ascertain depolarization within the ventricles is regular. Measure the distance between one R to another R. Check all other R-R distance, whether they are equal within a given amount of time, typically 6–10 seconds. If case of any irregularities is noted, check with the patient or previous ECG if these abnormalities are persisted. If so, look for symptoms associated with CHAPS—chest pain, hypotension, altered mental state, poor perfusion, or shortness of breath
2. *Calculate heart rate*: Check and count radial pulse also. Determine from the reading whether the patient is experiencing bradycardia, tachycardia, supraventricular tachycardia, or ventricular tachycardia with a pulse
3. *Diagnose the P waves*: Check presence of the upright P waves and followed by the QRS segment. Check the same on the monitor also. If these are within normal limits, chances are the electrical impulse, are generating from in the SA node, as it should
4. *Measure the P-R interval*: Normal P-R interval is 0.12—0.20 seconds. Calculation is done by counting the time between the P wave and the beginning of the QRS segment. Prolonged P-R interval suggestive of impulse conduction delay through the AV node
5. *Measure the QRS segment*. QRS segment of 0.04–0.10 seconds is considered normal duration. A prolonged QRS segment suggestive of a bundle branch block. Bundle branch blocks may be incidental findings, but associated with symptoms may indicate heart disease
6. *Check the T wave*: The upright T wave followed by the QRS segment is considered normal. Inverted T waves may indicate a myocardial ischemia, peaked tall and tented T waves suggestive of hyperkalemia, flat T waves may indicate hypokalemia, and a raised ST segment may suggest acute coronary syndrome
7. *Note any ectopic beats*: Accessory fibers outside the SA node that stimulate the heart to beat cause premature atrial contractions, premature junctional contractions, or premature ventricular contractions. Determine characteristics of the ectopic beats, the interval, shape, and whether they are single or in groups
8. *Determine the origin*: After calculating the all the above information, following point should be noted:
   - *Sinus*: Regular rhythm with 60–100 beats/min; P waves upright, round, and occurring before the QRS segment; normal P-R interval; normal QRS duration
   - *Atria*: Rhythm may or may not be regular; QRS segment is normal with abnormal P waves (premature, flat, notched, peaked, inverted, or hidden)
   - *Junctional*: Is the P wave junctional, inverted before, during or after the typical QRS segment?
   - *Ventricular*: If the rhythm originates below the SA node, the QRS segment will be wide and unusual with no P waves
   - *Paced rhythm*: Low voltage pacer spikes before the QRS should be reviewed
9. *Correctly identify the rhythm*: Correlate the information from the ECG and the patient's symptoms and vital signs. This will give a much better understanding about the management

CHAPTER

Cardiac Biomarkers

Omar Ghazanfar, Israa M Salih, Saleh Fares

INTRODUCTION

Biomarkers are fundamental in establishing the diagnosis and managing cardiovascular diseases (CVD), the leading cause of morbidity and mortality in the world. The delicate nature and time sensitivity of CVD, in which minutes can hugely impact the outcome, have made biomarkers an area of continuous research and development. In the United States, cardiac biomarker testing occurs in nearly 30 million emergency department visits nationwide each year. The National Institutes of Health defined a biomarker as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention."

Biomarkers are tools of screening, diagnosis, prognosis, and monitoring. Multiple molecules are classified as biomarkers and exist in the forms of enzymes, proteins, peptides, the newly added microRNAs, and many others. There are multiple markers for each disease process, the decision of what to use should be justified by indications, standard guidelines, and cost effectivity. Cardiac troponin and the B-type cardiac natriuretic peptides are the two best markers utilized in clinical settings; due to their major role in diagnosis and risk stratification in acute coronary syndromes (ACS) and heart failure. The myocardial infarction (MI) fourth universal consensus definition by the European Society of Cardiology (ESC) and American College of Cardiology (ACC) takes troponin as the key factor in case definition, owing to its high sensitivity and specificity for myocardial injury. History and physical exam remains the most important portion in clinical assessment and diagnosis, any laboratory test including biomarkers should not be taken out of context or as an independent parameter.

IDEAL CARDIAC BIOMARKER

As discussed above, biomarkers can have several roles and it is an ideal situation, if a single biomarker provides multiple information which are pivotal to the management in the emergency. An ideal cardiac biomarker is thus expected to have most of the attributes (**Box 1**) such as early detection in blood, highly specific for cardiac injury, be low cost, and have a sensitive assay to detect it. Clearly no such ideal cardiac biomarker exists and usually a multimarker strategy (discussed later) is practiced depending on the clinical scenario, for optimal outcomes. In the subsequent sections, we discuss the common cardiac emergencies along with the role of appropriate blood biomarkers.

BOX 1: Attributes of an ideal biomarker.

- Found in high concentration in heart and not in other tissue even in pathological state
- Should have low molecular weight so released early in blood, before myocardial necrosis
- Should peak early and remain elevated in for many days
- Level in blood should be proportional to severity of myocardial injuries
- There should be sensitive assay available to detect it and low cost and widely available

TROPONIN

Troponin is the biomarker of choice in the diagnosis of MI, as indicated in the fourth universal consensus definition of MI, and a detrimental factor in subcategorizing ACS. This protein is a component of the contractile apparatus found in skeletal and cardiac myocytes; it regulates the interaction between actin and myosin filaments. Cardiac troponin (cTn) is a three subunits complex: (1) Troponin T, (2) Troponin C, and (3) Troponin I. Troponin T and I isoforms are highly specific and sensitive for cardiac myocytes, and are indicators of cardiac damage. Whereas troponin C is found in both skeletal and cardiac muscles. The half-life of troponin T and troponin I in the blood is about 2 hours. Fluctuating readings might indicate reversible ischemia rather than necrosis, where a time-dependent fall over a longer period (4–10 days) would be expected because of gradual degradation of myofibrils and release of the troponin complex, which makes serial testing a requirement in some cases. The sensitivity of troponin is about 95%, and the specificity is about 80% when ACS is the primary suspected diagnosis, after excluding renal disease and sepsis which can give false positive results. Various

cardiac conditions other than ACS can cause elevated serum troponin which includes pericarditis, myocarditis, heart failure, and chest trauma. Troponin can also be increased in noncardiac conditions such as sepsis, renal disease, pulmonary embolism (PE), chronic obstructive pulmonary disease (COPD), strenuous exercise, and hypertension.

High-sensitivity cardiac troponin (hs-cTn T and I) has substituted the old cTn tests. It can detect troponin at concentrations 10- to 100-fold lower than the old assays, with higher sensitivity, precision, and NPV at an earlier point of time. Cardiac troponins are detected in the serum by the use of highly specific monoclonal antibodies. The European Society of Cardiology and American College of Cardiology consensus document recommends using laboratory cutoffs at the 99th centile of normal with 10% coefficient of variation. This will make serum cTnI values from 0.1 to 2 μg/L indicative of myocyte necrosis. American College of Emergency Physicians (ACEP) and American Heart Association (AHA) guidelines recommend the use of Troponin as level A class 1 in diagnosis of ACS. Cardiac troponin also has a prognostic value in mortality and adverse cardiac events.

CREATININE KINASE-MB

Creatinine kinase-MB (CK-MB) played a major role for decades in the diagnosis of acute MI (AMI) prior to troponin. CK-MB is not specific for myocardium and is also found in skeletal muscles. Noncardiac conditions can cause elevated levels, commonly seen with trauma, rhabdomyolysis, heavy exertion, and myopathy. It appears 4–6 hours after symptoms onset, peaks at 24 hours, and returns to normal in 48–72 hours. A trend rather than a single measurement is more helpful to aid in detection of MI. A more useful way to help differentiate rise due to myocardial pathology from other causes of increased CK-MB is the relative index; in which the ratio of the CK-MB to total CK is measured, a ratio > 5% is indicative of myocardial injury. CK-MB testing is still ordered in many hospitals and emergency departments; however, many efforts have been made to stop routine use.

MYOGLOBIN

Myoglobin is a heme protein exists in skeletal and cardiac muscles. Due to its sensitivity and early rise, it can be serviceable in early detection of MI. It typically rises 2–4 hours after onset of infarction, peaks at 6–12 hours, and returns to normal within 24–36 hours.

NATRIURETIC PEPTIDE

Natriuretic peptides are secreted by ventricles in response to pressure and stretch. These peptides are considered markers of hemodynamic stress, and are involved in diuresis, natriuresis, vasodilation, inhibition of renin and aldosterone, and in reduction of blood pressure. The half-life of B-type natriuretic peptide (BNP) is (≤20 min), and for N-terminal pro-B-type natriuretic peptide (NT-proBNP) half-life is (60–120 min). BNP levels of >100 pg/mL are diagnostic of heart failure with an accuracy of 85%. According to (PRIDE) study, NT-proBNP >900 pg/mL were highly sensitive and specific for the diagnosis of acute congestive heart failure ($p < 0.001$). An NT-proBNP level <300 pg/mL was optimal for ruling out acute congestive heart failure, with a negative predictive value of 99%. ACEP and AHA recommend both BNP and NT-pro BNP (level 1 class A) in acute setting and hospitalization, for supporting diagnosis of HF and establishing prognosis and disease severity.

OTHER MARKERS

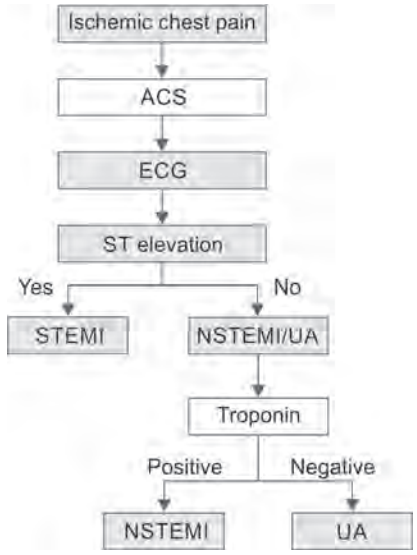
Along with troponin, CK-MB, and myoglobin, there are other molecules that can be classified as myocardial biomarkers. Those promising markers such as ischemia-modified albumin and heart-type fatty acid-binding protein might aid in the diagnosis of ACS but till now their role is limited. It is also important to mention that inflammatory markers play a considerate role in assessing ACS, for their described prognostic value. The famous among which are the high sensitivity CRP and homocysteine, the latter has been linked to direct vascular injury, and both are used in risk assessment. The soluble CD40 ligand (sCD40L) is another marker that is also linked to inflammation and plaque instability in ACS.

MULTIPLE MARKER APPROACH

In the emergency setting, it is often necessary to differentiate diverse clinical conditions, having similar clinical presentation but markedly different treatment and prognosis. There is thus a need to test for the possibility of multiple clinical conditions rapidly and accurately in order to diagnose and institute appropriate therapy at the earliest. It clearly implies that use of biomarkers one by one would be detrimental in this scenario. In view of this need, several biomarkers are used together according to the clinical scenario and several point-of-care kits incorporating these multiple markers have also been made available. For example, in a patient who presents with acute onset dyspnea where it is necessary to differentiate between acute PE and AMI, the use of D-dimer, along with troponin could be useful. Also, multiple biomarkers could be used to provide additional information related to prognosis and timing of the index event. For example, in a patient with ischemic chest duration of very short duration will require the use of troponin along with myoglobin while in a patient with typical electrocardiogram (ECG) changes but a history of ischemic chest discomforts 2–3 weeks before will require the use of troponin and CPK-MB in view of the temporal profile of these markers. The disadvantage of this approach is increased cost and sometimes leading to inappropriate management. Besides, these have not been recommended as a preferred strategy and exercising clinical judgment in choosing the appropriate biomarkers, in a given clinical situation is recommended.

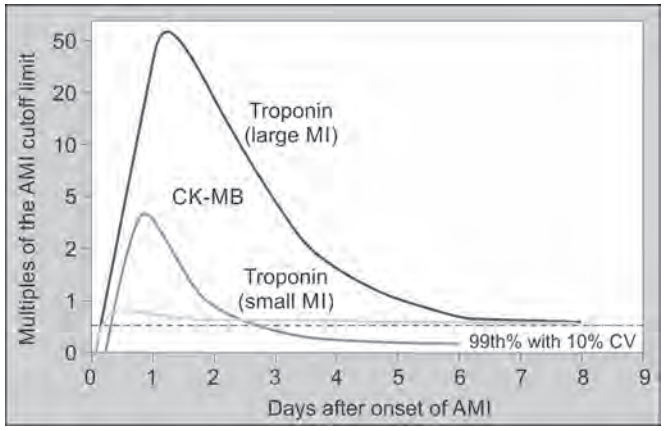
Acute Coronary Syndrome

Acute coronary syndrome is one of the most common cardiac emergencies with devastating consequences. It results from the rupture or erosion of an atherosclerotic plaque leading to formation of coronary thrombus. The working diagnosis of ACS is made based on the presence of typical symptoms, which is further characterized by ECG changes (**Flowchart 1**). The final diagnosis, however, is based on the detection of elevated cardiac specific biomarker (**Fig. 1**) preferably cardiac specific troponin. Based on these findings, ACS is subclassified into one of the three clinical syndromes: (1) ST segment elevation myocardial infarction (STEMI), (2) non-ST segment elevation



(ECG: electrocardiogram; STEMI: ST segment elevation myocardial infarction; NSTEMI: non-STEMI)

FLOWCHART 1: Algorithm for diagnosis of acute coronary syndrome (ACS).



(AMI: acute myocardial infarction; CK-MB: creatinine kinase-MB)

FIG. 1: Cardiac specific biomarkers.

myocardial infarction (NSTEMI), or (3) unstable angina. As clear from the names of these, ECG plays an important role in the working diagnosis of these entities but a key role is played by the cardiac biomarker, now almost exclusively cardiac specific troponin.

Elevated cardiac specific troponin is much more specific for cardiac tissue, is very sensitive for myocardial necrosis, and has a useful temporal profile as compared to other cardiac enzymes used previously (such as CK and CK-MB). It has also been shown to relate directly with infarct size and thus act as a prognostic marker also. It has been shown that the acute or short-term prognosis for patients with troponin-positive, CK-MB negative infarcts is better than that for patients with elevated troponin and CK-MB values.

Therefore, it is the preferred biomarker recommended for use in MI and the new definition of MI is based solely on the level of troponin. It is recommended that any patient coming to the emergency with suspected MI should have troponin

TABLE 1: Cardiac markers trends relative to time.

Cardiac biomarker	*Time to appear*	*Time to peak*	*Time to return normal*
cTn	6–12 h	24 h	Up to 14 days
cTn I/T	3–4 h	24 h	4–10 days
CK-MB	4–6 h	24 h	48–72 h
Myoglobin	2–4 h	6–12 h	24–36 h

done immediately and another value 3–6 hours later (**Table 1**). Rather than only absolute elevated values, temporal rise and fall is very important for diagnosis of MI. Although troponin is quite specific to cardiac injury, it cannot differentiate ischemic injury (in MI) from other types of myocardial injury (such as in sepsis, acidosis, and trauma). As such elevations of troponin can be seen in a variety of clinical conditions and disease states but the clinical scenario and time trend of the values should be carefully looked at in these situations to arrive at a diagnosis of MI. This approach of using troponin only for diagnosis of MI has resulted in diagnosis of more episodes of MIs correctly owing to its sensitivity and specificity, but also has been shown to be more cost effective than doing both, troponin and CK-MB. Myoglobin is also a cardiac biomarker which is detectable quite early in blood following AMI (within 2 h). However, it is not specific for cardiac injury and is also not widely available. However, it can be used sometimes as part of a multimarker strategy for diagnosis of AMI. CM-MB similarly is sometimes utilized since it remains elevated till much later after AMI. Cardiac specific troponins (I or T), however, remain the preferred biomarkers for diagnosis for ACS.

Deep Vein Thrombosis and Pulmonary Embolism

Acute PE is associated with high mortality and morbidity. Besides, there are no specific sign or symptoms of PE. As such, it is also known as the "great mimic." The clinical presentation may resemble AMI, dissection of aorta, acute heart failure, acute asthma, or even syncope. It is very important to diagnose and institute appropriate treatment for PE in the emergency department. Deep vein thrombosis (DVT) is a related entity equally important to diagnose. D-dimer is the only biomarker which is used in the scenario of DVT and PE.

Endogenous fibrinolysis breaks down the fibrin rich clot to D-dimers. The detection of elevated circulating D-dimer by enzyme-linked immunosorbent assay (ELISA) is therefore an indicator of clot formation and endogenous fibrinolysis due to any reason. *It is a sensitive indicator of DVT and PE but is not specific for DVT/PE*. Elevated D-dimer can be seen in any systemic illness such as sepsis, MI, cancer, or even postoperatively up to months. However, it has a great negative predictive value. It is most useful thus in ruling out acute PE/DVT in appropriate clinical setting. For example, in a patient presenting to emergency, suspected of having acute PE, with no other systemic illness, a negative D-dimer virtually rules out DVT/PE and no further testing is required for this purpose. In case of an elevated value in this scenario, further testing in the form of ultrasound of leg veins or computed tomography (CT) angiography of chest is required to diagnose PE. However, it has a limited role in the admitted patient with multiple

comorbidities or in a patient with recent history of trauma, surgery, or any systemic illness, owing to its nonspecificity. D-dimer can also be used as part of multimarker strategy where there is a need to rule out other conditions such as MI or acute heart failure which may have similar presentation (as discussed later). The use of D-dimer is thus very useful in the emergency for triage of patients who require costly and potentially harmful testing (like CT scanning) and potentially life-saving treatment, by optimizing the resource utilization in busy emergency room settings.

Cardiac Biomarkers in Heart Failure

B-type natriuretic peptide and NT-proBNP are polypeptides secreted mainly by the ventricles of the heart in response to excessive stretching of heart muscle cells (cardiomyocytes). They have vasodilator and natriuretic properties and are also released from blood vessels and kidneys. Circulating BNP and NT-proBNP is measured by immunoassay and elevated levels are shown to be indicative of heart failure (left as well as right, acute as well as chronic). Systematic studies have shown that elevated natriuretic peptides, released as a response to myocardial stretch, can be used as indicators of elevated myocardial load. They have been found to be a useful triage tool for diagnosis, prognosis, and monitoring response to treatment in patients with acute decompensated heart failure. In a study, the negative predictive value was 96% for BNP < 50 pg/mL and the positive predictive value was 83% for a cutoff value of 100 pg/mL, relative to clinical assessment by cardiologists. BNP and NT-proBNP have been recommended for use in acute decompensated heart failure scenario by the guidelines from heart failure association of America and from the UK. It has now been shown that BNP and NT-proBNP are elevated in chronic heart failure with preserved ejection fraction (HFpEF). The European Society of Cardiology guidelines of 2016 have incorporated this approach in the diagnosis of HFpEF and cutoffs have been proposed. There is no difference between BNP and NT-proBNP when used as markers of heart failure but different cut-off values are to be used for each of these (>35 pg/mL for BNP; >125 pg/mL for NT-proBNP). Elevated BNP and NT-proBNP are also predictors of prognosis and can be used as markers of response to treatment. As discussed above, they are not specific for heart failure and elevated values can be found in diverse situations such as pulmonary hypertension, AMI, severe sepsis, renal disease, etc.

FUTURE PERSPECTIVE

Cardiac biomarkers are an indispensable tool for diagnosis, prognosis, and risk stratification in the emergency department. The use of biomarkers results in optimizing scarce resources in busy emergency departments. Judicious use of biomarkers results in rapid triage, institution of appropriate therapy in a timely manner and is also very useful in preventing mishaps on account of missing out on critical diagnosis. Some of the cardiac biomarkers such as troponin and natriuretic peptides also contribute to prediction of future risk and thus, in devising of aggressive approach for sicker patients. A multimarker approach is sometimes used as a point-of-care device but it requires more experience and refinement before it can be widely recommended. There are several biomarkers being studied for their higher sensitivity, specificity, and prognostic value in different clinical conditions. A very sensitive troponin assay is being developed for early detection and risk stratification in MI. Similarly, markers of inflammation [high-sensitivity C-reactive protein (hsCRP)] are being evaluated for defining their role in the scenario in acute coronary syndrome. Numerous other biomarkers (metalloproteinases) are being evaluated for different stages of atherosclerosis and we are likely to see greater use of low cost, easy to use biomarkers with superior diagnostic and prognostic accuracy in the emergency room.

SUMMARY

Biomarkers part is integral in defining and managing CVD. Cardiac troponin and natriuretic peptides are superior to others due to their higher sensitivity and specificity; these two are highly recommended in dealing with ACS and heart failure, respectively. When ordered correctly and judiciously biomarkers can markedly improve healthcare delivery and limit unnecessary utilization of resources.

Echocardiography in Emergency Department

63 CHAPTER

Manish Bansal

INTRODUCTION

Prompt diagnosis and rapid institution of appropriate therapeutic measures are the most important goals in the management of patients presenting to the emergency room (ER). Given the time-sensitive and critical nature of the illnesses leading to ER presentation, the diagnosis must be established quickly, which limits the scope of the investigative work-up available for the initial evaluation of these patients. Therefore, in most patients, a focused clinical assessment combined with bedside diagnostic tools such as X-ray, electrocardiogram (ECG), and laboratory investigations need to form the basis for initial triaging. However, since a cardiac etiology may underlie almost every clinical presentation resulting in ER admission, some form of cardiac evaluation is invariably required in many of these patients. Echocardiography has emerged as a highly useful diagnostic modality for this purpose. Its portability, safety, easy availability, and ability to provide comprehensive information about cardiac structure and function within a short period of time make it ideally suited for use in the ER setting. Because of these attributes, echocardiography has now become almost an extension of clinical examination. Previous studies have shown that addition of a screening echocardiogram significantly improves the diagnostic accuracy of physical examination and reduces unwarranted downstream diagnostic and therapeutic referrals. In this chapter, we discuss the role of echocardiography in the initial evaluation and management of patients presenting to ER with various clinical presentations.

ECHO IN ASSESSMENT OF ACUTE CHEST PAIN

Chest pain is one of the most common reasons for ER visits. A number of cardiac and noncardiac conditions can cause chest pain such as acute coronary syndrome (ACS), aortic dissection, pulmonary embolism, acute pericarditis, lower respiratory tract infection, acute cholecystitis, acute pancreatitis, and costochondritis. Echocardiography plays an important role as a first-line diagnostic modality in the differential diagnosis of these conditions and plays a pivotal role in the overall management of patients presenting with ACS.

Acute Coronary Syndrome

The term ACS encompasses a wide spectrum of clinical presentations ranging from unstable angina, non-ST elevation myocardial infarction (NSTEMI) and ST elevation MI (STEMI) to even sudden cardiac death. The diagnosis of ACS is traditionally based on clinical presentation, ECG changes, and the abnormalities in the cardiac biomarkers. However, many patients with ACS present with nondiagnostic ECGs and cardiac biomarkers typically take 6–8 hours to become abnormal. Given these constraints, echocardiography can be a useful tool for establishing the diagnosis of ACS and has a class I indication for this purpose.

In the ischemic cascade, abnormalities of left ventricular (LV) systolic and diastolic function develop very early, much before the appearance of ECG changes. Accordingly, the presence of new regional wall motion abnormalities (RWMA) on echocardiography will strongly support a diagnosis of ACS in a patient with typical chest pain but nondiagnostic baseline ECG. However, echocardiography may not be much helpful for diagnosing ACS in a patient with known coronary artery disease (CAD) when the extent of preexisting RWMA is not known.

For the purpose of initial diagnosis of ACS, a positive echocardiogram should meet one of the following criteria:

- Abnormal wall motion of two or more contiguous segments visible in two different views, or
- Global LV hypokinesia with an ejection fraction (EF) of <40%.

In patients who do not have any evidence of LV systolic dysfunction and also have normal cardiac biomarkers, stress echocardiography (either dobutamine or exercise) can be performed to rule out significant CAD prior to discharge from the ER. Such approach has ≥90% sensitivity and specificity for identifying subjects at risk for having cardiac events. Abnormalities of LV diastolic function appear even before the development of RWMA and therefore have even greater sensitivity for detection of myocardial ischemia. However, these abnormalities are too nonspecific to be used routinely for this purpose. Their utility currently lies mainly in the assessment of intracardiac hemodynamics and guiding management, rather

than in the initial diagnosis of ACS. However, the diastolic phase abnormalities may have diagnostic value on strain imaging as discussed below. Apart from establishing the diagnosis of ACS, echocardiography also permits recognition of the underlying culprit vessel, assessment of the extent of myocardial damage, and its hemodynamic consequences, and helps in detection of mechanical complications of MI, if any.

In CAD, LV-RWMA usually follows the distribution of coronary vascular territory. Therefore, the pattern of regional myocardial involvement during ACS helps in identification of the underlying culprit artery (**Fig. 1**). This information not only has diagnostic utility, but also helps in determining the choice of treatment modality and the urgency with which such treatment needs to be instituted.

The extent of myocardial damage can be determined by estimating either *wall motion score index* (WMSI) or, more commonly, LVEF. For estimation of WMSI, segmental wall motion of each LV myocardial segment is scored as (1) normal, (2) hypokinetic, (3) akinetic, and (4) dyskinetic or aneurysmal, in a 16-segment model. The score for each segment is then added and the total score is divided by the number of segments analyzed to obtain WMSI. *WMSI provides a semiquantitative estimate of overall LV systolic function* with higher WMSI signifying greater amount of myocardial damage and thus, worse LV systolic function. In clinical practice, however, LVEF is the most commonly used measure of LV systolic function. In patients with ACS, LVEF has immense diagnostic, prognostic, and therapeutic value and is central to almost every therapeutic decision-making, not just during the acute stage, but during the entire course of illness.

Estimation of LVEF by echocardiography is simple and easy to perform. Modified biplane Simpson's technique is the recommended method for this purpose. This method requires tracing of endocardial border of the LV in apical four-chamber and two-chamber views in both end-diastolic and end-systolic frames. The automated software in the echocardiography machine performs the calculations required to estimate LV volumes and EF. Alternately, LVEF can also be estimated visually by eyeballing, which, in fact, is the most common method used in real-life clinical practice. With experienced echocardiographers, LEVF estimation by eyeballing has been shown to have high degree of accuracy. More recently, three-dimensional echocardiography has also become available and has been shown to be more accurate than two-dimensional (2D) echocardiography for estimation of LV volumes and EF.

Role of Adjunctive Techniques

As discussed above, the diagnostic evaluation of CAD by echocardiography traditionally relies on segmental wall motion analysis, either at rest or during stress. While this approach has been extensively validated over the years, it has certain limitations. Most important of these are inability to defect subtle changes in myocardial contractile function and the lack of information about myocardial perfusion. Strain imaging and myocardial contrast echocardiography (MCE) overcome these limitations and their incorporation during conventional echocardiography has been shown to have incremental value in the evaluation of chest pain patients in the ER.

Strain imaging is a sensitive modality for detection of myocardial contractile dysfunction. The currently used speckle tracking echocardiography (STE) permits comprehensive assessment of myocardial deformation in different directions, which has important diagnostic implications in the evaluation of CAD (**Figs. 2A** and **B**). As longitudinal deformation of LV is determined predominantly by subendocardial myocardial fibers, longitudinal strain (LS) is the first one to get affected with the onset of myocardial ischemia (**Fig. 3**). In contrast, circumferential deformation which is determined primarily by the subepicardial fibers gets involved much later when the myocardial injury has become transmural. This unique

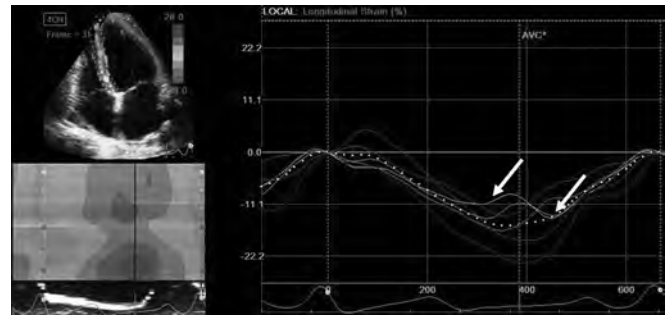

FIG. 4: Reduced systolic longitudinal strain with post-systolic shortening (arrows) in basal septum (yellow trace). ***(For color version, see plate 5)***

structural-functional relationship of LV myocardial contractile apparatus can be exploited for the purpose of early detection of myocardial ischemia, for differentiating subendocardial injury from transmural injury, and for predicting myocardial viability.

Subendocardial myocardial fiber dysfunction can be detected by strain imaging either as reduced systolic LS, increased postsystolic strain (PSS), and/or as delayed decay of peak LS during diastole (**Fig. 4**). These strain abnormalities can be used for diagnosing CAD and may have incremental value over wall motion analysis. Furthermore, increased PSS and impaired diastolic decay of strain may persist for a reasonable period of time after acute myocardial ischemia and can serve as ischemic myocardial memory.

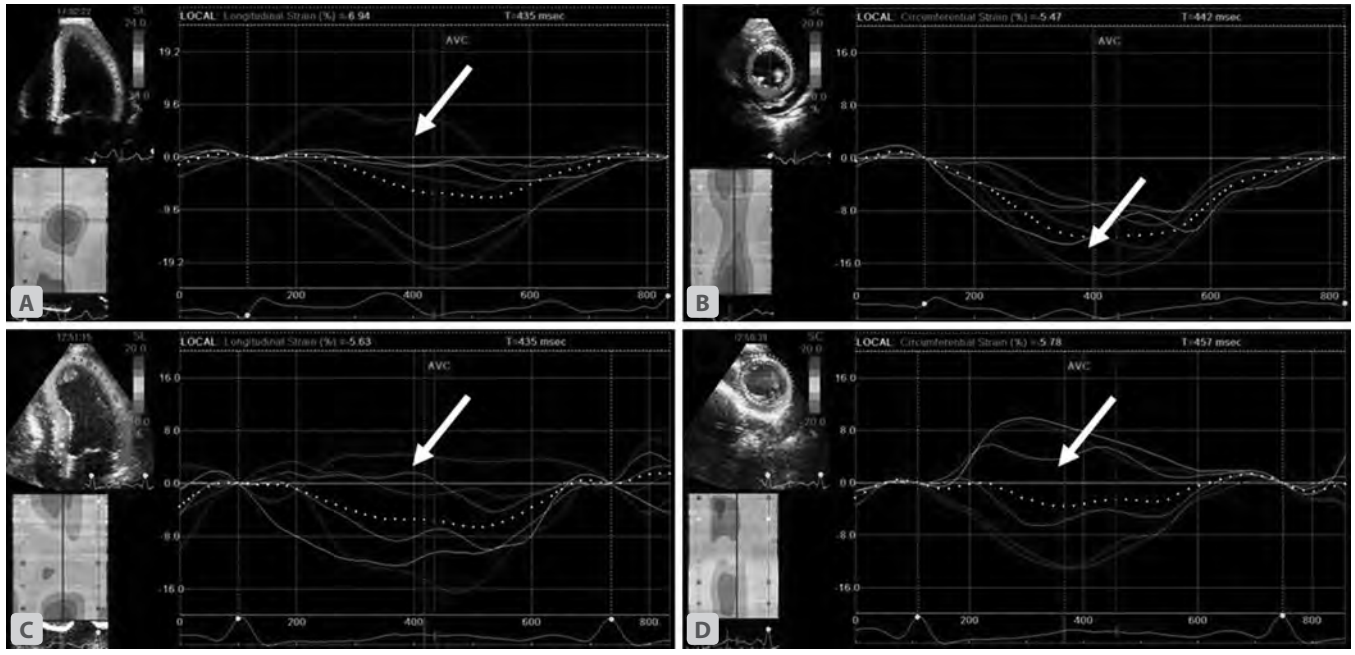
When impairment of LS is not accompanied by concomitant reduction in circumferential strain (CS), it usually indicates nontransmural injury whereas concomitant reduction of both LS and CS indicates transmural infarct. Thus, assessment of CS can be helpful not only in diagnosing ACS, but more importantly, in identifying total coronary occlusions and in predicting late LV remodeling and overall clinical outcomes (Figs. 5A to D). Furthermore, CS can also help in differentiating STEMI from acute myocarditis which may have similar clinical presentations. As myocarditis preferentially affects epicardial myocardial layers, it causes more marked impairment of CS, unlike ischemia which generally results in greater impairment of LS. Accordingly, in patients with preserved LVEF, impaired global CS (less negative than -19.3%) has been shown to differentiate acute myocarditis from STEMI with sensitivity 72% and specificity 74%.

Unlike strain imaging, MCE provides information about myocardial perfusion and thus bridges the gap between echocardiography and nuclear imaging. Because of its ability to assess myocardial perfusion, MCE has been shown to have high sensitivity for detection of subendocardial ischemia and can be useful in triaging the patients presenting with suspected ACS. In a study involving 400 patients presenting to ER with chest pain but normal ECG and biomarkers, dipyridamole-atropine stress echocardiography with MCE had significantly higher accuracy (sensitivity and specificity 97% and 74%, respectively) for diagnosing as compared to wall motion analysis alone (sensitivity and specificity 63% and 91%, respectively).

Aortic Dissection

Acute aortic dissection is a potentially fatal disease which presents as acute severe chest pain often radiating to interscapular region. Although chest pain in aortic dissection generally has typical character, it has often been misdiagnosed as ACS because of low index of suspicion and also because of occurrence of nonspecific ECG changes in aortic dissection. Sometimes, aortic dissection may result in a true STEMI also, due to occlusion of a coronary artery ostium by the dissection flap. Since the management of ACS is completely opposite of that of acute aortic dissection, accurate distinction between the two conditions is of paramount importance.

The patient profile, pattern of chest pain, and the presence unequal peripheral pulses provide important clues to the underlying diagnosis of aortic dissection, which can then



FIGS. 5A TO D: Differential involvement of left ventricular longitudinal and circumferential strain in patients with subendocardial and transmural infarcts. (A and B) Longitudinal strain is impaired (A) but circumferential strain is preserved (B) in basal segments in a patient with subendocardial infarct; (C and D) Both longitudinal and circumferential strains are impaired in apical segments in a patient with transmural infarct. ***(For color version, see plate 6)***

be confirmed with the help of imaging. Echocardiography is an excellent modality for initial evaluation of patients with aortic dissection, particularly those with proximal aortic dissection (**Figs. 6A** to **D**). Transthoracic echocardiography (TTE) has 77–80% sensitivity and 93–96% specificity for diagnosing proximal aortic dissection, whereas the same for transesophageal echocardiography (TEE) are 98% and 95% respectively. The sensitivity of TTE for detecting distal aortic dissection is much lower, but TEE can generally diagnose most of the dissections involving descending thoracic aorta. *The diagnosis of aortic dissection on echocardiography is based on detection of an undulating intimal flap within the aortic lumen that separates the true and false channels and has motion independent of that of the aortic wall. The flap should be identified in more than one view.* TEE can demonstrate intimal tear in the vast majority of cases and also permits recognition of true and false lumina. The false lumen is often larger and has less blood flow than the true lumen. Partial thrombosis of the false lumen is seen frequently and total thrombosis is an occasional finding. Doppler study can also be used for differentiating true lumen from the false lumen. Apart from diagnosing aortic dissection, echocardiography is also helpful in detecting its potential complications such as hemopericardium, coronary involvement, and aortic insufficiency.

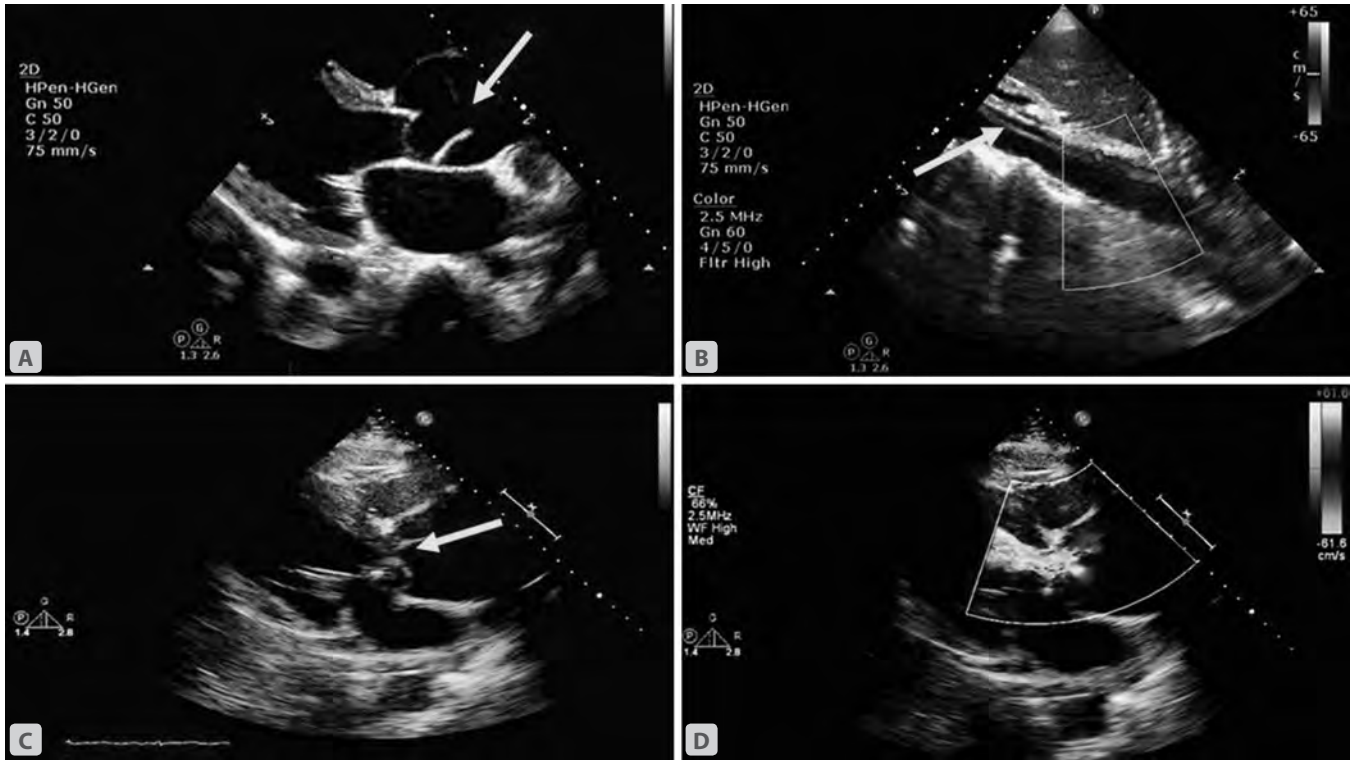
Pulmonary Embolism

Pulmonary embolism is a less common but potentially lethal cause of chest pain. It more often presents as shortness of breath or as hemodynamic collapse. Chest pain usually occurs when emboli are relatively small resulting in peripheral pulmonary infarction. *The imaging modality of choice for diagnosing acute pulmonary embolism is computed tomographic pulmonary angiography (CTPA)*. However, echocardiography provides useful initial clues toward the possibility of underlying pulmonary embolism, permits assessment of the hemodynamic significance of the embolism—an important determinant of the treatment strategy and in some cases may also reveal thrombi in main pulmonary artery and its branches, right atrium (RA), and/or right ventricle (RV) (**Figs. 7A** and **B**).

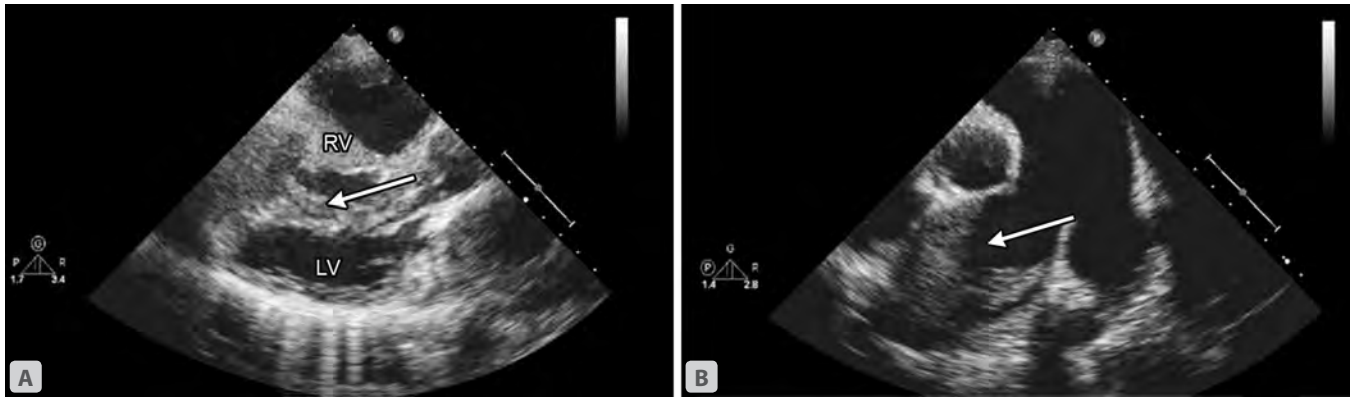
Echocardiographic features corroborative of pulmonary embolism include dilatation of pulmonary artery with evidence of increased RV afterload in the form of RV dilatation/dysfunction, D-shaped LV cavity caused by leftward shift of the interventricular septum and Doppler evidence of pulmonary hypertension with or without evidence of increased RA pressure. RV systolic dysfunction in pulmonary embolism often has a typical regional pattern, affecting mainly the free wall with sparing of RV apex. This is known as *McConnell's sign* and is highly specific for pulmonary embolism but has low sensitivity. As such, echocardiography itself has low sensitivity to rule out pulmonary embolism. Therefore, while an abnormal echocardiogram can help to confirm the diagnosis of pulmonary embolism, particularly in a hemodynamically compromised patient in whom CTPA may not be feasible, it should not be the only modality to rule out the diagnosis or for risk stratification in patient with stable hemodynamics. Additionally, emergency physicians should also be vigilant about other causes of RV pressure/volume overload such as obstructive airway disease, idiopathic pulmonary hypertension, right ventricular myocardial infarction (RVMI), and primary tricuspid regurgitation (TR), when diagnosing pulmonary embolism based on echocardiography alone.

ECHO IN ASSESSMENT OF DYSPNEA/ SHORTNESS OF BREATH

Acute onset dyspnea can be due to cardiac or noncardiac conditions. Echocardiography is very helpful in distinguishing



FIGS. 6A TO D: Two examples of acute aortic dissection. (A) Intimal flap (arrow) is seen in the aortic root; (B) In the same patient, the dissection flap (arrow) is seen extending into the abdominal aorta also; (C and D) Intimal flap (C, arrow) in another patient is prolapsing through the aortic valve causing severe aortic regurgitation. ***(For color version, see plate 6)***



(LV: left ventricle; RV: right ventricle)

FIGS. 7A AND B: A patient with massive pulmonary embolism. (A) Right ventricle is grossly dilated and the interventricular septum (arrow) is deviated towards the left ventricle; (B) Markedly dilated main pulmonary artery with complete occlusion of right pulmonary artery with thrombus (arrow).

between the two and in providing detailed description of the underlying cardiac pathology when such a condition is found. Dyspnea is therefore a class I indication for performing echocardiography. There are a number of cardiac conditions that can result in acute dyspnea. The common ones include:

- Predominant LV systolic dysfunction—due to MI, dilated cardiomyopathy, stress cardiomyopathy, etc.
- Predominant LV diastolic dysfunction—due to long-standing hypertension, hypertrophic cardiomyopathy, restrictive cardiomyopathy, aortic stenosis, etc.
- Valvular heart diseases—mitral stenosis, mitral regurgitation (MR), aortic stenosis, aortic regurgitation, prosthetic heart valve (PHV) malfunction, etc.
- Pericardial diseases such as cardiac tamponade and constrictive pericarditis
- Cardiac tumors such as LA myxoma.
- Pulmonary embolism, idiopathic pulmonary hypertension, etc.

In all the above conditions, echocardiography is able to demonstrate the underlying structural abnormality in detail. In addition, it also permits comprehensive assessment of intracardiac hemodynamics which helps in determining the role of these abnormalities in causation of dyspnea and in planning appropriate treatment strategy.

Predominant LV diastolic dysfunction has recently emerged as an important cause of dyspnea. It is estimated that

almost half of all patients presenting with heart failure have normal or near-normal LVEF with LV diastolic dysfunction being the dominant abnormality. *This entity is termed as "heart failure with preserved EF" or HFpEF.* Assessment of LV diastolic function is central to the recognition of this entity and echocardiography is the most commonly utilized modality for this purpose. Using echocardiography, LV diastolic function is assessed by integrating information derived from interrogation of mitral inflow pattern, mitral annular motion, pulmonary vein flow pattern, etc. The American Society of Echocardiography has recommended algorithms for step-wise assessment of LV diastolic function and LV filling pressure in different patient populations (**Figs. 8A** and **B**).

Estimation of LV filling pressure is of paramount importance even in patients with frank LV systolic dysfunction. In these patients, elevated LV filling pressure is not only an adverse prognostic marker, it has major therapeutic implications as well. The need for diuretics, intravenous fluids, inotropes, vasodilators, etc.; timing of introduction of beta-blockers; timing of coronary intervention; ambulation and mobilization of patients after acute MI; etc. are all influenced by the status of LV filling pressure.

Among valvular lesions, mitral stenosis is the most common condition that presents with acute shortness of breath. Development of atrial fibrillation is the usual culprit in these patients. In contrast, acute shortness of breath in other

FIGS. 8A AND B: Algorithm for echocardiographic assessment of left ventricular diastolic function and estimation of left ventricular filling pressure in presence of normal (A) or reduced (B) left ventricular systolic function.

Source: Nagueh SF, Appleton CP, Gillebert TC, Byrd BF 3rd, Dokainish H, Edvardsen T, et al. Recommendations for the evaluation of left ventricular diastolic function by echocardiography. J Am Soc Echocardiogr. 2009;22:107-33.

valvular heart diseases generally occurs due to worsening LV systolic dysfunction, development of infective endocarditis (IE) or traumatic disruption of valvular apparatus. Aortic stenosis may result in acute dyspnea even in absence of LV systolic dysfunction because of LV hypertrophy with consequent LV diastolic dysfunction. PHV malfunction can occur because of valve thrombosis, structural degeneration, and progressively worsening pannus formation or IE.

ECHO IN ASSESSMENT OF HYPOTENSION AND HEMODYNAMIC INSTABILITY

Hypotension and shock are commonly encountered in the ER. They can be cardiogenic in origin or may result from noncardiac causes such as hemorrhage, hypovolemia, or sepsis. As shock requires aggressive early intervention in order to prevent end-organ damage due to inadequate tissue perfusion, distinguishing cardiogenic shock from shock of other etiologies is extremely important. *The major advantage of echocardiography is that it can quickly determine whether the shock is cardiogenic or noncardiogenic*, apart from also providing plenty of hemodynamic information that is useful irrespective of the type of shock. *A brief 2D echocardiographic examination itself can help in excluding common cardiac causes of hypotension such as*:

- Extensive MI with severe LV systolic dysfunction
- Right ventricular infarction
- Mechanical complication of MI
- Nonischemic severe LV systolic dysfunction
- Pericardial effusion with tamponade
- Massive pulmonary embolism, etc.

Even in patients with noncardiogenic shock, echocardiography often provides useful clues to the underlying etiology. For example, in patients with hypovolemic shock, echocardiography often reveals a small under-filled and hyperdynamic LV, which is a reliable indicator of intravascular volume depletion. Similarly, a collapsed IVC in a patient with unexplained shock indicates an urgent ultrasound evaluation of the peritoneal cavity to look for abdominal hemorrhage.

A more formal assessment of hemodynamics can also be performed by echocardiography, which helps in characterization of the type of shock. LV filling pressure can be estimated as described above, whereas RV filling pressure (same as mean RA pressure or central venous pressure) is derived from IVC size and collapsibility (**Table 1**). Mean and systolic pulmonary pressures can be estimated from pulmonary regurgitation and TR jets. For systemic cardiac output, LV stroke volume is calculated first which is then multiplied with heart rate. LV stroke volume is usually calculated by multiplying 2D-derived LV outflow tract (LVOT) area with Doppler-derived LVOT velocity time integral. Alternately, it can also be calculated by subtracting LV end-systolic volume from LV end-diastolic volume derived using the modified Simpson's method.

By combining all this data, systemic vascular resistance (SVR) can be calculated as:

SVR (Wood units) = [Mean aortic pressure (mm Hg) – mean RA pressure (mm Hg)]/systemic cardiac output (liter/min)

In the above equation, mean systemic blood pressure is used as a surrogate for mean aortic pressure whereas the other two values are obtained from echocardiography. Once systemic cardiac output, LV filling pressure, pulmonary pressures, and central venous pressure are available, it is quite easy to determine the underlying mechanism of shock, i.e., hypovolemic, cardiogenic, septic, or a combination of these.

TABLE 1: Estimating mean right atrial pressure from inferior vena cava size and collapsibility.

Inferior vena cava diameter	*Collapse on sniff*	*Mean right atrial pressure (mm Hg)*
<2.1 cm	>50%	3 (range 0–5)
>2.1 cm	<50%	15 (range 10–20)
Indeterminate cases		8 (range 5–10)

Right Ventricular Myocardial Infarction

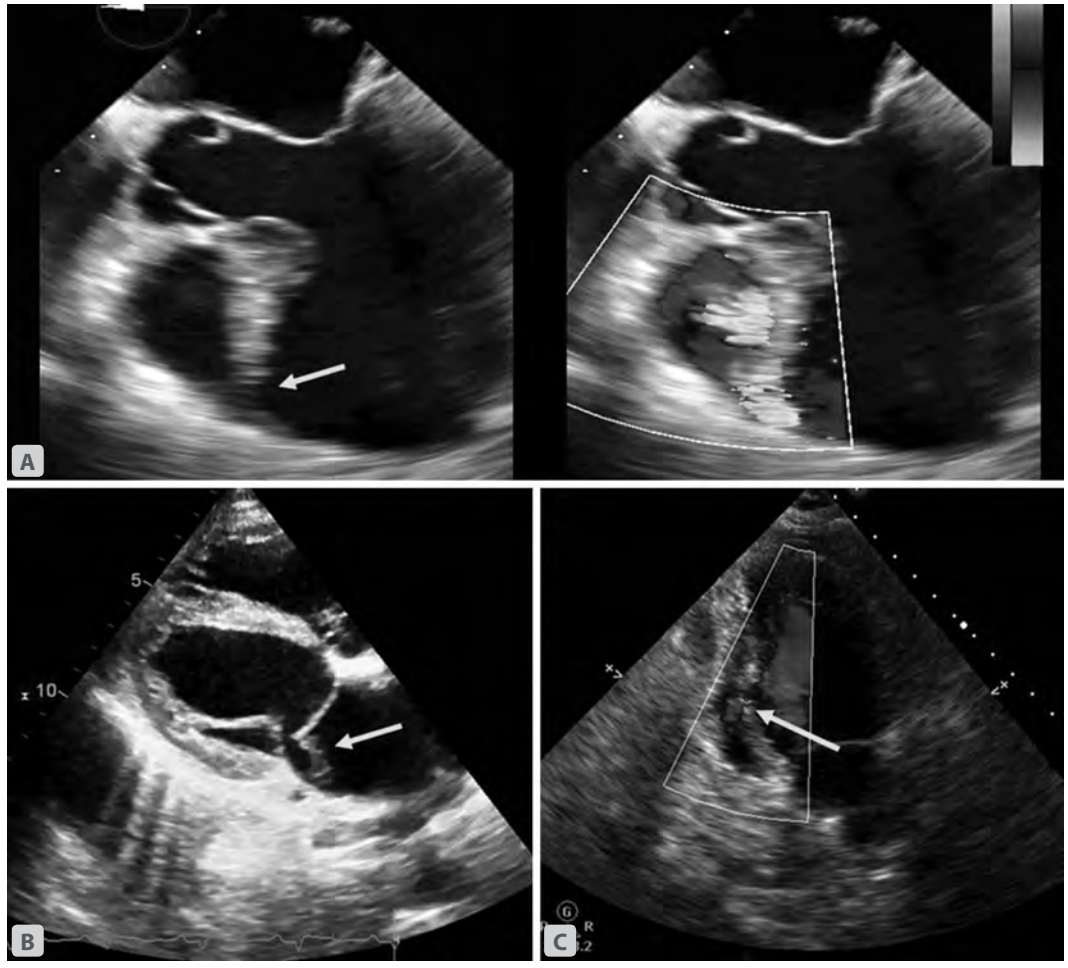
Right ventricular myocardial infarction occurs in almost 50% of all cases of inferior wall MI, but hemodynamically significant RVMI is less common. Recognition of RVMI in patients with inferior wall MI is important because not only RVMI is associated with worse prognosis, the management of the two conditions is also vastly different. *Echocardiography plays a vital role in the diagnosis of RVMI. In these patients, it usually reveals a dilated RV with regional RV hypokinesia/akinesia. TR is common due to dilatation of the tricuspid annulus.* Tissue Doppler imaging may provide additional information. A study revealed that a tricuspid annular peak systolic velocity < 12 cm/s had a sensitivity of 81%, specificity of 82%, and negative predictive value of 92% for diagnosing RVMI in patients presenting with acute inferior wall MI.

Mechanical Complications of Myocardial Infarction

Acute MI can result in several mechanical complications that are among the few most catastrophic cardiac conditions and are associated with very high mortality rates despite best treatment. Early recognition is extremely crucial for improving outcome of these conditions and echocardiography is the most useful modality for this purpose. Common mechanical complications of MI include ventricular septal rupture (VSR), chordal or papillary muscle rupture leading to acute MR, contained free wall rupture with pseudoaneurysm formation, and complete free wall rupture (**Figs. 9A** to **C**).

Post-MI VSR occurs in roughly 1–3% of all STEMI, mainly during the early phase of acute infarction. In case of anterior wall MI, the defect is usually located in the distal part of the septum whereas inferior wall MI results in basal septal rupture. 2D echocardiography may reveal a discrete defect, or there may be multiple channels traversing though the necrotic myocardium. The diagnosis of large discrete defect can be easily made by TTE but small defects may not be visible. TEE is required when TTE is suboptimal and there is high clinical suspicion.

Papillary muscle necrosis and rupture occurs in roughly 1% of all cases of STEMI. It is more common after inferior wall MI and can result from even a modest size infarct. Rupture usually involves the posteromedial papillary muscle as it has single blood supply. Echocardiography is useful in delineating the exact anatomic defect and in assessment of MR severity. However, conventional parameters of MR severity may not



FIGS. 9A TO C: *Examples of mechanical complications of myocardial infarction*. (A) There is apical ventricular septal rupture (arrow) with left to right shunt through the defect; (B) One of the *papillary muscles has got ruptured* and is seen attached to the anterior mitral leaflet and prolapsing into the left atrium. The anterior mitral leaflet itself is flail; (C) Contained *rupture of the inferior wall*. Blood flows through the defect (arrow) into a small pseudoaneurysm. ***(For color version, see plate 7)***

be applicable in this setting due to small regurgitant volume with nondilated LA and LV. Accordingly, a chordal or papillary muscle rupture should always be suspected when there is an eccentric jet of MR with a relatively normal-sized LA in a patient of acute MI.

Rupture of the free wall of the LV occurs in about 1% of the patients with MI. It mainly occurs in patients with a transmural MI involving the inferolateral wall. When there is complete free wall rupture, it usually results in immediate cardiac tamponade and sudden death. However, when the defect is small, the patients may sometimes escape immediate death. In such cases, echocardiography will reveal pericardial collection of variable magnitude with features of cardiac tamponade. However, it is often difficult to visualize the actual defect as the defect may appear just like a "slit" in the myocardium and the location of the pericardial collection also does not always correlate with the site of rupture.

A pseudoaneurysm is the contained rupture of LV free wall, but rarely it may also form as a result of VSR. Majority of pseudoaneurysms are seen in inferoposterior or inferolateral regions. It is important to distinguish a pseudoaneurysm from a true aneurysm as the former has high risk of spontaneous rupture whereas a true aneurysm seldom ruptures spontaneously. In a true aneurysm, there is continuity of the endocardium in the area of dilatation and the wall of the aneurysm is formed by the stretched but intact LV myocardium. In contrast, in a pseudoaneurysm there is breach of endocardial continuity and the wall of the sac is composed of pericardium with little or no myocardial tissue. In addition, the size of communication relative to the size of the aneurysm may also help in making this distinction. The ratio of the diameter of entry to the maximum diameter of the pseudoaneurysm is usually <0.5, whereas it is much larger in a true aneurysm. However, this feature has only 60% sensitivity.

Cardiac Tamponade

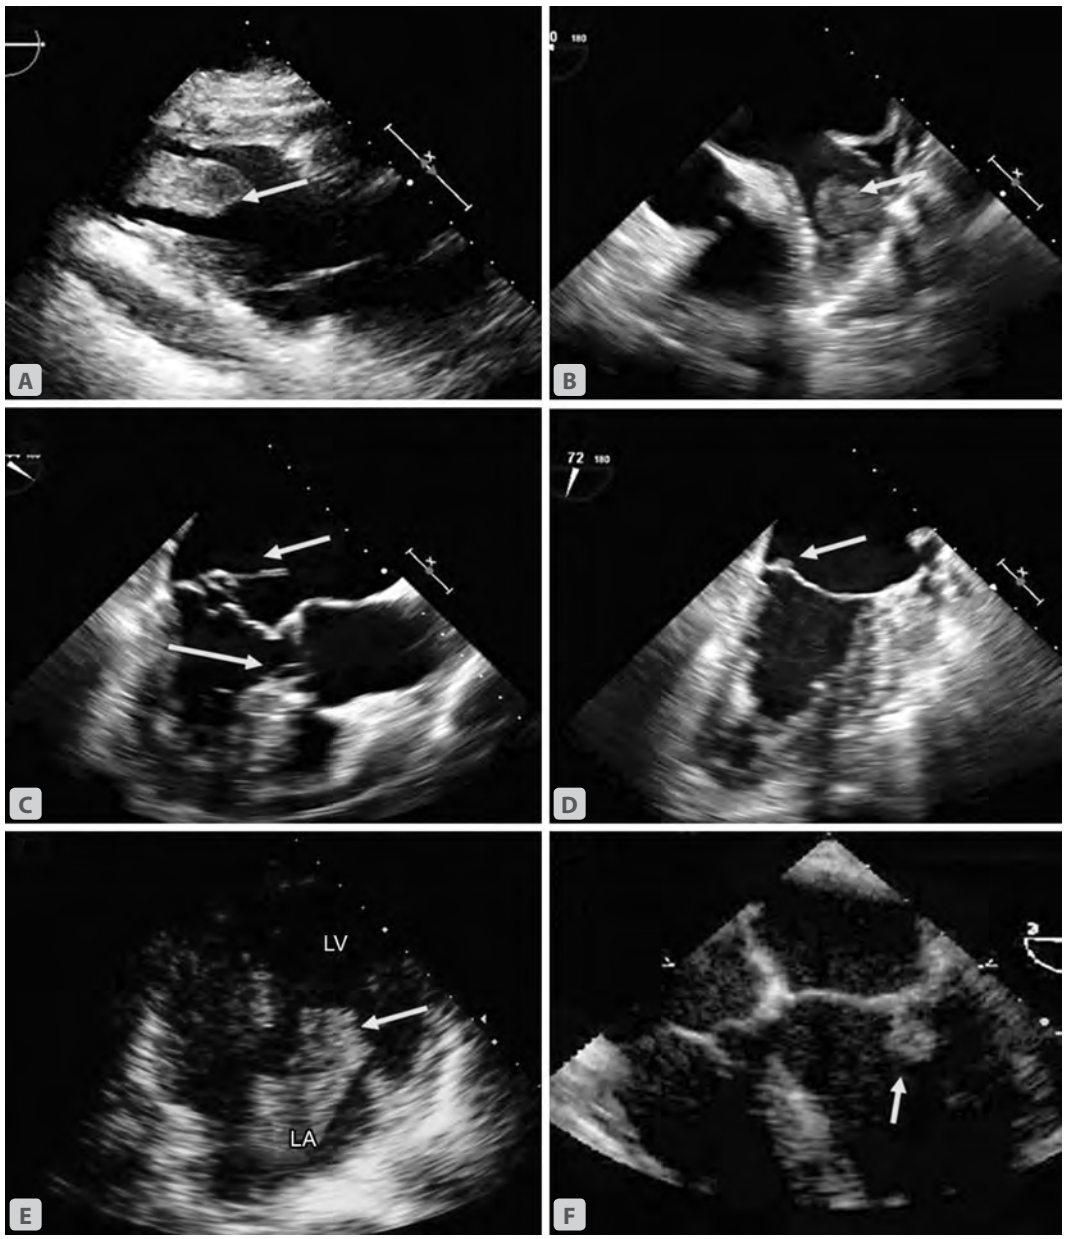
Cardiac tamponade should be suspected in every patient presenting with acute breathlessness with hypotension. Immediate pericardiocentesis is life-saving in such patients and an echocardiogram is very helpful in making the diagnosis. On echocardiography, pericardial effusion is seen as an echo-free space between pericardium and the heart. *The characteristic finding in cardiac tamponade with large effusion is a "swinging heart" appearance*. The 2D echocardiographic and Doppler signs that indicate increased intrapericardial pressure and presence of tamponade in patients with large pericardial effusion include early diastolic RV collapse, late diastolic RA

inversion, abnormal ventricular septal motion, characteristic respiratory variation in mitral and tricuspid inflow velocities, and dilated and noncollapsing IVC. Apart from establishing the diagnosis, echocardiography is also helpful in guiding pericardiocentesis by demonstrating the maximum site of fluid accumulation, suggesting the best trajectory for needle insertion, helping confirm the intrapericardial position of the needle tip, and finally by assessing the immediate postprocedure outcome.

ECHO IN ASSESSMENT OF STROKE PATIENTS

Cardiogenic embolus is an important cause of stroke, accounting for approximately 20% of all ischemic strokes. Therefore, cardiac evaluation is required in all stroke patients who present with clinical features suggestive of cardioembolism (i.e., young age, presence of atrial fibrillation, known valvular heart disease, etc.). A variety of cardiac conditions can lead to systemic embolism. *The common sources of cardioembolism include (**Figs. 10A** to **F**):*

- Left atrial (LA)/LA appendage (LAA) thrombus
- Left ventricular thrombus
- Vegetations (infective/noninfective)
- Cardiac tumors
- Prosthetic heart valve thrombi
- Paradoxical embolism through patent foramen ovale (PFO)/atrial septal defect (ASD)
- Miscellaneous—mitral annular calcification, sclerotic aortic valve, and mitral valve prolapse



FIGS. 10A TO F: *Common causes of cardioembolic stroke.* (A) Large left ventricular apical clot (arrow) in a patient with anterior wall myocardial infarction; (B) Left atrial appendage clot (arrow); (C) Vegetations (arrows) attached to both mitral and aortic valve leaflets; (D) Sessile vegetation (arrow) on the atrial surface of the mitral leaflet in a patient with non-bacterial thrombotic endocarditis; (E) Large left atrial myxoma (arrow) prolapsing into the left ventricular cavity through the mitral orifice; and (F) Papillary fibroelastoma (arrow) attached to the mitral leaflet. ***(For color version, see plate 8)***

Left Atrial/Left Atrial Appendage Thrombus

Left atrial/LAA thrombi accounts for >45% of cardiogenic thromboembolic events. They are most often associated with atrial fibrillation or rheumatic mitral stenosis. TEE is the modality of choice for detection of LA/LAA thrombi and has nearly 100% sensitivity for this purpose. In comparison, the sensitivity of TTE for detection of LA/LAA thrombi is only 39–63%. However, both TTE and TEE can easily detect spontaneous echo contrast within LA, which is a precursor to thrombus formation and has strong association with the risk of systemic embolism. Systemic emboli are frequently seen among patients with dilated cardiomyopathy as well. Though LV thrombi are supposed to be the source of emboli in these patients, LA thrombi are four times more frequent than LV thrombi.

Left Ventricular Thrombus

Left ventricular Thrombus is mainly seen in patients with recent MI, LV aneurysm, or dilated cardiomyopathy. Thrombi most often occur in the apical region of LV, in the presence of regional akinesis or dyskinesis. TTE in combination with ultrasound contrast is a good modality for detection of LV thrombi and TEE is usually not required. Echocardiography also helps in assessing the risk of embolism. A large-sized, mobile thrombus hanging in the LV cavity is associated with high risk of embolism. Similarly, hyperkinetic segments adjacent to the thrombus and an echo-lucent center (suggesting actively growing thrombus) also indicate high risk of embolization.

Valvular Sources of Systemic Embolism

Systemic embolism is a common complication in patients with PHVs, particularly mechanical PHVs. The risk is much higher in patients with subtherapeutic anticoagulation level. Although echocardiography is the modality of choice for evaluation of PHV-related thrombi, acoustic shadowing due to valve structure often proves a limiting factor. TEE provides much better visualization as compared to TTE, particularly in case of mitral PHVs.

Infective endocarditis is another common cause of valve-related embolic events. Echocardiography is useful in detecting the underlying heart disease responsible for IE, identifying vegetations and diagnosing complications of IE. A vegetation is an irregularly shaped, often flagellar, echogenic, and mobile mass, usually attached to the valve leaflets but may also be attached to chordae, chamber walls, or any intracardiac implant such as pacemaker lead, indwelling catheter, or PHV sewing ring. Vegetations may be sessile or pedunculated. Large vegetations (>10 mm size) with high mobility and multiple sites of involvement are at higher risk of embolization. For detection of vegetations and abscesses, TEE is more sensitive than TTE with overall sensitivity 90–100% as compared to only 40–63% for the latter. In a comparative study involving 66 cases of suspected IE, TEE had a sensitivity of 94% compared with 44% for TTE, but both had high specificity approaching 100%.

Vegetations can also form in absence of IE. This is known as nonbacterial thrombotic endocarditis (NBTE) and is usually seen in patients with connective tissue disorders, malignancies, etc. Vegetations in NBTE are most commonly found on the mitral valve and usually on the atrial side of the leaflets. Unlike IE, these vegetations are generally sessile and not >5–10 mm in size.

Finally, calcific specks or fragments of valve tissue can also embolize rarely in patients with mitral annular calcification, aortic sclerosis, etc.

Cardiac Tumors

Cardiac tumors that are commonly associated with systemic embolization are LA myxoma and papillary fibroelastomas. A young patient in sinus rhythm presenting with embolic stroke should raise the suspicion of cardiac tumor or IE. LA myxomas are most often attached to the interatrial septum, in the region of fossa ovalis. They are usually pedunculated and have a nonhomogeneous "cluster of grapes" appearance with areas of echolucency and calcification. LA myxomas can often be confused with LA thrombus and need to be differentiated from the latter. Unlike LA myxoma, an LA thrombus has an amorphous echogenic appearance, is usually sessile and is commonly located in the posterior portion of the LA. Papillary fibroelastomas most often arise from aortic or mitral valve. These tumors are small in size (generally 0.5–2.0 cm in diameter) and have distinct appearance. They are irregular and frond-like in shape, pedunculated, mobile, and attached to the downstream side of the valve. Mobility makes them prone to embolization. Because of the attachment on the valve, fibroelastomas are often mistaken for vegetations. However, the lack of any evidence of infection and their appearance should help in differentiating fibroelastomas from vegetations.

Paradoxical Embolism

In patients with ASD or PFO, blood flow is predominantly in left to right direction. However, there can be a transient reversal of the shunt when RA pressure exceeds LA pressure as occurs during coughing or straining. During these brief periods of shunt reversal, a thrombus from the venous system may travel to the left side of the heart, resulting in systemic embolism. While it is easier to diagnose ASD by echocardiography, diagnosis of a PFO may be challenging. Injecting agitated saline contrast along with Valsalva maneuver or coughing can help uncover intermittent right-to-left interatrial shunting. TEE with saline contrast is superior to TTE with contrast for the diagnosis of PFO. A PFO is considered potentially significant for causing stroke when >10 microbubbles appear in the LA within three cardiac cycles.

ECHO IN ASSESSMENT OF SYNCOPE

Syncope is defined as "sudden temporary loss of consciousness associated with a loss of postural tone and spontaneous recovery not requiring electrical and chemical cardioversion." It is a clinical diagnosis and a detailed history and good physical examination should be able to suggest the diagnosis in the vast majority of the cases. However, echocardiography is often required to rule out underlying structural heart disease. *Various structural heart diseases that can result in syncope include*:

- Acute MI
- Ischemic or nonischemic LV systolic dysfunction (usually due to ventricular tachyarrhythmias)
- Severe aortic stenosis—valvular, subvalvular, or supravalvular
- Hypertrophic obstructive cardiomyopathy
- Large atrial myxoma

- Cardiac tamponade
- Aortic dissection
- Massive pulmonary embolism
- Severe pulmonary hypertension
- Severe pulmonary stenosis, etc.

Echocardiography aids in the accurate diagnosis of the underlying structural heart disease when present. However, it should be remembered that echocardiography should not be a routine diagnostic tool for evaluation of syncope, unless the underlying cause is unexplained by history and physical examination or when the patient has significant cardiac history or has an abnormal ECG.

ECHO IN ASSESSMENT OF PYREXIA OF UNKNOWN ORIGIN

Echocardiography is generally not required in the evaluation of most patients with fever. However, when patients with cardiac conditions predisposing to IE present with fever, echocardiography is routinely indicated. In addition, it is also needed to rule out IE in some patients with no underlying heart disease when no other cause for fever is found despite extensive evaluation.

SUMMARY

Noninvasive nature, portability, and instantaneous diagnostic capability render echocardiography a highly suited diagnostic modality for use in the ER. It offers vital information for early diagnosis, provides extensive anatomic and hemodynamic information, and is also very useful in guiding therapeutic procedures. However, echocardiography is an operator-dependent technique and this becomes even more relevant in ER setting where diagnosis needs to be established quickly and the acoustic window may not always be good. Therefore, proper training of the users and following standardized imaging protocols are essential to maintain optimum diagnostic accuracy of this technique.

Coronary Computed Tomography in Chest Pain Evaluation

64 CHAPTER

Devendra Richhariya

INTRODUCTION

We all know that chest pain and related symptoms such as chest discomfort with squeezing pressure, burning sensation in epigastric, and precordial or pericardial area are the most common presentation in emergency department (ED). About 60–85% of patient with chest pain presenting to ED do not have acute coronary syndrome. Presentation of patient with chest pain is increasing in ED and emergency physician has to very careful while discharging these patients from ED because mortality in wrongly discharge patient is about 25%. Meanwhile observing all the patients in emergency for longer period of time are neither logical nor economical. Initial triaging is to identify the patient with low-risk chest pain and discharge them safely but this is also true that traditional cardiovascular risk factors and clinical scores are not enough to discharge the patient safely because even in low-risk patient adverse events are about 1–2%. This is a challenge for emergency physician to accurately and efficiently diagnose the myocardial infarction (MI) and also noncardiac fatal causes of acute chest pain such as aortic dissection and pulmonary embolism at the same time. Electrocardiogram and cardiac enzyme are traditional methods used as first diagnostic tool for chest pain evaluation and in some institute exercise treadmill, stress echo, and myocardial perfusion imaging are also performed for risk stratification and to look for functional ischemia and these tests carry false-positive and false-negative results. At the same time, package of tests exerts logistic burden on emergency medical services and on patients. So early imaging is necessary for risk stratification. Coronary computed tomography (CT) is an advanced cardiac noninvasive imaging modality with excellent diagnostic accuracy for the detection of coronary artery disease (CAD) and safe efficient and cost-effective tool. Coronary CT angiography (CTA) has been shown to be a highly sensitive test for the detection of CAD with negative predictive values approaching 97–99%. *Triple rule out (TRO) CT examines coronary, pulmonary, and thoracic aorta in single test* and helpful in the diagnosing the fatal causes of acute chest pain such as acute pulmonary embolism and aortic dissection. *Coronary CT is attractive modality for rapid triaging of chest pain*, reduces the hospitalization, and cost effective without compromising the safety and quality of care. Inclusion and exclusion criteria for performing the CTA are summarized in **Table 1**.

TABLE 1: Inclusion and exclusion criteria for coronary CT.

Inclusion criteria	*Exclusion criteria*
Chest pain	Atrial fibrillation
Low-to-intermediate risk	Known CAD
TIMI score 0–2	History of PTCA
Normal ECG and cardiac enzyme	Deranged creatinine
Inconclusive cardiac enzyme	Beta blocker or
Admission to rule out CAD	contrast allergy
	obesity weight >150 kg

INDICATIONS OF CORONARY CT ANGIOGRAPHY

- Coronary CTA is useful in patients with nonacute symptoms representing an ischemic equivalent and low or intermediate group of CAD.
- It is also appropriate in patients who have low or intermediate probability of CAD and normal, nondiagnostic, or uninterpretable ECG or cardiac biomarkers.
- Cardiac CT is excellent for detection and quantification of calcified portions of coronary plaque and for differentiation of calcified, mixed, and noncalcified plaques.
- Coronary CTA is an appropriate first test in patients who are unable to exercise due to osteoarthritis, and who have either a low or intermediate probability of CAD.
- Coronary CT has promise as a novel imaging modality in the acute setting because it is readily available, rapid and requires minimal additional expertise to perform the imaging.
- Coronary CT is useful screening tool for the assessment of coronary arteries for obstructive disease in young and middle-aged patients presenting for noncoronary cardiac surgery such as valve repair, resection of cardiac masses, and aortic surgery.
- Coronary CT is safe test with newly diagnosed heart failure. The objective is to exclude CAD as a cause of heart failure.

- Coronary CT gives accurate assessment of in-stent restenosis in postpercutaneous transluminal coronary angioplasty (PTCA) patients coming in ED with nonacute chest pain.
- Coronary CT is indicated for symptomatic patients with prior CABG to evaluate for graft patency, graft thrombosis, malposition, aneurysms, and pseudoaneurysms.
- Cardiac CT can be used to differentiate between a subacute and an old MI. An acute myocardial infarct will appear as a hypoperfused, akinetic area of myocardium with normal wall thickness. In old MI, patients usually develop wall thinning in relation to normal, adjacent myocardium. In some instances, fatty metaplasia or calcification may be seen in CTA in old MI.
- Cardiac CT is a reasonable choice as the first modality in assessing all of the congenital anomalies in a single study, e.g., patients with suspected Turner's syndrome may have multiple congenital anomalies, including a bicuspid aortic valve, coarctation of the aorta, elongation of the transverse aortic arch, atrial or ventricular septal defect, and partial anomalous pulmonary venous return. All anomalies can be screened in a single study of CTA.
- Prior to invasive procedures, cardiac CT is useful for pulmonary vein mapping, coronary vein mapping, and for localizing bypass grafts and other retrosternal anatomy.
- Coronary CT is useful for evaluating the right ventricular morphology and function, including in cases of suspected arrhythmogenic right ventricular dysplasia (ARVD).
- It is useful for evaluating native or prosthetic cardiac valves in the setting of valvular dysfunction and for evaluating cardiac masses.
- Finally, cardiac CT is an appropriate test for evaluation of the pericardium.

CONTRAINDICATIONS FOR CORONARY CT

- If patient not able to hold breath, follow instruction or remain still.
- Renal insufficiency
- Cardiac arrhythmias
- Beta-blockers are given to patients undergoing CTA to bring the heart rate (HR) down so as to allow gating. If a patient has a contraindication to beta-blockade, such as asthma.
- Anaphylactic reaction to intravenous iodinated contrast agents is considered an absolute contraindication, though less severe allergic reactions may be acceptable if the patient has been adequately premedicated, usually with a combination of intravenous or oral diphenhydramine and corticosteroids.

FACTORS AFFECTING THE QUALITY OF CORONARY CT IMAGES

- *Fast HR*: Image quality will be poor if HR is >65 beats/min. Patient with high HR is unsuitable for CT coronary. Patient with HR > 70 beats/min, beta blocker should be given to achieve the HR < 65 beats/min. Calcium channel blockers are alternative to beta-blockers. HR reducing medication and fast scan (64–320 cross-section per rotation) help in acquiring the images with no artifact.
- *Atrial fibrillation*: Ectopy or ECG artifacts result in degradation of image quality.
- *Extensive coronary calcification*: It obscures the coronary lumen make analysis of segments or even entire arteries difficult.
- *Preexisting CAD*: Patients with history of CAD usually have extensive coronary calcifications, and/or coronary stents produces metal artifacts and prior coronary bypass grafting with extensively calcified native vessels and small caliber distal coronary arteries also make interpretation of images difficult.
- *Obesity (body mass index over 40 kg/m^2)*: It increases radiation scatter within the patient's body and consequently degrades image quality.

PREPARATION AND INSTRUCTIONS FOR CORONARY CT

- Patient undergoes coronary CT while in ED or after completing observation protocol.
- Troponin and creatinine test are performed simultaneously. Coronary CT is performed only after creatinine result. Usually, the troponin results are repeated while patients are in observation unit.
- Contrast is calculated on the basis of weight of the patient and given as the bolus technique.
- Radiology technician/attending physician instructs the patient about breath holding.
- Image acquisition during single breath hold
- Patient should not move during the image acquisition.
- Patient may feel warm sensation during contrast injection.
- Low radiation exposure with lower tube voltage technique and with advanced CT scan

TRIPLE RULE-OUT PROTOCOL

Acute chest pain is the most common presentation in ED. In view of wide spectrum causes of acute chest pain, not all life-threatening causes are of cardiac origin. Emergency physician should consider other noncardiac causes of chest pain such as pulmonary embolism and acute aortic syndrome which are less common than acute coronary syndrome but immediately life threatening. Apart from initial triaging, other investigations such as D-dimer are used for diagnosis but nonspecific and elevated in other conditions also. Whenever there is high clinical suspicion multidetector row CT (MDCT) used to examine three vascular territories simultaneously pulmonary aorta and coronary arteries. *"TRO"* CT protocol is associated with higher radiation dose. Coronary CT imaging with TRO protocol is modality of choice for suspected pulmonary embolism and aortic pathology such as aortic dissection and aneurysm. TRO protocol covers the whole chest and helpful in assessment of vascular as well as nonvascular pathologies of entire chest.

Patient selection—triple rule CT protocol recommended in acute chest pain patient with inconclusive cardiac enzyme and ECG and combine suspicion of acute pulmonary embolism, acute coronary syndrome, and aortic dissection.

Patient with elevated cardiac enzyme, ECG changes of acute coronary syndrome, pregnancy, previous contrast reaction, nephropathy, should be excluded. *"TRO" protocol* helpful in diagnosis of following conditions—acute aortic syndrome (including aortic dissection, aneurysm, penetrating aortic ulcer, and intramural hematoma), pulmonary embolism, and acute coronary syndrome.

INTERPRETATION OF CORONARY CT

Interpretation and reporting of CTA are done by radiologist with special training in cardiac imaging and CT angiography. Degree of stenosis is observed and measured by electronic calipers. Narrowing of left main, left anterior descending, right coronary artery, circumflex, and their branches is expressed and reported in percentage:

- Mild stenosis (<50% luminal narrowing)
- Moderate stenosis (50–69% luminal narrowing)
- Severe stenosis (>70% luminal narrowing)

Value of calcium scoring in ACS evaluation of patient in ED is debatable. Large calcium deposits in coronaries make interpretation of images difficult. Calcification in coronary arteries is a marker of atherosclerosis and may be considered for long-term management of cardiac risk in outpatient but not for acute setting in ED.

CORONARY CT AS DECISION MAKING TOOL

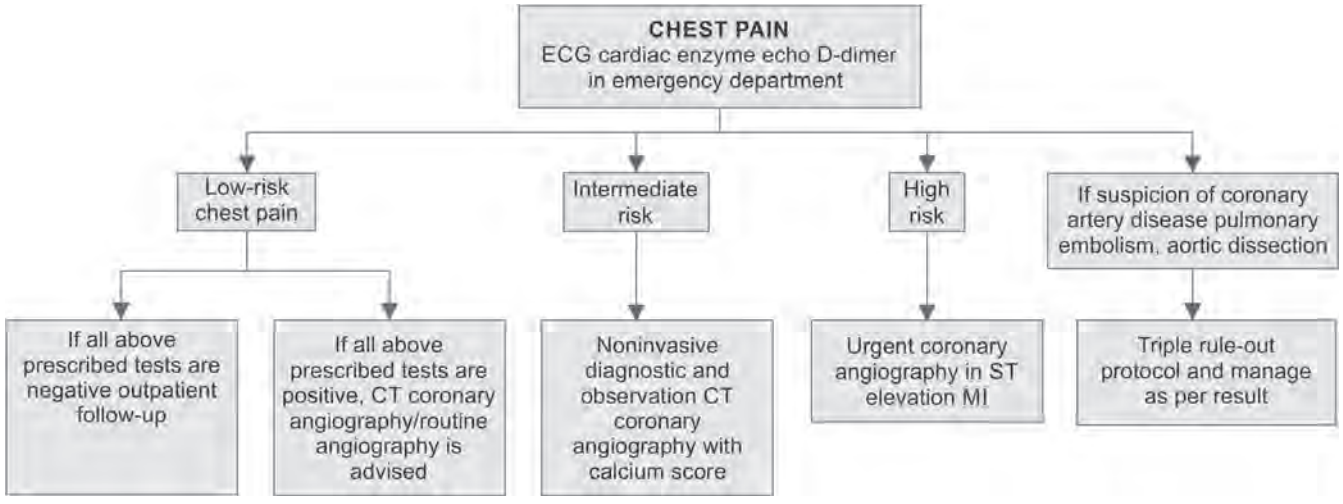
Coronary CT in ED act as a surrogate for cath lab angiography. Coronary CT helpful in risk stratification and disposition of chest pain patient in ED. Provide better understanding of disease, CT is safe, efficient, costs effective, reduces ED visits and hospitalization, physicians and patients believe the results. Higher satisfaction rates, improves chest pain triaging and helpful as *decision making tool in disposition of patient with chest pain* (**Table 2**).

SUMMARY

Coronary CT has been shown to be a safe and efficient way to determine which patients have no significant CAD. CTA is a valuable asset to clinical decision-making in that it allows for the discharge of many patients who would otherwise be admitted for further observation and testing. CTA is not without its limitations, but as technology improves, so will the detail of images, which will improve the diagnostic capabilities of the modality. TRO protocol not only diagnose acute coronary syndrome but also noncardiac life-threatening emergencies such as acute pulmonary embolism and acute aortic dissection. Early implementation of CTA in the ED, for the evaluation of low to intermediate risk chest pain associated with reduced length of stay and a safe alternative to standard ED evaluation (**Flowchart 1**). Rules out CAD by direct visualization of the coronary arteries.

TABLE 2: Coronary CT as decision making tool.

Degree of stenosis	*Recommended action*
0–25%	Patient can be discharged safely follow-up in OPD
26–49%	Patient can be discharged OPD follow-up for preventive measures
50–69%	Possible CAD further evaluation needed before discharge
>70%	Possible CAD hospitalization and evaluation



CHEST PAIN
ECG cardiac enzyme echo D-dimer in emergency department
Low-risk chest pain
Intermediate risk
High risk
If suspicion of coronary artery disease pulmonary embolism, aortic dissection
If all above prescribed tests are negative outpatient follow-up
If all above prescribed tests are positive, CT coronary angiography/routine angiography is advised
Noninvasive diagnostic and observation CT coronary angiography with calcium score
Urgent coronary angiography in ST elevation MI
Triple rule-out protocol and manage as per result

(CT: computed tomography; ECG: electrocardiography; MI: myocardial infarction)

FLOWCHART 1: Showing role of computed tomography in evaluation of chest pain.

CHAPTER

Acute Coronary Syndrome

Naveen Bhamri, Devendra Kumar Agarwal, Sudhanshu Sekhar Parida

INTRODUCTION

Acute coronary syndrome (ACS) refers to the clinical spectrum of coronary artery diseases (CADs) that include ST-segment elevation myocardial infarction (STEMI) and non-ST elevation ACS (NSTE-ACS). The NSTE-ACS encompasses non-ST-segment elevation myocardial infarction (NSTEMI) and unstable angina (UA). Acute myocardial infarction (AMI) is any ACS with clinical evidence of: (1) Myocardial injury with serial elevated cardiac troponin (cTn) levels and at least one cTn value above the 99th percentile of upper reference limit (URL); and (2) Cardiac tissue necrosis consistent with myocardial ischemia.

According to a recent US survey by the American Heart Association (AHA) more than one million patients were hospitalized annually with primary or recurrent ACS. Approximately one in every seven deaths in the US occurs due to CAD. Of all the premature deaths (before 70 years) due to noncommunicable diseases, 82% occur in low middle income countries, of which 37% are caused by CADs. The overall prevalence of CAD has risen dramatically in India in the last decade with CAD occurring at a much younger age in India than in Western population. Therefore, prevention, early diagnosis, and timely management of CAD including ACS based on evidence-based guidelines [European Society of Cardiology (ESC) for STEMI and the 2014 AHA guidelines for NSTE-ACS] are of utmost importance in India.

ETIOPATHOGENESIS AND RISK FACTORS

Acute coronary syndrome mainly occurs due to acute thrombus in an atherosclerotic coronary artery or its branches (**Fig. 1**) causing obstruction of blood flow to the myocardium, triggering increased myocardial oxygen demand and unbalancing oxygen demand and supply. Not all plaque ruptures result in ACS, majority remain asymptomatic. The possibility of a plaque causing ACS depends on severity of rupture, blood flow in the area, the blood thrombogenicity, and the degree of inflammation at the site. The *risk factors* associated with atherosclerosis are dyslipidemia, diabetes mellitus (DM), hypertension, obesity, family history of ACS, number of diseased vessels, history of previous ACS or MI, alcohol abuse, and smoking.

The etiopathogenesis of ACS differs with the type of clinical setting (**Table 1**) and the ACS subcategory of (STEMI/NSTE-ACS).

Clinical Presentation

Substernal chest pain is the classic symptom of ACS, often described as crushing or pressure-like feeling, radiating to the jaw, and/or left arm. If a patient has pain radiating to the left arm or both arms, there is a high possibility of ACS. A study found that even 22% of low-risk patients who had ACS presented with sharp or stabbing pain. Many times, presenting complaints can be atypical like breathing difficulty, lightheadedness, isolated jaw or left arm pain, nausea, epigastric pain, diaphoresis, and weakness. Although atypical symptoms could typically mean no possibility of ACS, however, physicians should be alert that these could be low ACS-risk patients. About 10–40% of patients with MI present without any chest pain. Female gender, DM, and older age are associated with atypical symptoms or MI without chest pain. Patients with NSTEMI are more likely to present without chest pain than those having STEMI. Mortality rate is higher in this patient group. Differentiating cardiac pain from noncoronary pain is very critical for an accurate diagnosis. Few examples of ailments causing noncardiac chest pain include pneumonia, pulmonary embolism, renal calculus, rib fracture, abdominal disorders, acute aortic dissection, splenic infarction, or esophageal spasm. Physical findings that may be suggestive of ACS include new mitral regurgitation murmur, hypotension, S3 gallop, and a new jugular venous distention. Frequently, physical examination of patients with ACS turns out to be normal.

MANAGEMENT OF ACUTE CORONARY SYNDROME

Initial Evaluation at Emergency Department/ When First Seen

Initial evaluation is aimed at establishing diagnosis of ACS, assessing risk and differentiating into STEMI, NSTEMI, and unstable angina for further management. Physicians initially make a working diagnosis of ACS based on the symptoms, medical history (including assessing risk factors for CAD),

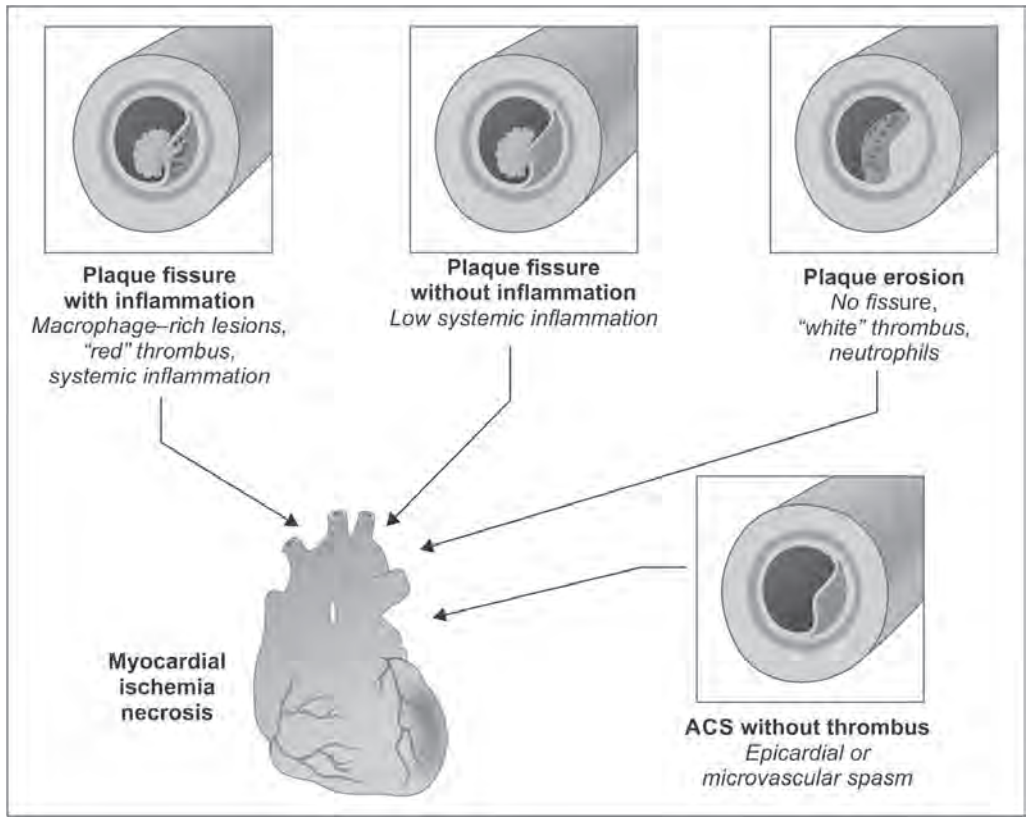

FIG. 1: Four diverse mechanisms causing acute coronary syndromes (ACS).

TABLE 1: Types of ACS presentation.

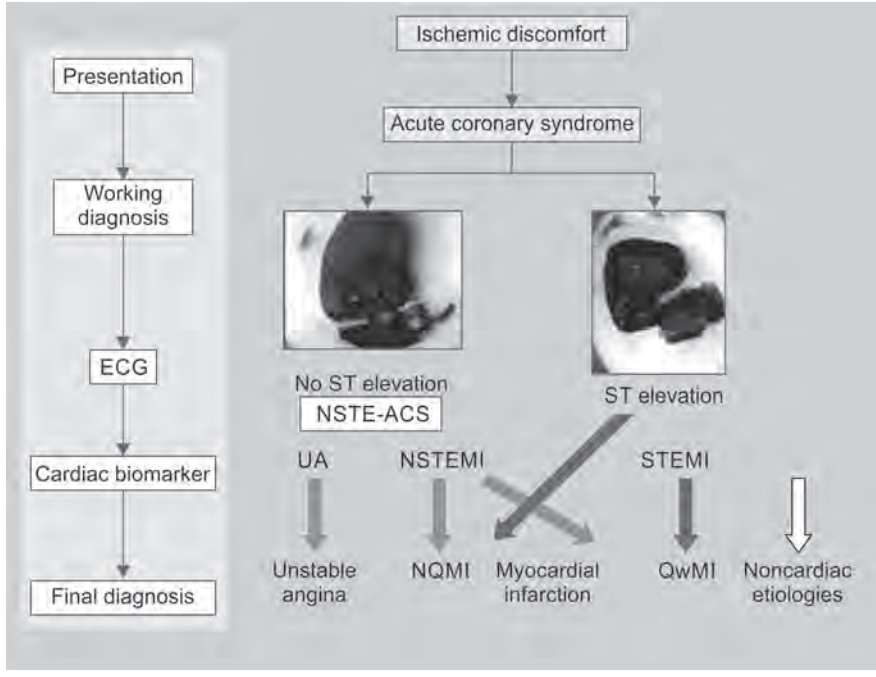
Type	*Clinical setting*	*Etiology/Findings*
Type 1	Spontaneous MI	• Rupture, ulceration, fissuring, erosion, or dissection of atherosclerotic plaque • Distal platelet emboli with resultant myocyte necrosis
Type 2	MI secondary to ischemic imbalance	Non-CAD-related condition such as arrhythmia, coronary embolus, coronary endothelial dysfunction, coronary artery spasm, anemia, tachycardia, respiratory failure, pulmonary embolism, severe aortic stenosis, hypotension, hypertension, sepsis, use of cardiotoxic drugs, stress, cocaine, and tobacco use
Type 3	MI resulting in death when biomarker values are unavailable	Death due to cardiac arrest before blood samples could be obtained or before cardiac biomarkers could rise ECG shows new ischemic changes or new LBBB
Type 4a	MI related to PCI (recurrent MI)	cTn elevation to >5 times the 99th percentile of URL or >20% in patients with normal pre-PCI values and one of the following: • Angina • *ECG*: New ischemic changes • *Angiography*: Either reduced blood flow or blockage • *Imaging studies*: New regional wall motion abnormality
Type 4b	MI related to stent thrombosis (recurrent MI)	Stent thrombosis on angiography or autopsy and rise and/or fall in cardiac biomarker levels
Type 5	MI related to CABG (recurrent MI)	Cardiac biomarkers values >10 times with 99th percentile of URL in patients with normal pre-CABG values and one of the following: • *ECG*: New pathological Q waves or LBBB • *Angiography*: Occlusion of a new graft or native coronary artery • *Imaging*: New regional wall motion abnormality

(CABG: coronary artery bypass surgery; CAD: coronary artery disease; cTn: cardiac troponin; ECG: electrocardiogram; LBBB: left bundle branch block; MI: myocardial infarction; PCI: percutaneous coronary intervention; URL: upper reference level)

and physical evaluation, which is further confirmed by serial electrocardiograms (ECG) and serial serologic cardiac markers (**Fig. 2**). Further management is based on risk prognosis assessed by *two commonly used risk assessment tools*—(1) thrombolysis in myocardial infarction (TIMI) risk score and (2) the Global Registry of Acute Coronary Events (GRACE) risk score (**Table 2**). After initial evaluation and risk stratification, treatment depends on whether patient has STEMI, NSTEMI, or UA. The primary aim of the treatment for ACS is to relieve distress, reduce cardiac workload, reverse ischemia, interrupt thrombosis, and prevent complications. Patients having confirmed STEMI require more intensive management and monitoring than NSTE-ACS.

Initial Electrocardiogram (ECG)

Timing of ECG, a 12-lead ECG is performed within 10 minutes of patient's arrival at an emergency facility. If the initial ECG is nondiagnostic and patient continues to be symptomatic, ECG is repeated at 15–30-minute intervals during the first hour. Serial ECGs are recommended for better diagnosis and management of ACS. Establishing diagnosis with ECG, in patients with



(ACS: acute coronary syndrome; NSTE-ACS: non-ST elevation ACS: NSTEMI: non-ST-segment elevation myocardial infarction; STEMI: ST-segment elevation myocardial infarction; UA: unstable angina)

FIG. 2: Initial evaluation of an individual presenting with symptoms suggestive of acute coronary syndrome (ACS): ascertaining the type of ACS. ***(For color version, see plate 9)***

TABLE 2: Risk scores for risk stratification of acute coronary syndrome.

TIMI risk score for STEMI	*TIMI risk score for NSTE-ACS*	*GRACE risk score for entire spectrum of ACS*
Score: 0–14 *(scores ≥3—high risk)*	*Score: 0–7* *(scores ≥3—high risk)*	*Range: 1–372* *Low risk <109* *Intermediate risk: 109–140* *High risk: >141*
Based on eight variables at admission: • ≥65 years • Risk factors: Diabetes mellitus, angina, and hypertension • SBP <100 • Heart rate >100 • Weight < 67 kg • Anterior STE or LBBB • Treatment start > 4 hours	*Based on one point each for seven variables at admission:* • ≥65 years of age • ≥3 risk factors for CAD • Prior ≥50% coronary stenosis • ST deviation on ECG • ≥2 anginal events in prior 24 hours • Aspirin use in prior 7 days • Elevated cardiac biomarkers	*Based on eight variables at admission:* • Age • Heart rate • SBP • Serum creatinine • Killip class • Cardiac arrest • ST-segment deviation on ECG • Elevated cardiac enzymes/markers

(ACS: acute coronary syndrome; ECG: electrocardiogram; LBBB: left bundle branch block; NSTE-ACS: non-ST elevation ACS; SBP: systolic blood pressure; STE: ST-segment elevation; STEMI: ST-segment elevation myocardial infarction)

STEMI, initial ECG shows ST-segment elevation (≥1 mm) in ≥2 contiguous leads reflecting the damaged area **(Fig. 3A)**. Conversely, in NSTE-ACS, there is horizontal or down-sloping ST depression **(Fig. 3B)**. Based on initial ECG findings or in patients with intermediate/high risk for ACS with initial nondiagnostic ECG, the following additional ECG recordings may be required.

- Posterior chest wall leads (V_7–V_9) in patients with high suspicion of posterior MI
- Right precordial leads (V_3R and V_4R) in patients with inferior MI
- Continuous monitoring with 12-lead ECG, if required

The ECG assists in risk stratification, diagnosing, and treatment decisions; however, accuracy improves when ECG is obtained in patients with ongoing chest pain.

Cardiac Markers for Diagnosis and Risk Stratification

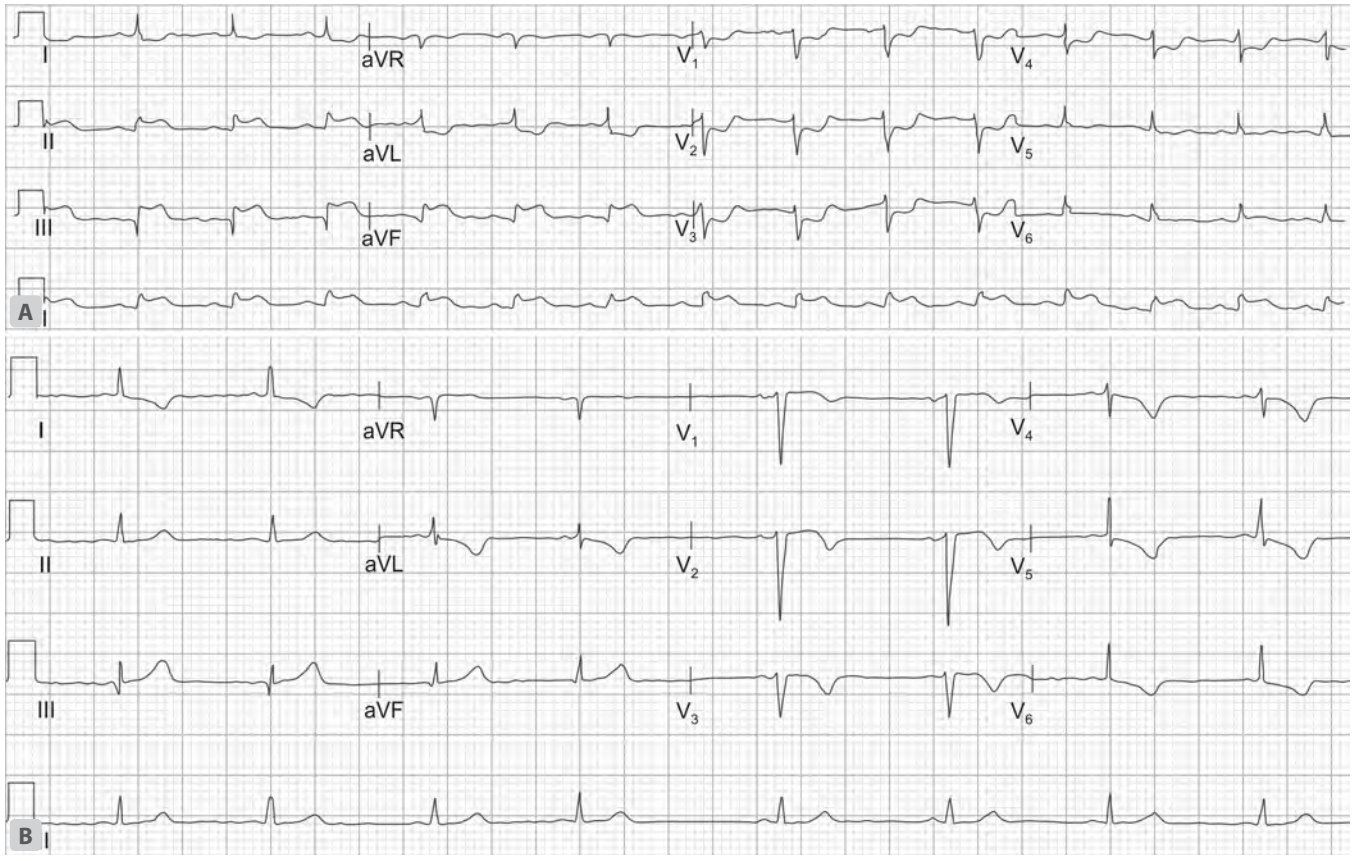
Timing of cardiac markers, in patients with symptoms consistent with ACS:

- Immediately send blood samples for cardiac troponin I (cTnI) or cardiac troponin T (cTnT)
- Reassess cTnI or cTnT 3–6 hours after symptom onset
- *After 6 hours*: If initial and serial cTn values are normal, and/or patient has ECG changes, and/or patient is in immediate-/high-risk category
- *Day 3 or 4*: In patients with MI to assess infarct size

An increased cTn suggests myocardial cell injury but does not throw light on cause of the injury as cTn values increase in many other cardiac/noncardiac causes. Imaging techniques such as angiography are used to find the cause and actual site of injury.

Role of Other Cardiac Markers in ACS Diagnosis

Other cardiac markers include creatinine kinase (CK), myoglobin, and B-type natriuretic peptide (BNP). The sensitivity and specificity of CK levels for cardiac damage are lower compared to other markers as raised CK levels are usually associated with many noncardiac conditions as well. CK myocardial isoenzyme (CK-MB) is useful for early diagnosis of acute MI. Unlike CK level, CK-MB is more specific to cardiac injury but it cannot help in ascertaining infarct size; however, it is useful in detecting early reinfarction. CK-MB and myoglobin are not required if contemporary troponin assays are being performed as they do not add any additional diagnostic value. BNP or N-terminal (NT)-pro-hormone BNP (NT–pro-BNP) is



FIGS. 3A AND B: (A) (STEMI): 12-lead electrocardiogram showing ST-segment elevation in the inferior leads (II, III, and aVF) with reciprocal ST-segment depression in leads V_1–V_4, I, and aVL. (B) (NSTEMI): 12-lead electrocardiogram showing anterolateral T-wave inversion (leads V_2–V_6, I, and aVL).

sometimes done in patients with suspected ACS to assess risk and as a prognostic marker.

COMMON STRATEGIES FOR STEMI AND NSTEMI MANAGEMENT

- Patients with confirmed MI are admitted to hospital care immediately:
  - *Low risk*: Admitted to intermediate step-down
  - *High risk*: Admitted to a coronary care unit (CCU). Nurses trained in rapid cardioversion and defibrillation should be deployed in such CCUs.
- Continuous ECG monitoring
- Supplemental oxygen is started only if oxygen saturation < 90% or there are respiratory distress/other hypoxemia features
- Antianginal, antiplatelet, and anticoagulant therapy are started.
  - *Antianginal*: Sublingual [nitroglycerin (NTG) is given every 5 minutes (three times) for continuing angina; then switched to intravenous (IV)] NTG for persistent angina, heart failure (HF), or hypertension. Nitrates are contraindicated if patient was recently on phosphodiesterase inhibitors.
  - *Antianginal*: IV morphine sulfate for persistent angina not relieved by nitrates. Nonsteroidal anti-inflammatory drugs are contraindicated, except aspirin as these are associated with high risk for major adverse cardiovascular event (MACE).
  - *Mild tranquillizer (usually a benzodiazepine)*: If patient is very anxious.
  - Nonenteric-coated, chewable aspirin (162–325 mg) is started immediately followed by maintenance dose (81–325 mg/day) indefinitely. This can be given before and after percutaneous coronary intervention (PCI) or coronary artery bypass surgery (CABG).
- *Antiplatelet*: P2Y12 inhibitor—ticagrelor (preferred), clopidogrel, or prasugrel is usually started with aspirin as part of dual antiplatelet therapy (DAPT).
- Lipid profile is obtained in first 24 hours; high-intensity statins started, unless contraindicated.
- Beta-blockers (calcium channel blockers if beta-blockers contraindicated) can be started within first 24 hours.
- Angiotensin-converting enzyme (ACE) inhibitors/angiotensin II receptor blocker (ARB) recommended especially for patients with impaired left ventricular ejection fraction (≤40%), early HF, hypertension, and DM.
- Patients remain on bed/chair rest with minimal ambulation.
- Nurse-patient ratio should allow continuous cardiac monitoring and repeated assessment of vitals and mental status.

NON-ST ELEVATION—ACS MANAGEMENT

Unstable angina patient group with ACS symptoms but normal serial cTn and inconclusive/normal serial ECGs:

- Before discharge from emergency unit or within 72 hours postdischarge; only if patients have been angina-free for 12–24 hours; and very low-risk patients:
  - Perform treadmill ECG if no ST changes in resting ECG
  - Perform stress echocardiography or stress myocardial perfusion imaging if ST changes in resting ECG.
- In case of persisting symptoms and clinical suspicion of ACS, perform coronary CT angiography or resting technetium-99m myocardial perfusion imaging.

Patients with low risk are referred for outpatient management and follow-up. These patients are usually prescribed aspirin, short-acting NTG, and other medications as required. If patients develop STEMI/NSTEMI changes on treadmill ECG or stress imaging, then further treatment depends on patient's condition and MACE risk.

STEMI MANAGEMENT

Reperfusion is indicated for all patients with ≤12 hours duration of symptoms and persistent ST-segment elevation (**Table 3**). Fibrinolysis with tenecteplase, alteplase, or reteplase is recommended if revascularization is expected to be delayed beyond 2 hours (**Table 4**). It is also important to distinguish between left ventricular myocardial infarction (LVMI) and the right ventricular myocardial infarction (RVMI) with the help of clinical features, ECG and the hemodynamic features because mortality risk due to primary RV dysfunction nearly as high as LV dysfunction. Differentiating features between LV and RV MI are shown in **Table 5**. Literature shows that primary PCI is better in terms of reducing mortality, nonfatal myocardial infarction, and stroke compared with fibrinolysis if performed on time.

Preferred Infarct-related Artery Reperfusion

- *Primary PCI*: Stenting recommended over balloon angioplasty
- New-generation drug-eluting stent (DES)—DESs are recommended over bare-metal stent.
- Radial access recommended over femoral access
- Routine use of thrombus aspiration or deferred stenting is not recommended.
- If infarct-related artery (IRA), PCI cannot be performed—CABG for patients with ongoing ischemia/jeopardized myocardium covering large areas

Non-IRA-related Reperfusion

- Routine preventive strategy in STEMI patients with multivessel disease
- During index IRA procedure in patients with cardiogenic shock

SPECIAL CONSIDERATION IN STEMI/NSTEMI MANAGEMENT

Further NSTEMI management involves either invasive strategy or an ischemia-guided strategy. Invasive strategy involves diagnostic angiography with intent to perform PCI; it can be immediate, early, or late invasive depending on patient's condition. CABG is another option for revascularization. On the contrary, early ischemic strategy is used for patients with low-risk score (conservative management). Patients with STEMI are usually intensively managed with invasive techniques such as angiography followed by PCI or CABG.

TABLE 3: Invasive treatment strategy for NSTEMI and STEMI.

Treatment strategy	*Timing*	*Patient group (NSTEMI)*	*Patient group (STEMI)*
Immediate	≤2 h (120 min)	• Refractory angina • Recurrent angina • Ischemia at rest/low activity level despite intensive medical therapy • HF • New or worsening MR • Hemodynamic instability • Sustained VT or VF	• Primary PCI within 120 min of presentation/ECG • IRA should ideally be perfused within 60 min • If a delay is expected then immediate fibrinolysis • Primary PCI in absence of ST segment elevation + persisting symptoms: ○ Hemodynamic instability ○ Cardiogenic shock ○ Life-threatening arrhythmias ○ Cardiac arrest ○ Mechanical complications of MI ○ Acute heart failure ○ Recurrent dynamic ST-segment or T-wave changes
Early	≤24 h	Not a candidate for immediate invasive GRACE risk score >140 Temporal change in cTn New or presumably new ST depression	• Early angiography if complete symptom relief and complete normalization of ST-segment elevation spontaneously or after NTG • *Routine primary PCI*: Symptoms onset of 12–24 h • If symptom onset is >12 h, primary PCI is indicated in the presence of persistent symptoms of ischemia, hemodynamic instability, and arrhythmias (life-threatening)
Delayed	≤25–72 h	Not a candidate for immediate/early invasive but patient has: • Diabetes mellitus • Renal insufficiency (GFR < 60 mL/min/1.73 m^2) • Reduced LV systolic function (EF < 0.40) • Early postinfarction angina • PCI within 6 months • Prior CABG • GRACE risk score 109–140; TIMI score ≥ 2	• Routine primary PCI: symptoms onset of 25-48 h • Routine PCI of an occluded IRA > 48 h after onset of STEMI is not indicated in asymptomatic patients

(CABG: coronary artery bypass surgery; EF: ejection fraction; GFR: glomerular filtration rate; GRACE: Global Registry of Acute Coronary Events; HF: heart failure; IRA: infarct-related artery; LV: left ventricular; MI: myocardial ischemia; NSTE-ACS: non-ST-elevation acute coronary syndrome; NTG: nitroglycerin; PCI: percutaneous coronary intervention; TIMI: thrombolysis in myocardial infarction; Tn: troponin; VF: ventricular fibrillation; VT: ventricular tachycardia; MR: mitral regurgitation)

TABLE 4: Fibrinolytic agents and doses.

Streptokinase	1.5 million IU Infused over 1 h in 45 mL NaCl
Alteplase	15 mg loading dose followed by 50 mg over 30 min and 35 mg over next 1 h (Total duration of infusion 90 min) and concurrent use of heparin 0.75 mg/kg not to exceed 50 mg over 30 min and 0.50 mg/kg and not to exceed 35 mg over next 1 h
Reteplase	• Given as double bolus by 10 U + 10 U (no infusion) • 10 U bolus over 2 min wait for 30 min and repeat 10 U over 2 min and concurrent use of heparin
Tenecteplase	30–50 mg single weight-based bolus over 5–10 sec and concurrent use of heparin

TABLE 5: Differentiating features of LVMI and RVMI.

	LV MI	*RVMI*
Clinical features	Pulmonary congestion S3, S4 new MR	Clear lung fields right-sided S3 new TR, hypotension with distended neck veins
ECG	ST elevation in standard leads	ST elevation in V_4R
Hemodynamics	Raised pulmonary wedge pressure	RAP > 10 mm Hg RAP/PAWP > 0.8
Specific management	• Fluid restriction • Preload and after-load reduction • Reperfusion therapy • Inotropes	• Fluid resuscitation • Avoid preload reduction • Reperfusion therapy • Inotropes

Anticoagulation: Special Considerations

Long-term anticoagulation is not routinely prescribed following ACS.

Commonly used anticoagulants in specific situations include:

- Bivalirudin until diagnostic angiography or until PCI
- Subcutaneous enoxaparin or fondaparinux for the hospitalized duration or until PCI
- Intravenous unfractionated heparin for 48 hours or until PCI
- *Antiplatelets*: P2Y12 inhibitor in loading dose followed by maintenance therapy; given in addition to aspirin, and continued for at least 12 months, especially in patients receiving a DES during PCI. DAPT can significantly reduce the risk of stent thrombosis and MACE. The STOPDAPT-2 trial showed that DAPT can be reduced up to one month with the new generation DES without any significant increase in MACE.
- Ticagrelor (loading dose: 180 mg; maintenance: 90 mg twice daily), clopidogrel (loading dose: 600 mg; maintenance: 75 mg daily), or prasugrel (loading dose: 60 mg; maintenance: 10 mg daily)
- In high-risk patients, glycoprotein (GP) IIb/IIIa inhibitors (abciximab, double-bolus eptifibatide, or high-dose bolus tirofiban) can be given at the time of PCI.

Stopping Anticoagulation before CABG

- *Elective CABG*: Clopidogrel or ticagrelor discontinued for at least 5 days and prasugrel for at least 7 days before surgery, if possible.
- *Urgent CABG*: Clopidogrel or ticagrelor discontinued for at least 24 hours before surgery to reduce major bleeding.
- Short-acting IV GP IIb/IIIa inhibitors (eptifibatide or tirofiban) are discontinued for at least 2–4 hours and abciximab for at least 12 hours before surgery to reduce major bleeding.

DISPOSITION

Patients are discharged from hospital once they are stable with detailed instructions on medications, activity level, recognition of warning symptoms requiring urgent care and follow-up details. Long-term cardiac rehabilitation that includes exercise, lifestyle changes, and education is stressed upon during routine cardiac follow-ups.

SUMMARY

Acute coronary syndrome encompasses NSTE-ACS—UA, NSTEMI, and STEMI. Diagnosis is based on medical history, physical assessment, ECG, and serum cardiac markers; cTn is most sensitive. Treatment and management of ACS based typically on the ACS subtypes and patient characteristics. STEMI needs more aggressive treatment approach than NSTE-ACS. Prolonged anticoagulation not recommended but aspirin should be continued indefinitely. DAPT is preferred over aspirin alone especially in patients who undergo PCI with DES.

66
CHAPTER

Cardiogenic Shock

Devendra Richhariya

INTRODUCTION

Shock is the final outcome of the circulatory collapse and inadequate supply of oxygenated blood to the tissues and the vital organs. Traditionally *shock is classified in-to four major types*—(1) Hypovolemic shock (excessive fluid loss from the body), (2) Obstructive shock (blood flow obstruction in the large blood vessels, conditions like pulmonary embolism, cardiac tamponade, and tension pneumothorax), (3) Distributive shock (sepsis and anaphylactic reaction), and (4) Cardiogenic shock caused by various conditions affecting the myocardium. Various characteristics of different types of shock are described in Chapter 48 "Approach to Shock". According to epidemiological data, septic shock (distributive shock) is the most common shock followed by cardiogenic and hypovolemic shock.

Cardiogenic shock is the syndrome develops due to primary cardiac dysfunction resulting in tissue and organ hypoperfusion with progressive multiorgan failure. Most common cause of cardiogenic shock is acute myocardial infarction (AMI) particularly involving the anterior wall. Other causes include impairment of mechanical function of the heart, cardiomyopathies, and arrhythmias. Sometime establishing the etiology of cardiogenic shock is not easy. Invasive hemodynamic monitoring, specific biomarkers echocardiography are helpful in establishing the cause. Management of cardiogenic shock is always difficult and mortality in cardiogenic shock is still high about 50–70%. Since myocardial infarction is common cause of cardiogenic shock, early recognition, utilization of advanced revascularization therapy, and circulatory support help in reducing the mortality and improve the survival also.

DEFINITION

Cardiogenic shock is defined by presence of specific clinical and hemodynamic criteria.

- *Clinical criteria*: Systolic blood pressure <90 mm Hg for >30 min or requirement of vasopressor to maintain BP >90 mm Hg. Clinical features of tissue and organ hypoperfusion such as altered mental status, cold and clammy skin, decreased urine output, and raised serum lactate.
- *Hemodynamic criteria*: Low cardiac output state with cardiac index <1.8 L/min/m^2 or <2–2.2 L/min/m^2 (on pharmacological or mechanical support) with elevated pulmonary capillary wedge presser 15 mm Hg, elevated indices of cardiac preload left ventricular end-diastolic pressure (LVEDP) >18 mm Hg and right ventricular end-diastolic pressure (RVEDP) >10–15 mm Hg.

Cardiogenic shock can easily be diagnosed by easy to assess clinical criteria. This is possible that hypotension may not present in early stage of compensated shock where normotension is maintained by high systemic vascular resistance compensating for low cardiac index. Group of people who are prone to cardiogenic shock are older age, female, myocardial infarction (anterior wall), hypertension, diabetes, multivessels coronary artery disease, and history of heart failure.

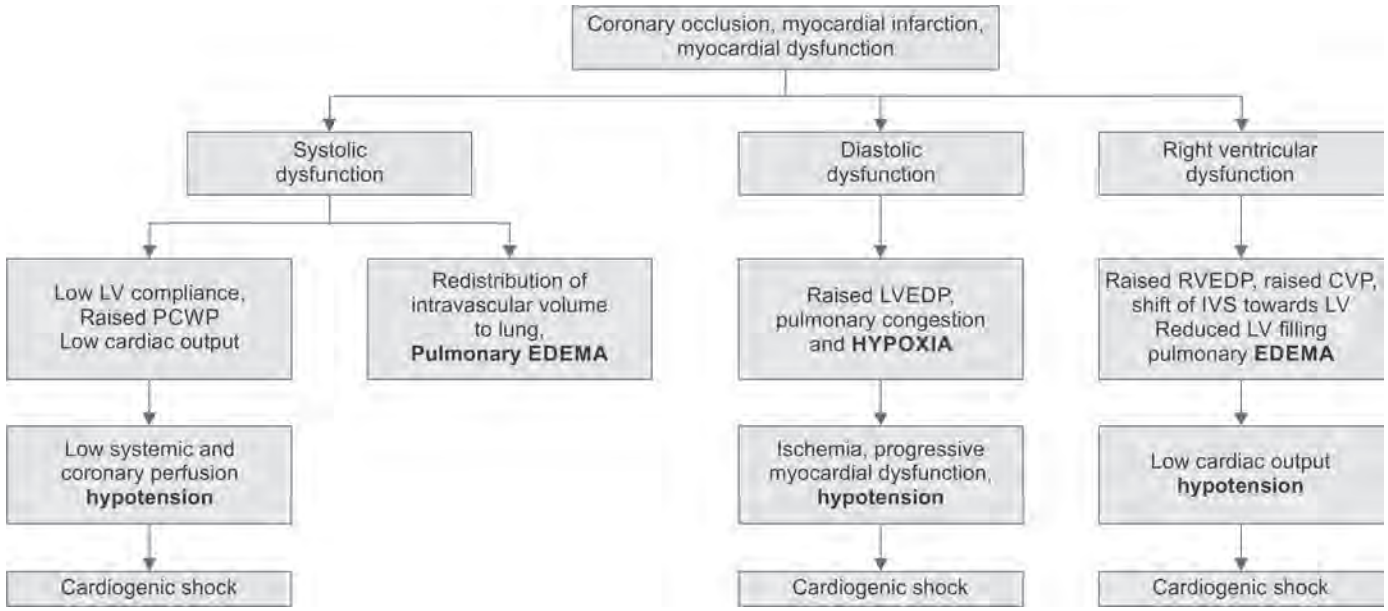
ETIOLOGY

Knowledge of etiology is important for management of cardiogenic shock. Etiology of cardiogenic shock is classified as conditions affecting the myocardium, mechanical cause, and arrhythmic causes. Most common cause of cardiogenic shock is AMI and related complications such as acute mitral regurgitation, ventricular septal defect, and cardiac tamponade due to cardiac free wall rupture. Other important causes of cardiogenic shock are right ventricular failure, myocarditis, valvular heart disease, arrhythmias, and advanced stage cardiomyopathies (**Table 1**).

PATHOPHYSIOLOGY

Cardiogenic shock occurs when about 40% of left ventricle is damaged predominantly due to ischemia. Right ventricular infarction is also recognized as the cause of cardiogenic shock in few cases. Thrombotic occlusion of artery supplying the major part of the heart is underlying pathology of the cardiogenic shock. Coronary occlusion induces depression of myocardial contractility. Reduction in myocardial contractility produces the low cardiac index and hypotension. Low cardiac index and hypotension cause severe tissue hypoperfusion which is measured by the raised serum lactate. Initially, compensatory vasoconstriction occurs in which normotensive state is maintained. If this preshock stage is not recognized early and not treated well, this condition progresses to severe or refractory cardiogenic shock (**Flowchart 1**). Inflammatory

TABLE 1: Etiology of cardiogenic shock.		
Myocardial causes	***Mechanical causes***	***Arrhythmic causes***
• Myocardial infarction left or right infarction • Cardiomyopathy • Myocarditis • Toxins and cytotoxic drugs • Medication (CCB, beta blockers, digoxin, antiarrhythmic drugs, and antidepressant) • Ventricular hypertrophy	• Valvular heart disease • Mechanical complications of MI (papillary muscle dysfunction, ventricular septal rupture, and cardiac free wall rupture) • Hypertrophic cardiomyopathy • Outflow tract obstruction • Atrial thrombus and atrial tumor • Aortic dissection • Cardiac trauma (myocardial contusion)	• Supraventricular or ventricular arrhythmia • Bradycardia



Coronary occlusion, myocardial infarction, myocardial dysfunction
Systolic dysfunction

FLOWCHART 1: Pathophysiology of the cardiogenic shock.

derangement capillary leakage and microcirculatory derangement also contribute to development of severe/refractory shock. According to various studies, older age group, low LVEF, low cardiac index, low systolic BP, requirement of vasopressor and mechanical support, and high serum lactate level are associated with high mortality rates in cardiogenic shock.

DIAGNOSIS

Cardiogenic shock develops gradually and can be categorised as Preshock stage (patient at risk of cardiogenic shock), mild shock (responsive to low dose inotropic support), severe shock [responsive to high dose inotropic support/Intra-aortic balloon pump (IABP)], and refractory shock (when mechanical support is required). Diagnosing the cardiogenic shock in early stage is challenging and vital as reversibility almost impossible in advanced and refractory stage. *Various clinical features and hemodynamics are suggestive of cardiogenic shock* (**Table 2**). This is also important to establish the type of shock for appropriate management. Emergency physician should be aware about the differentiating features of hypovolemic, distributive, and cardiogenic shock (**Table 3**).

TABLE 2: Diagnosis of cardiogenic shock on the basis of clinical and hemodynamic features.	
Clinical features	***Hemodynamic features***
• Signs of hypo-perfusion such as cool moist skin, pale or cyanosis, slow speech, low sensory perception, lethargy, confusion • Oliguria or anuria	• Systolic BP < 90 mm of Hg for >30 min • Requirement of vasopressors to maintain the systolic BP > 90 mm of Hg • Low cardiac index (<2.2 L/min/m^2) • Raised pulmonary wedge pressure (>15 mm Hg)

Various supporting test such as biochemical test hemodynamic monitoring and echocardiography also helpful in this regard. Bedside echocardiography is key investigations along with electrocardiogram (ECG) and biochemical test for acute coronary syndrome as myocardial infarction is important cause of cardiogenic shock. Important cardiac parameters such as global systolic function, pressers, pericardial fluid, and inferior vena cava can be assessed by the bedside echocardiography. Pulmonary artery catheterization is helpful

in providing the information about left or right ventricular filling pressures, systemic and pulmonary vascular résistance, right ventricular ejection fraction, and oxygen saturation. Monitoring of mixed venous oxygen saturation (SvO_2) not only useful for diagnostic purpose but maintaining the therapeutic target of SvO_2 during the initial hours of shock treatment helpful in reducing the mortality. It is also important to distinguish between left ventricular myocardial infarction (LVMI) and the right ventricular myocardial infarction (RVMI) as the cause of cardiogenic shock with the help of clinical features, ECG, and the hemodynamic features because mortality risk for cardiogenic shock due to primary RV dysfunction nearly as high as LV dysfunction. Differentiating features between LV and RV MI are shown in **Table 4**.

TABLE 3: Hemodynamic features of various types of shock.

	Hypovolemic shock	*Distributive shock*	*Cardiogenic shock*
Pulmonary wedge pressure	Low	Low or normal	Raised
Cardiac output	Low	Raised	Low

(ECG: electrocardiogram; LVMI: left ventricular myocardial infarction; PAWP: pulmonary artery wedge pressure; RVMI: right ventricular myocardial infarction; RAP: right atrial pressure)

MANAGEMENT

Management of cardiogenic shock should be started as early as possible to normalize hemodynamic parameter and to prevent the further damage of organ and deterioration of the patient. Management of the cardiogenic shock should target to maintain hemodynamic parameter within therapeutic range (**Fig. 1**). Maintaining the hemodynamic parameters within therapeutic range suggestive of adequate management strategies and positive outcome.

Management of cardiogenic shock is multiphasic, and various modalities of treatment used in cardiogenic shock are summarized in **Figure 2**. Immediate management of shock includes fluid therapy, vasoactive therapy, and ventilator therapy along with correction of electrolyte imbalance. Along with the symptomatic treatment therapy should be directed at the underlying cause. Most cases of cardiogenic shock are due to myocardial infarction, prompt reperfusion therapy should be instituted. Revascularization therapy [percutaneous transluminal coronary angioplasty or coronary artery bypass grafting (PTCA or CABG)] reduce the hospitalization, long-term mortality and MI-related mechanical complication.

CRITICAL CARE SUPPORT

Fluid Administration

First step of management is assessment of intravascular fluid status and fluid responsiveness. Fluid therapy should be used cautiously under the guidance of invasive monitoring and maintenance of target CVP. Generally, 250–500 mL of crystalloid fluid given over 30 minutes.

Vasopressor and Inotrope Support

Vasopressor agents are added to the ongoing therapy when hypotension persists despite fluid therapy. For maintaining the MAP (>60 mm Hg), vasopressor agents are required to maintain adequate coronary and tissue perfusion. *Noradrenaline*—primarily is vasoconstrictor and weak inotrope. Noradrenaline is vasopressor of choice in cardiogenic shock, helpful in increasing the coronary blood flow. Dose of noradrenaline is 0.02–1 μg/kg/min. *Vasopressin*—primarily a vasoconstrictor usually added to the noradrenaline when requirement to noradrenaline exceeds 0.4 μg/kg/min. *Phenylephrine*—pure vasoconstrictors are used when hypotension associated with tachycardia. Mean arterial pressure (MAP) mostly correlating to central hemodynamics but does not correlate peripheral tissue perfusion. There is compensatory peripheral vasoconstriction mechanism due to which compromised tissue perfusion occurs. Inotropes are indicated when feature of tissue hypoperfusion despite adequate fluid and target

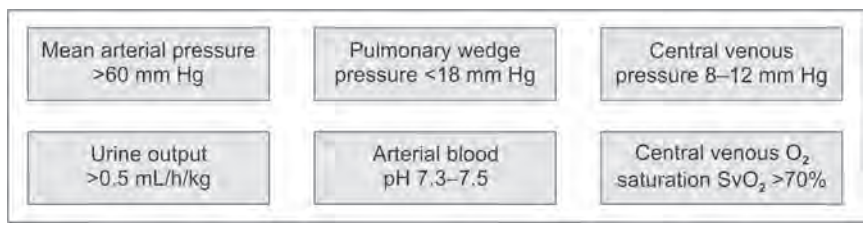

FIG. 1: Therapeutic target for hemodynamic parameters.

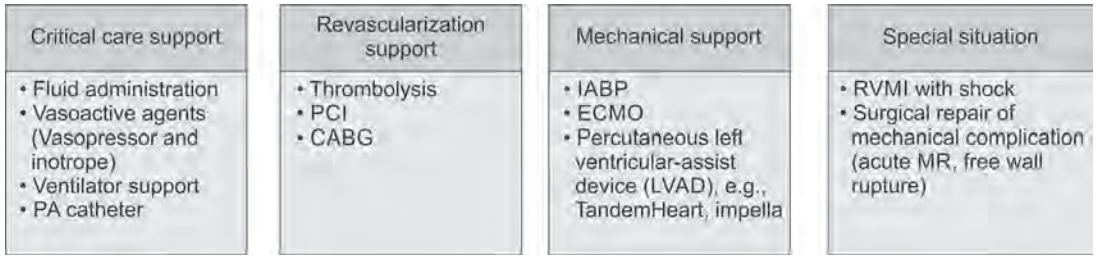


(CABG: coronary artery bypass grafting; ECMO: extracorporeal membrane oxygenation; IABP: intra-aortic balloon pump; RVMI: right ventricular myocardial infarction; PCI: primary coronary intervention; PA: pulmonary artery)

FIG. 2: Modalities of treatment in cardiogenic shock.

TABLE 5: Vasopressors and inotropes for cardiogenic shock.

Medication	*Vasopressor/Inotropes*	*Use in cardiogenic shock*
Phenylephrine	Vasopressors	• Increased afterload of systemic and pulmonary circulations • Generally, not used in CS, useful in LVOTO to decrease gradient across outflow tract
Vasopressin	Vasopressors	• Increased afterload of systemic but not pulmonary circulation • Useful in isolated RV disease or vasoplegia with tachycardia
Norepinephrine	Vasopressors mild inotropes	First-line vasopressor for CS in ED
Epinephrine	Inopressor	• Increased risk of arrhythmias • Recommended for symptomatic bradycardia or refractory hypotension
Dopamine	Inopressor	• Increased risk of arrhythmias • Only used in symptomatic bradycardia
Dobutamine	Inodilator	• First-line inotrope for CS in ED • Fast-acting, easily titratable
Milrinone	Inodilator	• Second-line agent, slower-acting with 2.5 h half-life • Renally cleared, can accumulate in AKI or CKD less arrhythmogenic than other inotropes, better pulmonary vasodilation

(AKI: acute kidney injury; CKD: chronic kidney disease; CS: cardiogenic shock; ED: emergency department; LVOTO: left ventricular outflow tract obstruction)

MAP. *Dobutamine*—inotrope of choice in cardiogenic shock. Started with the dose of 2–20 μg/kg/min when systolic BP > 90 mm Hg. It improves the peripheral perfusion but produces hypotension and tachyarrhythmia due to mild systemic vasodilatory and positive chronotropic effect. *Milrinone*—the main use of milrinone is in decreasing the RV load in advanced nonischemic cardiomyopathies. Milrinone provides inotropic with less chronotropic and less arrhythmic effects. *Dopamine and adrenaline* are less commonly used in cardiogenic shock due to their arrhythmic and undesirable hemodynamic results.

This is very important that emergency physician should be aware about characteristics of vasopressors and inotropes (**Table 5**) and also be able to select the appropriate vasopressors and inotropes in specific situation (**Flowchart 2**).

Positive Pressure Ventilation Support

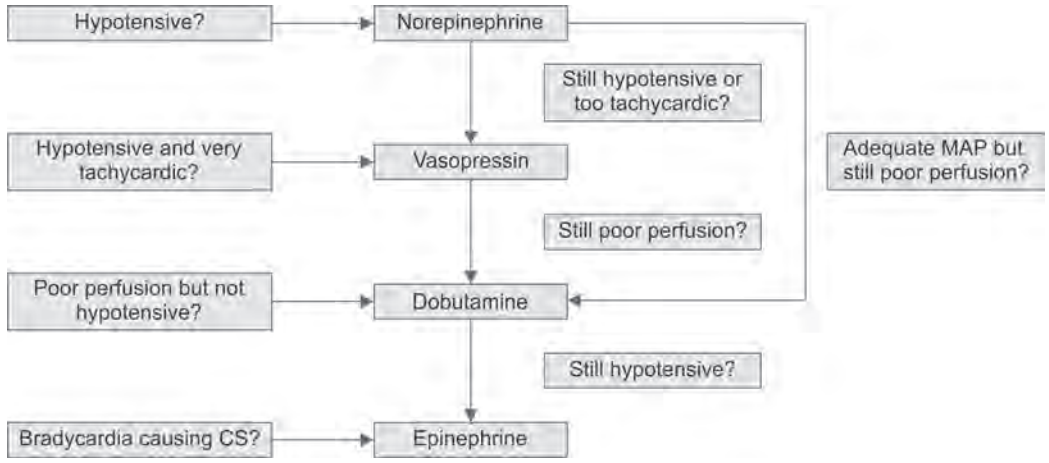
Positive pressure ventilation (PPV) provides different effects for the RV and the LV, as shown in **Figure 3**. In cases of LV failure leading to cardiogenic shock, PPV may unload the LV by decreasing preload and afterload. However, if patients are preload dependent, or in RV failure, intubation may precipitate hemodynamic collapse. For patients in overt shock, intubation may be warranted to minimize work of breathing and oxygen consumption by respiratory muscles**.** Mechanical ventilation improves patient comfort, reduces stress, fatigue and correct acidosis, and hypoxia and improves tissue perfusion. Intensive care support summarized as VIP mnemonic *V* (ventilation), *I* (infuse-fluid therapy), *P* (pump-vasoactive drugs).

Pulmonary Artery Catheterization

Pulmonary artery catheter (PAC) insertion may be helpful in monitoring of patient with cardiogenic shock. It gives information about hemodynamic parameters such as right and left ventricular filling pressures, systemic and pulmonary vascular resistance, right ventricular ejection fraction, and SvO_2 saturation, and thermodilution derived cardiac out. PAC associated with various periprocedural complications so should be performed by expert. Appropriate interpretation of data of PAC is helpful in differentiating the different type of shock and guide appropriate management.

REVASCULARIZATION SUPPORT

Myocardial infarction is important cause of cardiogenic shock. Early revascularization (PCI or CABG) is the lifesaving intervention in cardiogenic shock management. Urgent coronary angiography with support of IABP and PTCA or CABG is recommended in patient with cardiogenic shock due to left ventricular failure complication acute MI or new left bundle branch block (LBBB) MI.



FLOWCHART 2: Algorithm for selecting vasopressors and inotropes in cardiogenic shock in the emergency department.

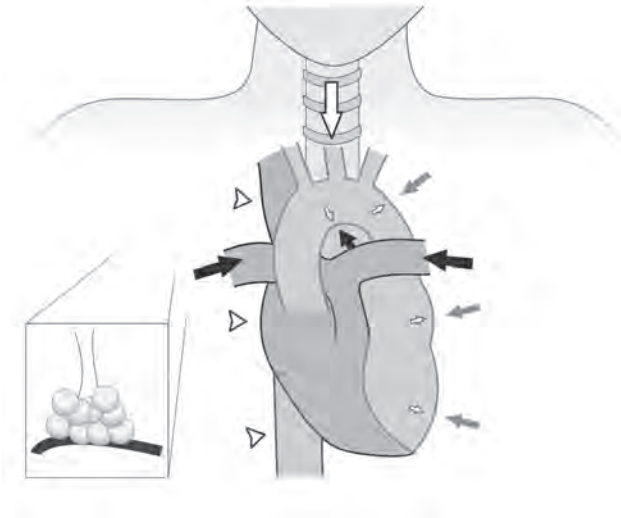


FIG. 3: Effects of positive pressure ventilation (PPV) can vary. PPV decreases preload (open black arrowheads) for the interior vena cava, superior vena cava, and right heart. PPV can also lead to alveolar distention, crimping capillaries (inset), thereby increasing RV afterload, as indicated by the large black arrows. PPV can also decrease afterload on the LV (black arrows) by decreasing the transmural gradient (small gray arrows).

TABLE 6: Fibrinolytic agents and doses.

Streptokinase	• 1.5 million IU • Infused over 1 h in 45 mL NaCl
Alteplase	• 15 mg loading dose followed by 50 mg over 30 min and 35 mg over next 1 h • Total duration of infusion 90 min and concurrent use of heparin 0.75 mg/kg not to exceed 50 mg over 30 min and 0.50 mg/kg and not to exceed 35 mg over next 1 h
Reteplase	• Given as double bolus by 10 U + 10 U (no infusion) • 10 U bolus over 2 min wait for 30 min and repeat 10 U over 2 min and concurrent use of heparin
Tenecteplase	30–50 mg single weight-based bolus over 5–10 sec and concurrent use of heparin

Fibrinolytic Therapy

Fibrinolytic therapy started if presentation of early or compensatory stage of cardiogenic shock with STEMI to hospital <3 hours, no contraindications to therapy and PCI intervention facility not available. Concurrent use of IABP is also beneficial. Currently available fibrinolytic agents are streptokinase, alteplase, reteplase, and tenecteplase. *Streptokinase*—1.5 million IU (infused over 1 h in 45 mL NaCl). *Alteplase*—15 mg loading dose followed by 50 mg over 30 minutes and 35 mg over next 1 hour (total duration of infusion 90 min) and concurrent use of heparin (0.75 mg/kg not to exceed 50 mg over 30 min and 0.50 mg/kg and not to exceed 35 mg over next 1 h). *Reteplase*—given as double bolus by 10 U + 10 U (no infusion), 10 U bolus over 2 minutes wait for 30 minutes and repeat 10 U over 2 minutes and concurrent use of heparin. *Tenecteplase*—30–50 mg single weight-based bolus over 5–10 s and concurrent use of heparin. Other fibrinolytic agents though less used, e.g., urokinase, prourokinase, and anistreplase are also available. Fibrinolytic agents and doses are summarized in **Table 6**.

Percutaneous Transluminal Coronary Angioplasty

Various studies show decrease in mortality rates if successful reperfusion done in cardiogenic shock caused by AMI. PTCA is especially helpful as reperfusion therapy in single or double vessels coronary artery disease.

Coronary Artery Bypass Grafting

Patient with cardiogenic shock with triple vessel disease or left main coronary artery disease, CABG provides favorable outcome.

MECHANICAL SUPPORT

Mechanical support is ultimate approach to improve hemodynamic parameters. Nowadays, a number of devices are available with different mechanism of action and effectiveness.

These devices provide cardiac chambers (right left biventricular) support. IABPs, extracorporeal membrane oxygenation (ECMO), and percutaneous left ventricular assist device (LVAD) are available for mechanical support. These devices are indicated when all ICU measures fail to provide adequate tissue and organ perfusion and risk of multiorgan failure develops. 30-day mortality was not reduced by use of IABP in cardiogenic shock complicating MI according to IABP-SHOCK II trials. No reduction of short-term mortality is noted by use of IABP and Impella pump and TandemHeart device are not found superior to IABP according to few randomized studies. Thus, further improvement in mechanical device is required which provides not only hemodynamic stabilization but also improves patient outcome.

Intra-aortic Balloon Pump

Several physiological parameters are improved with the use of IABP. Use of IABP commonly used to improve hemodynamic parameters. IABP provides reduction in myocardial oxygen demand, pulmonary wedge pressure, LV afterload along with Improvement in coronary blood flow, and cardiac output (**Figs. 4A to C**).

Indications

Various indications of IABP are summarized in **Table 7**.

Selection of Balloon and Mechanism of Action

For optimal hemodynamics effect, balloon should be deflated just before LV ejection (at QRS complex). Ideal balloon function in 1:3 sequence where every third ventricular beat is augmented by IABP. If heart rate >140 switch to 1:2 sequence until rate slow. Hemodynamic effect of IABP depends on the balloon volume, heart rate and rhythm, and systemic vascular resistance. Selection of balloon size (**Table 8**) in specific patient is helpful in achieving maximum output.

Complication of Intra-aortic Balloon Pump

Be aware of presence of pulse in left arm, indicate tip of balloon not obstructing subclavian orifice, and subclavian flow is not occluding. IABP associated with various complications such as arterial wall trauma, limb ischemia, thrombus dislodgement, thrombocytopenia hemolysis, hemorrhage, balloon rupture or leak, and infection.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation consists of blood pump, the heat exchanger, and the oxygenator. Indicated in severe hypercapnia with pH < 7.20, PaO_2:FiO_2 < 50–1,000 mm Hg, alveolar—arterial oxygen gradient >600 mm Hg, transpulmonary shunt >30%. Main challenges in ECMO are patient selection system logistic and complication such as limb ischemia bleeding complications. Currently ECMO is used as bridge therapy to heart transplantation.

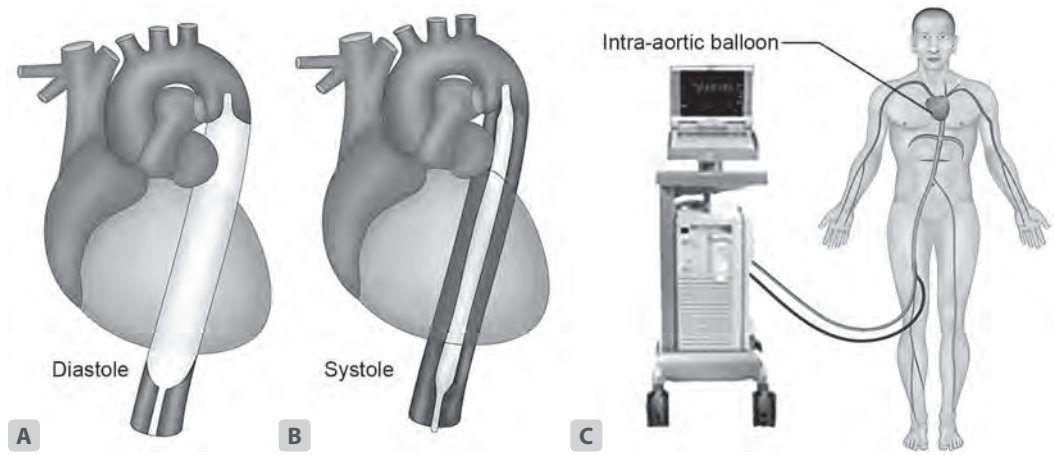
TABLE 7: Indication of IABP in various conditions apart from cardiogenic shock.

Medical	*Surgical*	*Others*
• Cardiogenic shock • Acute anterior wall MI • Complications of MI like acute MR VSR • High-risk angioplasty • Ventricular arrhythmia secondary to ischemia	• High-risk cardiac patient • Bridge to CABG and heart transplant • Postoperative low cardiac output • Weaning from bypass open heart surgery	• Drug-induced heart failure • Myocardial contusion aortic stenosis
IABP contraindicated in acute aortic dissection, aortic regurgitation, chronic end-stage heart disease, and irreversible brain damage		

(CABG: coronary artery bypass grafting; IABP: intra-aortic balloon pump; MI: myocardial infarction; MR: mitral regurgitation; VSR: ventricular septal rupture)

TABLE 8: Selection of IABP balloon size.

Height of patient	<5′	5′–5′4″	5′4″–6′
Balloon volume	25 mL	34 mL	40 mL
Length	165 mm	221 mm	258 mm
Diameter	15 mm	15 mm	15 mm
Catheter size	7.5 F	7.5 F	7.5 F



FIGS. 4A TO C: Intra-aortic balloon pump (IABP) and mechanism of action: Balloon inflated in diastole with closure of aortic valve. Balloon remains inflated till ventricular systole inflation of balloon displaces the blood toward aorta and coronaries and promotes coronary perfusion and blood flow. Collapse of balloon decreases the LV work by reducing the resistance of LV ejection.

Percutaneous Left Ventricular Assist Device

Currently available percutaneous LVADs are TandemHeart and Impella. They are inserted percutaneously through femoral artery and provide pulsatile support via pump. LVADs provide higher cardiac index, higher MAP, and lower pulmonary wedge pressure. There are no 30 days survival benefits by using LVAD. They are used in refractory cardiogenic shock as bridging strategies to heart transplantation.

Heart Transplantation

Heart transplantation is particularly indicated in patient who required biventricular mechanical circulatory support and is the only hope for long-term survival. LVADs are used in patient refractory to treatment and as bridging therapy to heart transplantation. All currently used durable mechanical circulatory support devices are continuous-flow devices, include an inflow cannula placed directly into the LV cavity and an outflow graft sutured into the ascending aorta, and can provide hemodynamic support with flow rates ranging from 5 to 10 L/min. In view of few organ availability, unpredictable donor availability, and various logistic factor, heart transplant is unreliable primary therapy in cardiogenic shock.

SPECIAL SITUATION

Right Ventricular Myocardial Infarction with Shock

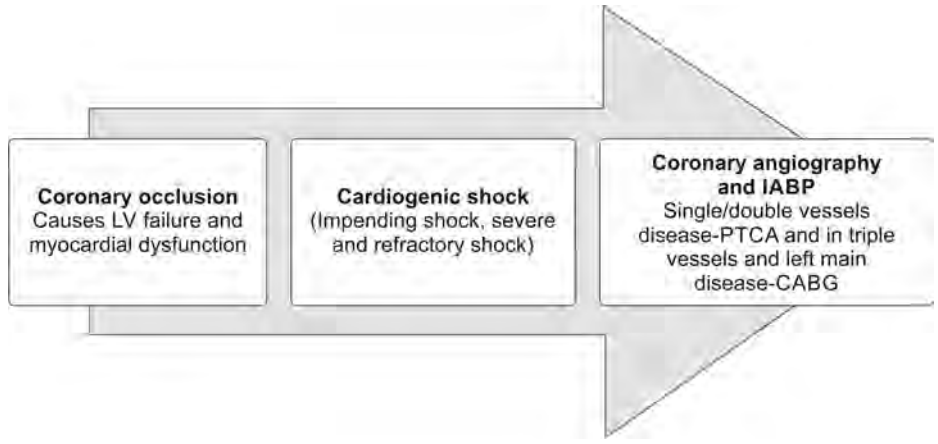
Right ventricular myocardial infarction is suspected in all patient with inferior wall MI with shock. RVMI mostly associated with inferior and posterior wall MI and mortality is also high. Clinically triad of raised JVP, clear lung fields in the presence of inferior or posterior MI, present ECG shows ST segment elevation in V_3R and V_4R echocardiography also helpful in diagnosis. Therapeutic approach is quite different from left ventricular failure. Maintain right ventricular preload with intravenous fluid, avoid use of nitrates and diuretics, and maintain A-V synchrony with the help of pacing in case of high degree of heart block. Use of pharmacological circulatory support revascularization support, mechanical support is the mainstay of therapy (**Table 9**).

Mechanical Complication of Acute MI (Acute Mitral Regurgitation, Papillary Muscle Rupture, Ventricular Septal Rupture, and Free Wall Rupture)

Acute mitral regurgitation is usually associated with inferior wall MI and ischemia of posterior papillary muscle. Acute MR develops within 2–7 days after the myocardial infarction and clinically present as pulmonary edema hypotension and cardiogenic shock. Echocardiography is extremely useful. All therapeutic measures should be implemented as described above. However, definitive therapy is surgical valve repair or replacement. Patient with ventricular septal rupture present with severe or refractory cardiogenic shock. Characteristic pansystolic murmur and parasternal thrill present on examination and echocardiography is diagnostic modality of choice. Early use of circulatory and mechanical support followed by surgical repair is definitive therapy.

TABLE 9: Management of cardiogenic shock from right heart failure.

Parameters	*Pathophysiology*	*Management*
Recognition	• Recognizing is often challenging such as RV infarct, or acute-on-chronic, such as with pulmonary hypertension	• Management complex • Consult, usually pulmonologist or cardiologist, early in course
Preload	• Acute RV dysfunction can be preload dependent • May be volume depleted, based on history (e.g., recent gastrointestinal illness) • Pulmonary hypertension patients often chronically overloaded because of neurohormonal upregulation • Volume status assessment challenging because of chronic adaptations	• If patient needs volume from acute RV dysfunction or by history, provide in small volume • Reassess frequently with vital signs, echocardiography, markers, or perfusion • In cases of volume overload, may benefit from diuresis • Often benefit from PA line placement
Contractility	• Hypotension can lead to decreased coronary perfusion, leading to worse contractility • Cannot tolerate arrhythmias	• Add early vasopressors to maintain coronary perfusion • Add inotropes for RV support • Manage arrhythmias aggressively
Afterload	• Hypoxemic vasoconstriction, acidemia increase RV afterload • Positive pressure ventilation can increase afterload • Inhaled pulmonary vasodilators can dilate pulmonary vasculature	• Avoid hypoxia and hypercapnia • Support oxygenation with high-flow nasal cannula • Judicious noninvasive ventilation • Avoid intubation if possible, • Prevent hypotension, hypoventilation/hyperventilation with intubation • Consider inhaled epoprostenol or nitric oxide



Coronary occlusion
Causes LV failure and myocardial dysfunction
Cardiogenic shock
(Impending shock, severe and refractory shock)
Coronary angiography and IABP
Single/double vessels disease-PTCA and in triple vessels and left main disease-CABG

(CABG: coronary artery bypass grafting; IABP: intra-aortic balloon pump; LV: left ventricular; PTCA: percutaneous transluminal coronary angioplasty)

FIG. 5: Summary approach to cardiogenic shock.

REVERSIBLE MYOCARDIAL DYSFUNCTION (MYOCARDITIS, SEPSIS-INDUCED MYOCARDIAL DYSFUNCTION)

Few reversible causes of myocardial dysfunctions such as sepsis-induced myocardial dysfunction, inflammatory myocarditis, and myocardial dysfunction after cardiopulmonary bypass. Inflammatory cytokines [tumor necrosis factor-alpha and interleukin-1 (TNF-α and IL-1)] play important role in sepsis and myocarditis. Combination of inotropic support, IABP required for days to week to allow sufficient time for recovery. If these measures fail, mechanical support with LVAD can be considered.

SUMMARY

Left ventricular failure and myocardial dysfunction occur due to coronary occlusion. Cardiogenic shock can be present as different stages, e.g., impending shock to severe and refractory shock. Cardiogenic shock develops due to multiple causes such as myocardial infarction cardiomyopathies and myocarditis. Restoration of effective tissue perfusion and cellular metabolism is the ultimate goal for the prescribed therapy. Early circulatory support (IABP) and revascularization (PTCA or CABG) are the mainstay of treatment and also improve the survival in cardiogenic shock complication of AMI (**Fig. 5)**.

CHAPTER

Acute Heart Failure

Devendra Richhariya

INTRODUCTION

Acute heart failure (AHF) is one of the most common causes of emergency admissions in India and the incidence is steadily rising. Increasing prevalence of coronary artery disease, greater survival after myocardial infarction and rising incidence of diabetes mellitus in our country are some of the important factors. Of late, there has been a greater awareness of heart failure with preserved ejection fraction where left ventricular ejection fraction (LVEF) is over 40%.

Quality of life and survival after heart failure have improved significantly for the last three decades. This has largely been due to understanding of the basic pathophysiology especially the role of neurohormonal activation, definitive interventional therapies, and support devices. New drugs on the horizon especially angiotensin receptor neprilysin inhibitor (ARNI) appear to be very promising and may yet to be the most significant advance in pharmacotherapy after angiotensin-converting enzyme (ACE) inhibitors. The readmission rate often AHF is still disturbingly high. This may be due to failure to uptitrate the doses and inadequate counseling regarding lifestyle modification. It is important to quickly triage these patients on presentation to the emergency ward to decide who requires or more aggressive approach to their disease. Such patients should be offered high tech solution to reduce mortality and morbidity.

Survivals of patients presenting with AHF have improved dramatically since 1980, the medical advances reflect understanding of the role of neurohormonal stimulation and antagonism, the physiology and evaluation of congestion leading to decompensation, and the indications for devices to avert sudden death and enhance synchrony.

PATHOPHYSIOLOGY

The key components of AHF are elevation of filling pressure and reduction of cardiac output which do not necessary occur together. Cardiac output is frequently reduced from normal but reaches critical levels only with patients with cardiogenic shock. In these patients, severe compromise of resting cardiac output and perfusion generally does not occur unless a patient has severe restrictive, infiltrative, or hypertrophic disease with very small left ventricular cavity or severe mitral regurgitation.

PRECIPITATING FACTORS

The most common cause of AHF is exacerbation of chronic heart failure. However, other important causes are accelerated hypertension, acute myocardial infarction, valvular disease, myocarditis, and renal failure. For patients with preexisting chronic heart failure, one should identify the precipitating factors and the status of fluid overload and perfusion. For patients with known coronary artery disease, new-onset ischemia is an important cause. Other common exacerbating factors are tachyarrhythmia, thyroid disease, anemia, infection, chronic kidney disease, chronic pulmonary disease, and pulmonary emboli. Excessive fluid and salt intake and coadministration of certain drugs are known to worsen heart failure and should also be enquired into. Common precipitating factors frequently lead to heart failure are shown in **Box 1**.

CLASSIFICATION

The European Society of Cardiology has classified AHF (**Box 2**) in various clinical syndromes and their presenting features may be overlapping but for specific therapeutic approach classification is important. Since the features are overlapping and due to heterogenicity of patient population, it is important to divide the patient with AHF on the basis of initial systolic blood pressure (important prognostic marker) and distinct clinical approach for management can be implemented for each group of the patient.

- Acute heart failure with hypertension (systolic blood pressure > 140 mm Hg)

BOX 1: Precipitating factors for acute heart failure.

- Medication noncompliance
- Dietary noncompliance
- Acute coronary syndrome
- Arrhythmias
- Acute valve dysfunction
- Anemia
- Infections

BOX 2: Classification of acute heart failure.

- Acute decompensated heart failure
- Hypertensive acute heart failure
- Pulmonary edema
- Cardiogenic shock
- Right heart failure
- Acute coronary syndrome complicated by acute heart failure

Source: Dickstein K, Cohen-Solal A, Filippatos G, McMurray JV, Ponikowski P, Poole-Wilson PA, et al. ESC guidelines for the diagnosis and treatment of acute heart failure 2008. Eur J Heart Fail. 2008;10:968.

- Acute heat failure with hypotension (systolic blood pressure < 90 mm Hg)
- Acute heart failure with normal blood pressure (systolic blood pressure 90–140 mm Hg)

CLINICAL FEATURES

Dyspnea is the most common complaint due to AHF. Additional features such as orthopnea paroxysmal nocturnal dyspnea and peripheral edema fatigue weakness are also present. Depending on cause, AHF condition may present with either hypertension or hypotension. Usually patient is tachycardic but due to medications (β-blockers) or high-degree atrioventricular (AV) block, bradycardia may be present. Clinical estimation of perfusion can be made by temperature of extremities, examination of pulses and sensorium, and presence of cyanosis. A good history and a thorough physical examination can yield important information. Orthopnea, nocturnal cough, and progressive effort intolerance are indicative of elevated filling pressure in this setting. Raised jugular venous pressure (JVP), hepatojugular reflux, pulmonary edema, hepatomegaly and bilateral crepitation third heart sound is usually present.

DIAGNOSIS
